The **branches of the transverse scapular** are:—(1) the **nutrient**, to the clavicle; (2) the **acromial** [ramus acromialis] to the arterial rete or plexus on the acromial process, to reach which it pierces the trapezius; (3) the **articular**, to the acromio-clavicular joint and shoulder-joint; (4) the **subscapular**, given off as the artery is passing over the transverse scapular ligament, descends to the subscapular fossa between the subscapularis and the bone, and anastomoses with the infrascapular branch of the circumflex (dorsal) scapular artery, and with the subscapular and transverse cervical arteries; (5) the **supraspinous** branches, which ramify in the supraspinous fossa, and supply the supra-spinatus muscle and the periosteum, and the nutrient artery to the bone; (6) the **infraspinous** branches, which ramify in a similar way in the infraspinous fossa, giving off twigs to the infra-spinatus muscle, the periosteum, and the bone.

Fig. 461.—Scheme of Anastomoses of the Right Scapular Arteries. (Walsham.)

THE TRANSVERSE CERVICAL ARTERY

The **tranverse cervical** artery [a. transversa colli], somewhat larger than the transverse scapular (suprascapular), runs like the latter vessel laterally across the root of the neck, but on a slightly higher transverse plane, and a little above the clavicle. At its origin from the thyreo-cervical trunk (thyreoid axis) it lies under the sterno-mastoid; on leaving the cover of this muscle, it crosses the upper part of the subclavian triangle, lying here only beneath the platysma and cervical fascia; further laterally, it passes beneath the anterior margin of the trapezius and omo-hyoid muscle, and at the lateral margin of the levator scapulæ divides into a descending (posterior scapular) and an ascending (superficial cervical) branch. In this course it crosses the phrenic nerve, the scalenus anterior, the brachial plexus, and the scalenus medius. Sometimes it passes between the cords of the brachial plexus.

The **branches of the transverse cervical artery** are:—(1) a descending (posterior scapular); and (2) an ascending (or superficial) cervical. The descending branch occasionally arises from the third portion of the subclavian artery.

(1) The **descending branch**, or **posterior scapular** [ramus descendens] the apparent continuation of the transverse cervical artery, begins at the lateral border of the levator scapulæ, and, continuing its course beneath this muscle to the upper and posterior angle of the scapula, turns downward and skirts along the posterior border of the scapula, between the serratus anterior

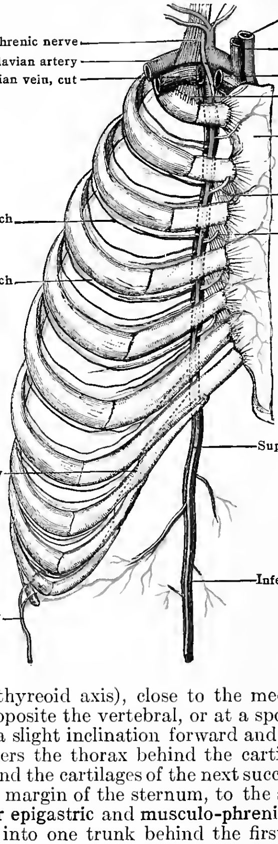
(magnus) in front and the levator scapulæ and rhomboideus minor and major behind, to the inferior angle, where it anastomoses with the subscapular artery. It gives off the following branches:—(*a*) **Supraspinous,** which ramifies between the supraspinous muscle and the trapezius, and sends branches through the muscle into the fossa, to anastomose with the transverse scapular artery. (*b*) **Infraspinous** branches, one or more of which enter the infraspinous fossa, and anastomose with the circumflex (dorsal) scapular. (*c*) **Subscapular branches,** which enter the subscapular fossa, and anstomose with the branches of the transverse scapular and subscapular arteries. (*d*) **Muscular** branches, to the muscles between which it runs and to the latissimus dorsi. These branches anastomose with the posterior divisions of the intercostal arteries.

(2) The **ascending branch** or **superficial cervical artery** [r. ascendens], smaller than the descending branch, ascends under the anterior margin of the trapezius, lying upon the levator scapulæ and splenius muscles. It supplies branches to the trapezius, levator scapulæ, and splenius muscles, and the posterior chain of lymphatic glands. It anastomoses with the superficial branch of the descending branch of the occipital between the splenius and semispinalis capitis (complexus). It is accompanied by two veins. This artery may arise directly from the thyreoid axis, or from the third part of the subclavian artery.

3. THE INTERNAL MAMMARY ARTERY

The **internal mammary** artery [a. mammaria interna] (figs. 457, 462) comes off from the lower part of the first portion of the subclavian, usually opposite the

FIG. 462.—SCHEME OF THE RIGHT INTERNAL MAMMARY ARTERY. (Walsham.)



thyreo-cervical trunk (thyreoid axis), close to the medial edge of the scalenus anterior, occasionally opposite the vertebral, or at a spot between these two vessels. It descends with a slight inclination forward and medialward, under cover of the clavicle, and enters the thorax behind the cartilage of the first rib, and thence passes down behind the cartilages of the next succeeding ribs, about 1.2 cm. ($\frac{1}{2}$ in.) from the lateral margin of the sternum, to the sixth interspace, where it divides into the **superior epigastric** and **musculo-phrenic.** It is accompanied by two veins, which unite into one trunk behind the first intercostal muscle; this passes to the medial side of the artery into the corresponding vena innominata, or occasionally on the right side into the vena cava superior direct. The artery may be divided into two portions, the *cervical* and the *thoracic.*

The **cervical portion** is covered by the sterno-mastoid muscle, subclavian vein, and internal jugular vein, and is crossed obliquely, in the latero-medial direction, by the phrenic nerve. It rests upon the pleura and courses around the upper part of the innominate vein. There is no branch from this part of the artery.

The **thoracic portion** lies behind the cartilages of the six upper ribs, and in the interspace between the ribs has in front of it the pectoralis major and the internal intercostal muscles and external intercostal ligaments. Behind, it is in contact above with the pleura, but it is separated from it lower down by slips of the transversus thoracis (triangularis sterni). On the left side, the artery between the fourth and sixth ribs may be said to be in the anterior mediastinum, the pleura here forming a notch for the heart. In the first, second, and third spaces the artery, if wounded, can be easily tied; but in the fourth space the operation is attended with more difficulty. The remaining spaces are so narrow that a portion of the cartilage would have to be removed to expose the vessel.

The **branches of the internal mammary artery** are:—(1) The pericardio-phrenic; (2) the anterior mediastinal and thymic; (3) the bronchial; (4) the pericardiac; (5) the sternal; (6) the anterior intercostals; (7) the perforating; (8) the lateral costal; (9) the superior epigastric; and (10) the musculo-phrenic.

(1) The **pericardio-phrenic** artery [a. pericaridiophrenica], is a long slender vessel which comes off from the internal mammary just after it has entered the chest, and descends with the phrenic nerve, at first between the pleura and innominate vein; then (on the right side) between the pleura and the vena cava superior; and lastly, between the pleura and the pericardium to the diaphragm, where it anastomoses with the other diaphragmatic arteries. It gives branches both to the pleura and pericardium.

(2) The **anterior mediastinal** and **thymic** arteries [aa. mediastinales anteriores et thymicæ] come off irregularly from the internal mammary. They are of small size, and supply the connective tissue, fat, and lymphatics in the superior and anterior mediastina and the remains of the thymus gland.

(3) The **bronchial** branches [rami bronchiales] are often wanting. When present they are supplied to the bronchi and the lower part of the trachea.

(4) The **pericardiac** branches are distributed to the anterior surface of the pericardium.

(5) The **sternal** branches [rami sternales] enter the nutrient foramina in the sternum, and also supply the transversus thoracis (triangularis sterni).

(6) The **anterior intercostal** branches [rami intercostales] (figs. 463, 478)—two in each of the five or six upper intercostal spaces—run laterally from the internal mammary artery, along the lower border of the rib above and the upper border of the rib below, and anastomose with the corresponding anterior and collateral branches of the aortic intercostals. Each pair of branches sometimes arises by a common trunk from the internal mammary, which in this case soon divides into an upper and a lower branch, as above described. They lie at first between the internal intercostal muscles and the pleura; afterward between the external and internal intercostal muscles. They supply the contiguous muscles, the pectoralis major, and the ribs.

(7) The **perforating** or **anterior perforating** branches [rami perforantes]—five or six in number, one corresponding to each of the five or six upper spaces—come off from the front of the internal mammary, between the superior and inferior anterior intercostals, and, perforating the internal intercostal muscles, pass forward between the costal cartilages to the pectoralis major, which they supply [*rami musculares*]. The terminal twigs perforate that muscle close to the sternum, and are distributed to the integument [*rami cutanei*]. The **second, third,** and **fourth perforating** supply the inner and deep surface of the mammary gland, and become greatly enlarged during lactation [*rami mammaria*]. They frequently require ligation in excision of the breast.

(8) The **lateral costal** branch [ramus costales lateralis] is given off close to the first rib, and descends behind the ribs just external to the costal cartilages. It anastomoses with the upper intercostal arteries. This vessel is often of insignificant size, or absent.

(9) The **superior epigastric** artery [a. epigastrica superior] (fig. 462), or medial terminal branch of the internal mammary artery, leaves the thorax behind the seventh costal cartilage by passing through the costo-xiphoid space in the diaphragm. It is the direct prolongation of the internal mammary downward. In the abdomen it descends behind the rectus muscle, between its posterior surface and its sheath, and, lower, entering the substance of the muscle, anastomoses with the inferior epigastric, a branch of the external iliac. It gives off the following small branches:—(*a*) The **phrenic,** to the diaphragm; (*b*) the **xiphoid,** which crosses in front of the xiphoid cartilage, and anastomoses with the artery of the opposite side; (*c*) the **cutaneous,** which perforate the anterior layer of the sheath of the rectus and supply the integuments; (*d*) the **muscular,** to the rectus muscle, some of which perforate the rectus sheath laterally, and are distributed to the oblique muscles; (*e*) the **hepatic** (on the right side only), which pass along the falciform ligament to the liver, and anastomose with the hepatic artery; (*f*) the **peritoneal,** which perforate the posterior layer of the sheath of the rectus, and ramify on the peritoneum.

(10) The **musculo-phrenic** artery [a. musculophrenica], or lateral terminal branch of the internal mammary artery, skirts laterally and downward behind the costal cartilages of the false ribs along the costal attachments of the diaphragm, which it perforates opposite the ninth rib. It terminates, much reduced in size, at the tenth or eleventh intercostal space by anastomosing with the ascending branch of the deep circumflex iliac artery. It gives off in its course the following small branches:—(*a*) The **phrenic** for the supply of the diaphragm; (*b*) the **anterior intercostals,** two in number for each of the lower five or six intercostal spaces, are dis-

tributed like those to the upper spaces, already described, and anastomose like them with the corresponding anterior branches of the lower aortic intercostals; (c) the **muscular** for the supply of the oblique muscles of the abdomen.

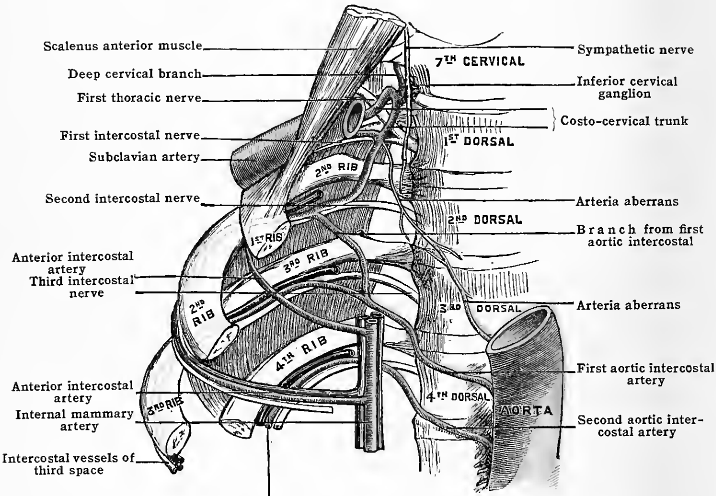
4. THE COSTO-CERVICAL TRUNK

The **costo-cervical trunk** [truncus costocervicalis] (figs. 444, 463) is a short stem which arises usually from the back part of the second portion of the subclavian artery, behind the scalenus anterior on the right side, but commonly just medial to that muscle on the left side. Its course is upward and backward above the dome of the pleura and then downward toward the thorax, before entering which it divides into its two terminal branches.

The **branches of the costo-cervical trunk** are:—(1) the superior intercostal and (2) the deep cervical.

(1) The **superior intercostal** [a. intercostalis suprema] (fig. 463) continues the direction of the costo-cervical trunk, passing downward into the thorax in front of the neck of the first rib. It sometimes terminates opposite the first intercostal space by becoming the first intercostal artery. Usually, however, it is prolonged downward over the neck of the second rib and supplies the second intercostal space in addition. It communicates with the highest aortic intercostal artery. As it crosses the neck of the first rib the superior intercostal lies anterior (ventral) to the first intercostal nerve and lateral to the superior thoracic ganglion of the sympathetic.

Fig. 463.—Scheme of the Right Costo-cervical Trunk. (Walsham.)



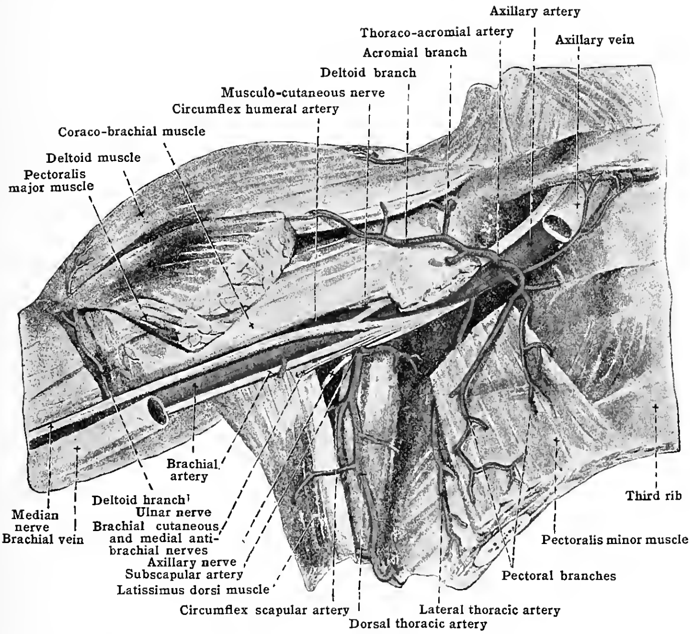
The branches to the first and second intercostal spaces resemble in course and distribution the succeeding intercostals derived from the thoracic aorta (see p. 588). Like the aortic intercostals they give off **dorsal** [rr. dorsales] and **spinal branches** [rr. spinales]. An **arteria aberrans**, when present, arises from the medial side of the right superior intercostal, or occasionally from the right subclavian itself. It descends as a slender vessel into the thorax, passing downward and medially behind the œsophagus as far as the third or fourth thoracic vertebra, where in some cases it anastomoses with a similar slender branch arising from the aorta below the ligamentum arteriosum. This anastomosis represents the remains of the embryonic right dorsal aortic arch, and it is by its occasional enlargement that the anomaly of the right subclavian artery rising from the descending portion of the aortic arch occurs (see p. 637).

(2) The **deep cervical** artery [a. cervicalis profunda] passes directly backward, first between the seventh and eighth cervical nerves, and then between the transverse process of the seventh cervical vertebra and the neck of the first rib, having the body of the seventh cervical vertebra to its medial side, and the intertransverse muscle to its lateral side. It then turns upward in the groove between the transverse and spinous processes of the cervical vertebræ lying upon the semispinalis colli. It is covered by the semispinalis capitis (complexus). Between these muscles it anastomoses with the deep branch of the descending branch (princeps cervicis) of the occipital artery. It gives off a spinal branch which enters the vertebral canal through the intervertebral foramen with the eighth cervical nerve.

THE AXILLARY ARTERY

The term axillary is applied to that portion of the main arterial stem of the upper limb that passes through the axillary fossa. The **axillary** artery [a. axillaris] (fig. 464) therefore is continuous with the subclavian above and with the brachial below. It extends from the lateral border of the first rib to the lower edge of the teres major muscle, and has the shoulder-joint and the neck of the humerus to its lateral side. When the arm is placed close to the side of the body, the artery forms a gentle curve with its convexity upward; but when the arm is carried out from the side at right angles to the trunk in the ordinary dissecting position, the vessel takes a nearly straight course, which will then be indicated by a line drawn from the middle of the clavicle to the groove on the medial side of the coraco-brachialis and biceps muscles. The axillary artery is at first deeply placed beneath the pectoral muscles, but in its lower third it is superficial, being covered

Fig. 464.—The Axillary Artery. (After Spalteholz.)



only by the skin and the superficial fascia and deep fascia. It is divided into three parts, first, second, and third, according as it lies respectively above, beneath, or below the pectoralis minor.

The First Part of the Axillary Artery

The **first part of the axillary artery** extends from the lateral border of the first rib to the upper border of the pectoralis minor. It measures about 2.5 cm. (1 in.) in length.

Relations.—In front it is covered by the skin, superficial fascia, lower part of the platysma, the deep fascia, the pectoralis major, the coraco-clavicular (costo-coracoid) fascia, the subclavius muscle and the clavicle when the arm hangs down by the side. The cephalic and thoraco-acromial veins, the external anterior thoracic nerve, and the axillary lymphatic trunk, cross over it. A layer of the deep cervical fascia which has passed under the clavicle also descends in front of it.

Behind, it rests upon the first intercostal space and first intercostal muscle, the first digitation and sometimes a portion of the second digitation of the serratus anterior (magnus) muscle, and a part of the second rib. The long thoracic nerve, on its way to the serratus anterior muscle, passes behind it.

To its **lateral side,** and somewhat on a higher plane, are the cords of the brachial plexus.

To its **medial side,** and on a slightly anterior plane, is the axillary vein. The internal anterior thoracic nerve courses between the vein and the artery.

The Second Part of the Axillary Artery

The **second part of the axillary artery** (fig. 464) lies beneath the pectoralis minor deep in the axilla. It measures 3 cm. (a little more than 1 in.) in length.

Relations.—In front, in addition to the pectoralis minor, it is covered by the pectoralis major and the integuments.

Behind, it is separated by a considerable interval, containing loose connective tissue and fat, from the subscapularis muscle; whilst behind, and in contact with it, is the posterior cord of the brachial plexus.

To the **medial side,** but separated from the artery by the medial cord of the brachial plexus, is the axillary vein.

To the **lateral side** is the lateral cord of the brachial plexus, and at some little distance the coracoid process.

It is thus seen that the second portion of the auxillary artery is surrounded on three sides by the cords of the brachial plexus—one behind, one medial, and one lateral.

The Third Part of the Axillary Artery

The **third part of the axillary artery** (fig. 464) extends from the lower border of the pectoralis minor to the lower border of the teres major. Its upper half lies deeply placed within the axilla, beneath the lower edge of the pectoralis major muscle, but its lower half is in the arm external to the axilla, and is uncovered by muscle. It measures about 7.5 cm. (3 in.) in length.

Relations.—In front it has, in addition to the skin and superficial fascia, the pectoralis major above, and lower down the deep fascia of the arm. It is crossed obliquely by the medial root of the median nerve and by the lateral brachial vena comitans.

Behind, it lies successively upon the subscapularis, the latissimus dorsi, and teres major muscles. From the first-named muscle it is separated at first by a considerable mass of fat and cellular tissue. The radial (musculo-spiral) and axillary (circumflex) nerves intervene between the artery and the muscles.

On its **lateral side** it is separated from the bone by the coraco-brachialis, by which it is partly overlapped, this muscle and the short head of the biceps serving as a guide to the artery in ligature. For a part of its course it has also the musculo-cutaneous nerve and the lateral root of the median nerve to its lateral side.

To its **medial side** it has the axillary vein, the ulnar nerve, the medial antibrachial (internal) and brachial (lesser internal) cutaneous nerves, and the medial root of the median nerve. The ulnar nerve is between the artery and the vein. The medial antibrachial (internal) cutaneous nerve is a little in front of the artery as well as medial to it.

Branches of the Axillary Artery

The **branches of the axillary artery** are exceedingly variable. In fig. 465 is shown what Hitzrot has found the usual type, in which the second portion of the artery has no named branches. The figure brings out the segmental relation of the branches of the axillary artery to the chest wall and suggests how one of the branches may supply the place of another. If the lateral thoracic arises directly from the axillary, it is generally from the second part as described below. In addition to the larger branches of the artery small twigs are supplied to the serratus anterior, coraco-brachialis, and subscapularis; also to the axillary lymph-nodes.

The **first part** gives off.—(1) The superior thoracic; and (2) the thoraco-acromial.

The **second part** gives off:—(3) The lateral thoracic.

The **third part** gives off:—(4) The subscapular; (5) the anterior humeral circumflex; and (6) the posterior humeral circumflex.

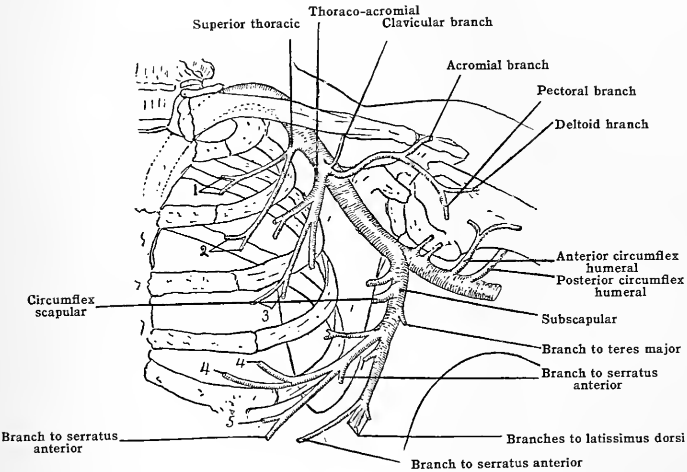
Branches of the Axillary Artery

1. The **superior thoracic** [a. thoracalis suprema] is variously given off from the axillary artery, usually either as a common trunk with the next branch, the

thoraco-acromial, or a little above. It passes behind the axillary vein across the first intercostal space, supplying the intercostal muscles and the upper portion of the serratus anterior, and anastomoses with the intercostal arteries. At times it sends a branch between the pectoralis major and minor, which then, as a rule, more or less takes the place of the pectoral branch of the thoraco-acromial (figs. 464 and 465).

2. The **thoraco-acromial** or **acromio-thoracic axis** [a. thoracoacromialis] arises from the front part of the axillary just above the upper border of the pectoralis minor. It is a short trunk, and, coming off from the front of the artery, pierces the coraco-clavicular fascia, and then divides into three or four small branches, named from their direction:—(*a*) the acromial; (*b*) the deltoid; (*c*) the pectoral, and (*d*) the clavicular.

Fig. 465.—The Branches of the Axillary Artery. (After Hitzrot.) The numbers 1–5 indicate the intercostal spaces.



(*a*) The **acromial** branch [r. acromialis] or branches pass laterally across the coracoid process, frequently through the deltoid muscle, which they in part supply, to the acromion, where they form, by anastomosing with the anterior and posterior circumflex and transverse scapular (suprascapular) arteries, the so-called acromial rete, or plexus of vessels on the surface of that process.

(*b*) The **deltoid** branch [r. deltoideus] runs downward with the cephalic vein in the interval between the pectoralis major and the deltoid, and, supplying lateral offsets to these muscles and the adjacent integument, anastomoses with the anterior and posterior circumflex humeral arteries.

(*c*) The **pectoral** branch [r. pectoralis] passes between the pectoralis major and minor muscles, both of which it supplies. In the female, one or more branches which perforate the pectoralis major are often of large size, and supply the superimposed mammary gland.

(*d*) The **clavicular** branch passes upward beneath the clavicle, supplies the subclavius muscle, and anastomoses with the transverse scapular artery.

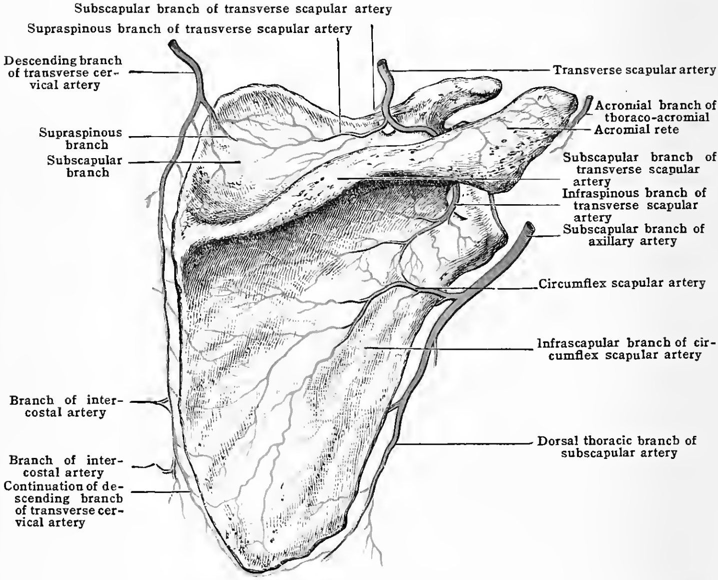
3. The **lateral thoracic** artery [a. thoracalis lateralis] descends along the lower border of the pectoralis minor, under cover of the pectoralis major, to the chest wall. It supplies both pectoral muscles and the serratus anterior (magnus), sends branches around the lower border of the pectoralis major to the mammary gland, and terminates in the intercostal muscles by anastomosing with the aortic intercostals and the internal mammary. It also furnishes branches to the lymph-nodes of the axillary fossa. The branches to the mammary gland in the female are often of large size.

4. The **subscapular** artery [a. subscapularis] is the largest branch of the axillary. It arises opposite the lower border of the subscapularis, and runs in a

downward and medial direction along the anterior border of that muscle under cover of the latissimus dorsi. It supplies the subscapularis, teres major, latissimus dorsi, and serratus anterior (magnus) muscles, and gives branches to the nodes in the axillary fossa. The course of this large vessel along the posterior border of the axillary fossa should be remembered in opening abscesses in the fossa, and in removing enlarged nodes from it. It is accompanied by two veins, which usually unite and then receive the circumflex (dorsal) scapular vein, and open as a single vein of large size either into the axillary or at the confluence of the medial brachial vena comitans with the basilic vein.

About 2.5 or 3.7 cm. (1 or $1\frac{1}{2}$ in.) from its origin, the subscapular artery divides into two end branches, (1) the circumflex (dorsal) scapular, and (2) the dorsal thoracic.

Fig. 466.—The Anastomoses about the Scapula.



(1) The **circumflex scapular** artery [a. circumflexa scapulæ], or dorsal scapular, arising from the subscapular, usually at the point above mentioned, passes backward through the triangular space bounded by the subscapularis above, the teres major below, and the long head of the triceps laterally, and then between the teres minor and the axillary border of the scapula, which it commonly grooves. It thus reaches the infraspinous fossa, where, under cover of the infra-spinatus, it anastomoses with the transverse scapular (suprascapular) artery and the descending branch of the transverse cervical (posterior scapular) (fig. 466). As it passes through the triangular space, it gives off a ventral branch which ramifies between the subscapularis and the bone, supplying branches to the subscapularis, to the scapula, and to the shoulder-joint. A second branch is often given off near the triangular space and passes downward between the teres major and teres minor, supplying both muscles (fig. 467).

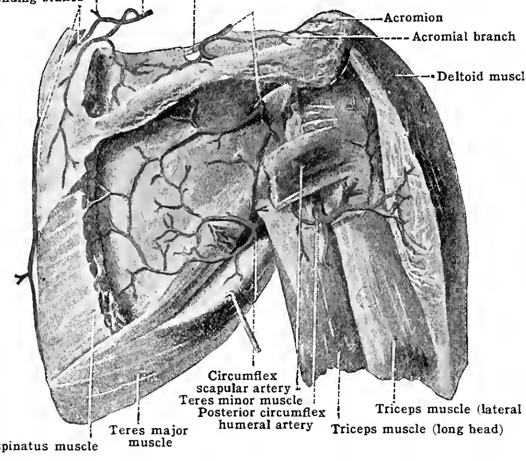
(2) The **dorsal thoracic** artery [a. thoracodorsalis] continues in the course of the subscapular as far as the angle of the scapula, where it anastomoses with the circumflex scapular, the descending branch of the transverse cervical (posterior scapular), the lateral thoracic, and intercostal arteries.

5. The **anterior circumflex humeral** artery [a. circumflexa humeri anterior], usually quite a small vessel, comes off from the lateral side of the axillary artery, generally opposite the posterior circumflex. It passes beneath the coraco-brachialis and short and long heads of the biceps, winding transversely round the front of the surgical neck of the humerus, across the intertubercular (bicipital) groove, and anastomoses with the posterior circumflex and thoraco-acromial arteries. It gives off the following small branches:

(*a*) The **bicipital** or ascending, which runs up the intertubercular groove to supply the long tendon of the biceps and the shoulder-joint; and (*b*) a **pectoral** or descending branch, which runs downward along the insertion of the pectoralis major, and supplies the tendon of that muscle. The anterior circumflex artery, in consequence of its being close to the bone, is sometimes difficult to secure in the operation for excision of the shoulder-joint.

6. The **posterior circumflex humeral** artery [a. circumflexa humeri posterior] (fig. 467) arises from the posterior aspect of the axillary, just below the lower border of the subscapularis muscle. It passes through the quadrilateral space, bounded by the teres minor above, the latissimus dorsi and teres major below, the humerus laterally, and the long head of the triceps medially, and, winding round the back of the humerus beneath the deltoid, breaks up under cover of that muscle into a leash of branches, which for the most part enter its substance. The axillary (circumflex) nerve and two venæ comitantes run with it. It anastomoses with the anterior circumflex, the arteries on the acromion, and the profunda artery.

Fig. 467.—The Arteries of the Shoulder. (After Spalteholz.)

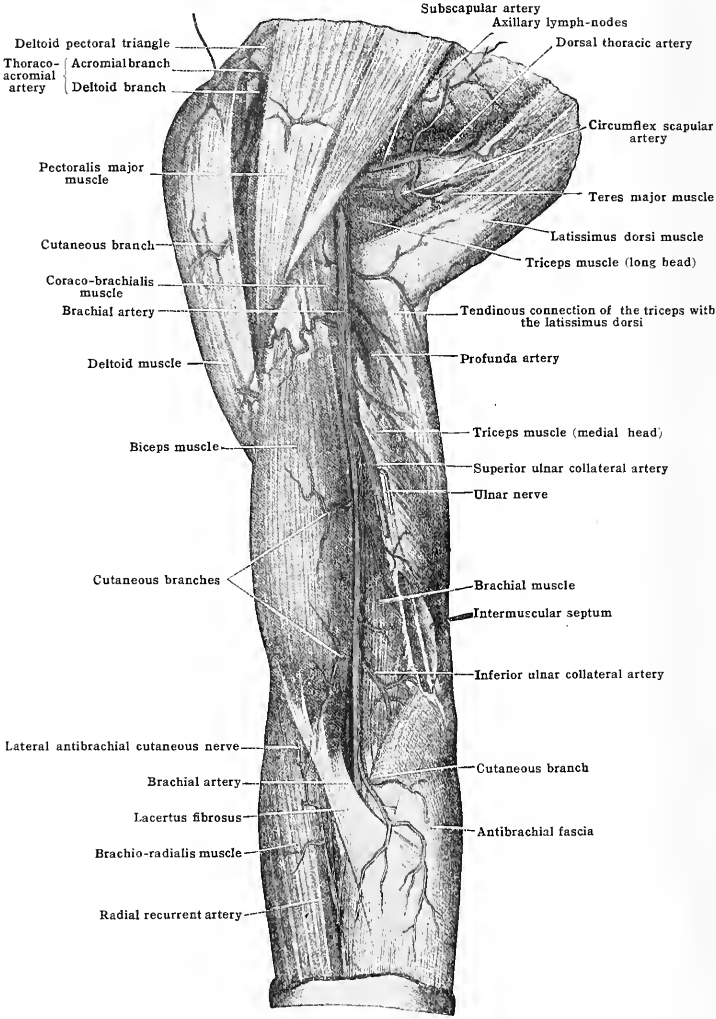


In addition to the leash of vessels to the deltoid, it gives off the following small branches: —(*a*) **nutrient,** to the greater tuberosity of the humerus; (*b*) **articular,** to the back of the shoulder-joint; (*c*) **acromial,** to the plexus on the acromion; and (*d*) **muscular,** to the teres minor and long and short heads of the triceps. One or more of these branches to the triceps descend either between the lateral and long head or in the substance of that muscle, to anastomose with an ascending branch from the profunda artery. It is by means of this anastomosis that the collateral circulation is chiefly carried on when the axillary or the brachial artery is tied between the origins of the posterior circumflex and profunda arteries.

THE BRACHIAL ARTERY

The **brachial** artery [a. brachialis] (fig. 468), the continuation of the axillary, extends from the lower border of the teres major to a little below the centre of the crease at the bend of the elbow, where it divides, opposite the junction of the head with the neck of the radius, into the radial and ulnar arteries. The artery is situated at first medial to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow lies midway between the two epicondyles. Hence, in controlling hæmorrhage, the artery should be compressed laterally against the bone in its upper third, laterally and backward in its middle third, and directly backward in its lower third. Throughout the greater part of its course the artery is superficial, being merely overlapped slightly on its lateral side by the coraco-brachialis and biceps muscles; but at the bend of the elbow it sinks deeply beneath the lacertus fibrosus of the biceps into the triangular interval (antecubital space) bounded on either side by the brachio-

Fig. 468.—The Brachial Artery. (After Toldt, "Atlas of Human Anatomy" Rebman, London and New York.)



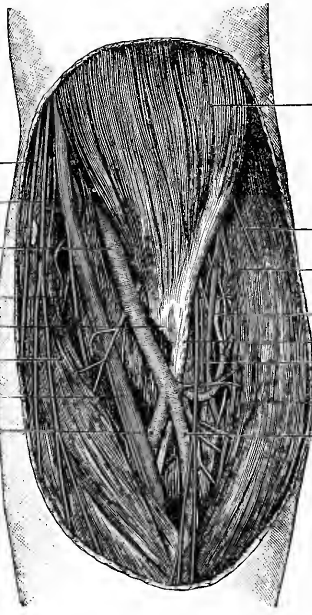
radialis and pronator teres, and at its bifurcation is more or less under cover of these muscles (fig. 469). The sheath of the brachial artery is closely incorporated with the fascia covering the biceps muscle, and it is for this reason that in the operation for ligaturing the vessel is apt to be retracted with the muscle.

A line drawn from the groove medial to the coraco-brachialis and biceps muscles to midway between the epicondyles of the humerus will indicate its course. It is accompanied by two veins which frequently communicate across the artery. In addition to the branches named below the brachial artery gives off numerous muscular branches and, occasionally, the nutrient artery to the humerus. The muscular branches usually come off from the lateral side of the artery; one in particular, which supplies the biceps muscle, is frequently of large size.

Relations.—**In front,** the artery is covered by the integument and superficial and deep fasciæ, and at the bend of the elbow by the lacertus fibrosus of the biceps, and in muscular subjects by the overlapping margins of the brachio-radialis and pronator teres. In the middle third of the arm it is crossed obliquely from the lateral to the medial side by the median nerve, and at the bend of the elbow by the median cubital vein, the bicipital fascia intervening (fig.475).

Behind, it lies successively on the long head of the triceps (from which it is separated by the radial (musculo-spiral) nerve and profunda artery), on the medial head of the triceps, on the insertion of the coraco-brachialis, and thence to its bifurcation on the brachialis muscle.

Fig. 469.—The Brachial Artery at the Bend of the Elbow, Left Side, Front View. (From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



Lateral to the artery is the coraco-brachialis above, and the muscular belly of the biceps below, both of which slightly overlap the vessel, and at the bend of the elbow the tendon of the biceps. The lateral vena comitans is also to its lateral side. The median nerve is in close contact with the lateral side of the artery in the upper third of its course, but in the middle third crosses the artery obliquely to gain the medial side.

Medial to the artery in the upper part of its course are the medial antibrachial (internal) cutaneous and the ulnar nerves; the latter nerve, however, leaves the artery about the origin of the ulnar collateral (inferior profunda) branch, to make, with that vessel, for the medial epicondyle. Lower down, the medial antibrachial cutaneous nerve also leaves the artery, by piercing the deep fascia. The median nerve is in close contact with the medial side of the artery in its lower third and at the bend of the elbow. The basilic vein is superficial to it, and a little to its medial side in the greater part of its course, but separated from it by the deep fascia. The medial vena comitans runs along its medial side.

Branches of the Brachial Artery

The **branches of the brachial artery** are:—(1) The profunda brachii; (2) the superior ulnar collateral (inferior profunda); (3) the inferior ulnar collateral (anastomotica magna); and (4) the terminal branches—the radial and ulnar arteries.

(1) The Profunda Artery

The **profunda brachii** (superior profunda) is the largest branch of the brachial. It arises from the medial and hinder aspect of that artery, a little below the inferior border of the tendon of the teres major. It at first lies to the medial side of the brachial, but soon passes behind that vessel, and, sinking between the medial and long heads of the triceps with the radial (musculo-spiral) nerve, curves around the humerus in the groove for the nerve, lying in contact with the bone between the medial and lateral heads of the triceps. On reaching the lateral supracondyloid ridge of the humerus it perforates the lateral intermuscular septum, and, continuing forward between the brachio-radialis and brachialis to the front of the lateral epicondyle, ends by anastomosing with the radial recurrent artery (figs. 468 and 474).

It gives off the following branches:—

(*a*) The **deltoid** branch [r. deltoideus] which may also arise from the brachial itself or from the superior ulnar collateral. It runs across the anterior surface of the humerus, under cover of the coraco-brachialis and biceps, and supplies the brachialis and deltoid.

(*b*) The **middle collateral** artery [a. collateralis media] runs in the substance of the middle head of the triceps as far as the elbow, where it terminates in the articular rete.

(*c*) The **radial collateral** artery [a. collateralis radialis] arises about the middle of the upper arm, and runs behind the lateral intermuscular septum to the rete at the elbow-joint.

(*d*) A **nutrient humeral** artery [a. nutritia humeri], which may come from the brachial itself or from a muscular branch, enters a canal in the humerus.

(2) The Superior Ulnar Collateral Artery

The **superior ulnar collateral** artery [a. collateralis ulnaris superior] (inferior profunda) arises from the medial side of the brachial, usually about the level of the insertion of the coraco-brachialis, at times as a common trunk with the profunda. It passes with the ulnar nerve medially and downward through the medial intermuscular septum, and then along the medial head of the triceps to the back of the medial epicondyle, where, under cover of the deep fascia and the origin of the flexor carpi ulnaris from the olecranon and medial epicondyle, it enters into the anastomoses around the elbow-joint. It frequently supplies the nutrient artery to the humerus. It gives branches to the triceps, to the elbow-joint, and a branch which passes in front of the medial epicondyle to anastomose with the anterior ulnar recurrent.

(3) The Inferior Ulnar Collateral Artery

The **inferior ulnar collateral** artery [a. collateralis ulnaris inferior] or anastomotica magna arises from the medial side of the brachial, about 5 cm. (2 in.) above its bifurcation into the radial and ulnar arteries, and, running medially and downward across the brachialis, divides into two branches, a posterior and an anterior. The **posterior** pierces the medial intermuscular septum, winds round the medial condyloid ridge of the humerus, and pierces the triceps, between which and the bone it anastomoses with the articular branch of the profunda artery, and to a lesser extent with the interosseous recurrent, forming an arterial arch or rete around the upper border of the olecranon fossa. The **anterior** branch passes medially and downward between the brachialis and pronator teres, and anastomoses in front of the medial epicondyle, but beneath the pronator teres, with the anterior ulnar recurrent. From this branch a small vessel passes down behind the medial epicondyle to anastomose with the posterior ulnar recurrent and superior ulnar collateral arteries (fig. 474).

THE ULNAR ARTERY

The **ulnar** artery [a. ulnaris] (fig. 470) the larger of the two terminal branches of the brachial, begins opposite the lower border of the head of the radius in the middle line of the forearm. Thence through the upper half of the forearm it runs beneath the pronator teres and superficial flexor muscles, and, having reached the ulnar side of the arm about midway between the elbow and the wrist, it passes directly downward, being merely overlapped by the flexor carpi ulnaris. Crossing the transverse carpal (anterior annular) ligament immediately to the radial side of the pisiform bone, it enters the palm, where it divides into two branches, which enter respectively into the formation of the superficial and deep volar arches. The artery is accompanied by two veins, which anastomose with each other by frequent cross branches, and usually terminate in the brachial venæ comitantes. The ulnar nerve is at first some distance from the artery, but approaches the vessel at the junction of its upper and middle thirds, and then lies close to its medial or ulnar side. The course of the artery in the lower two-thirds of the forearm is indicated by a line drawn from the front of the medial epicondyle to the radial side of the pisiform bone; and in the upper third of the forearm by a line drawn in a gentle curve with its convexity to the medial side from 2.5 cm. (1 in.) below the centre of the bend of the elbow to a point in the former line at the junction of its upper with its middle third. The artery throughout its course is best reached through the interval between the flexor carpi ulnaris and the flexor digitorum sublimis.

The relations of the artery will be given in detail in the forearm, and in the palm of the hand.

The **relations in the forearm** are:—

In front.—In the upper half of the forearm the ulnar artery is deeply placed beneath the pronator teres, the flexor carpi radialis, the palmaris longus, and the flexor digitorum sublimis. In the lower half it is comparatively superficial, being merely overlapped above by the tendon of the flexor carpi ulnaris, whilst the last inch or so of the vessel is only covered as a rule by the skin and superficial and deep fasciæ. As the artery lies beneath the pronator teres, it is crossed from the medial to the lateral side by the median nerve, the deep head of origin of the muscle usually separating the nerve from the artery. The lower part of the artery is crossed by the palmar cutaneous branch of the ulnar nerve.

Behind.—For about 2.5 cm. (1 in.) of its course the artery lies upon the brachialis; but thence, as far as the transverse carpal (anterior annular) ligament, upon the flexor digitorum profundus, which separates it above from the interosseous membrane and bone, and at the wrist from the pronator quadratus. The artery is bound down to the flexor digitorum profundus by bands of fasciæ.

To the **lateral side** in the lower two-thirds of its course is the flexor digitorum sublimis.

To the **medial side** in the lower two-thirds is the flexor carpi ulnaris, the guide to the vessel. The ulnar nerve, as it enters the forearm from behind the medial epicondyle, is at first some distance from the artery, being separated from it in its upper third by the flexor digitorum sublimis, but in its lower two-thirds is in close contact with the vessel and on its ulnar side.

The **branches of the ulnar artery in the forearm** are:—1. The ulnar recurrent arteries. 2. The common interosseous. 3. Muscular. 4. Dorsal ulnar carpal. 5. Volar ulnar carpal.

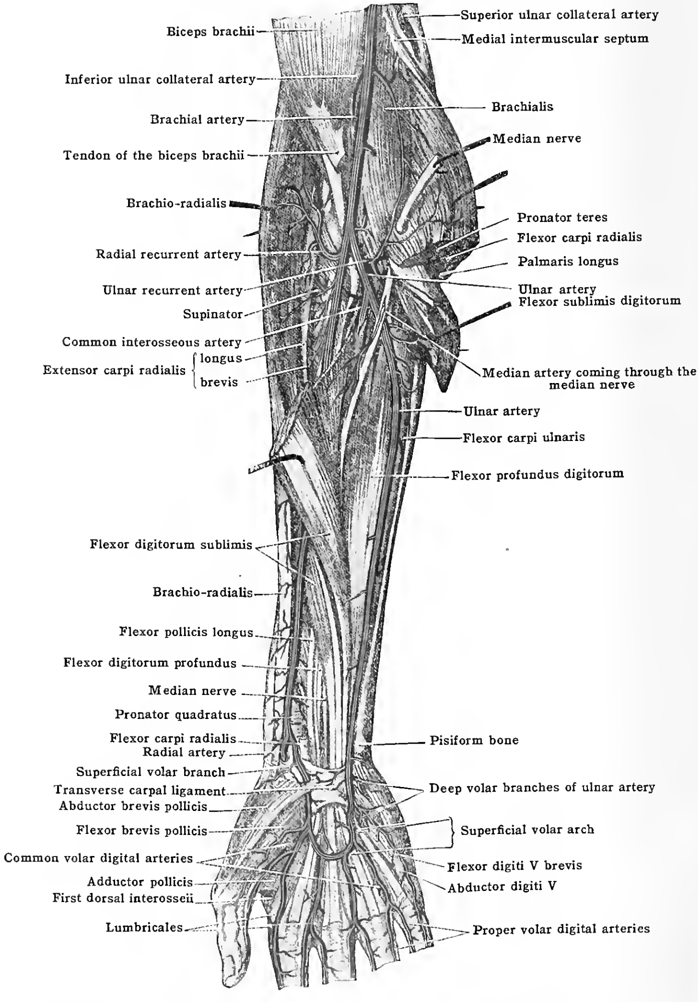
1. The **ulnar recurrent** arteries [aa. recurrentes ulnares] are two, the volar, and dorsal. The *volar* is a small branch which arises from the medial side of the ulnar artery, or the dorsal ulnar recurrent, and, running between the lateral edge of the pronator teres and the brachialis, anastomoses in front of the medial epicondyle with the inferior and superior ulnar collaterals. It supplies branches to the muscles between which it runs, and to the skin. The *dorsal*, larger than the volar, comes off from the medial side of the ulnar artery, either a little below the latter branch, or else as a common trunk with it, and, passing between the flexores digitorum sublimis and profundus, turns upward to the back of the medial epicondyle, where it lies with the ulnar nerve between the two heads of origin of the flexor carpi ulnaris. It supplies the contiguous muscles—the flexor carpi ulnaris, the palmaris longus, and the flexores digitorum sublimis and profundus—the elbow-joint, and the ulnar nerve, and anastomoses with the inferior and superior ulnar collaterals, and with the interosseous recurrent forming the so-called rete olecrani.

2. The **common interosseous** artery [a. interossea communis] is a short thick trunk 1.2 cm. ($\frac{1}{2}$ in.) or so in length, which comes off from the lateral and back part of the ulnar artery about 2.5 cm. (1 in.) from its origin, and just before that artery is crossed by the median nerve. It passes backward and downward between the flexor pollicis longus and the flexor digitorum profundus, toward the triangular interval bounded by the upper border of the interosseous membrane, the oblique ligament, and the lateral border of the ulna, where it divides into the volar and dorsal interosseous arteries.

(*a*) The **volar interosseous** artery [a. interossea volaris], smaller than the dorsal, but apparently the direct continuation of the common trunk, courses downward in front of the interosseous membrane. It lies under cover of the overlapping edges of the flexor digitorum profundus and flexor pollicis longus, to both of which muscles it supplies branches. At the upper border of the pronator quadratus it divides into two branches, an anterior terminal and a posterior terminal (fig. 473).

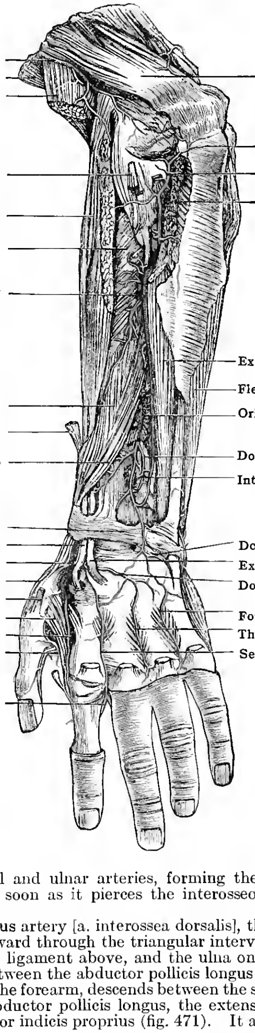
The volar interosseous artery is accompanied by two veins and by the deep branch of the median nerve which lies to its radial side. The artery is bound down to the interosseous membrane by aponeurotic fibres.

Fig. 470.—The Volar Arteries of the Forearm and Hand. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **branches** of the volar interosseous artery are:—(i) The **median** artery [a. mediana] is a long slender vessel which arises from the volar interosseous immediately after the latter is given off from the common trunk. It passes forward between the flexor digitorum profundus and the flexor pollicis longus to the median nerve, with which it descends beneath the transverse carpal (anterior annular) ligament into the palm, and when of large size sometimes enters into the formation of the superficial palmar arch. At times the artery arises from the common interosseous before its division. (ii) The **nutrient arteries** of the radius and ulna are usually derived from this vessel. (iii) The **volar terminal** division of the volar interosseous artery passes either in front of or behind the pronator quadratus, but in either case in front of the interosseous membrane, and anastomoses with the volar carpal branches of the radial and ulnar arteries, and with the recurrent branches from the deep volar arch, forming the so-called **volar carpal rete.** (iv) The **dorsal terminal,** the larger division, pierces the interosseous membrane, and continues its course downward behind the interosseous membrane, under cover of the extensor muscles, to the back of the wrist, where it ends by anastomosing with the dorsal

FIG. 471.—THE BACK OF THE LEFT FOREARM, WITH THE DORSAL INTEROSSEOUS ARTERY AND BRANCHES OF THE RADIAL AT THE BACK OF THE WRIST.
(From a dissection in the Hunterian Museum.)

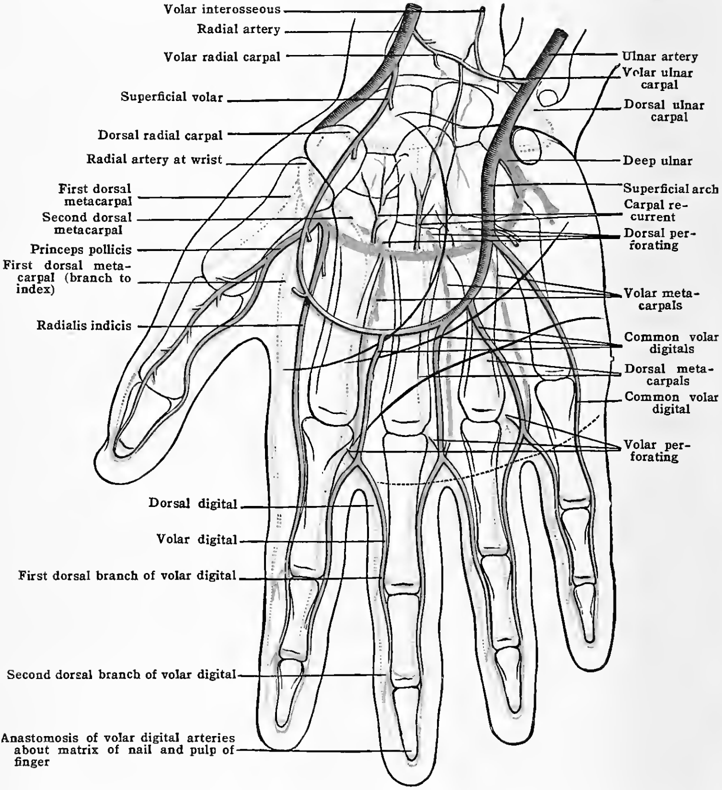


carpal branches of the radial and ulnar arteries, forming the so-called **dorsal carpal rete.** This branch anastomoses, as soon as it pierces the interosseous membrane, with the dorsal interosseous artery.

(*b*) The **dorsal interosseous** artery [a. interossea dorsalis], the larger division of the common interosseous, turns backward through the triangular interval bounded by the interosseous membrane below, the oblique ligament above, and the ulna on the medial side, and emerging at the back of the forearm between the abductor pollicis longus and the supinator, under cover of the superficial extensors of the forearm, descends between the superficial and the deep muscles, crossing in this course the abductor pollicis longus, the extensor pollicis brevis, the extensor pollicis longus, and the extensor indicis proprius (fig. 471). It anastomoses at the lower border of this muscle and just above the wrist joint, with the dorsal branch of the volar interosseous which here, as above described, has perforated the interosseous membrane. It is separated from the deep radial nerve at first by the radius and supinator, and on the back of the forearm by the extensores pollicis longus and indicis proprius.

The chief branch of the dorsal interosseous artery, the **interosseous recurrent** artery [a. interossea recurrens] arises from the dorsal interosseous as the latter emerges from beneath the supinator. It runs upward between the anconeus and supinator, usually under cover of the former, to the interval between the lateral epicondyle and the olecranon, where it anastomoses with the profunda, inferior ulnar collateral, radial recurrent, and dorsal ulnar recurrent arteries, and gives branches to the retiform plexus over the olecranon—the rete olecrani.

Fig. 472.—Anastomoses and Distribution of the Arteries of the Hand. (Walsham.)

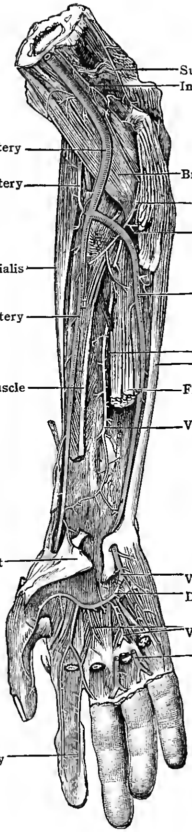


3. The **muscular** branches [rami musculares] are numerous. They supply the deep and superficial flexors of the fingers, the flexor carpi radialis and ulnaris, and the pronator radii teres.

4. The **dorsal ulnar carpal** [ramus carpeus dorsalis] comes off from the ulnar artery a little above the transverse carpal (anterior annular) ligament, and, winding medially round the end of the ulna or the ulnar collateral ligament of the wrist, beneath the flexor carpi ulnaris, ramifies on the back of the carpus beneath the extensor tendons. It forms by its anastomosis with the dorsal radial carpal, with the dorsal terminal branch of the volar interosseous and with the dorsal interosseous arteries a plexus or rete, the so-called dorsal carpal rete. The branches given off from this plexus or arch are described with the dorsal carpal branch of the radial artery.

5. The **volar ulnar carpal** [ramus carpeus volaris] is a small branch given off from the ulnar artery opposite the carpus. It passes beneath the flexor digitorum profundus to anastomose with the volar radial carpal, with terminal twigs of the volar branch of the volar interosseous, and with recurrent branches from the deep volar arch, forming an anastomotic arch across the front of the carpus—the **volar carpal arch** or **rete**.

Fig. 473.—The Arteries of the Right Forearm and the Deep Volar Arch.



The Ulnar Artery at the Wrist

The **ulnar artery at the wrist** may be said to extend from the upper to the lower border of the transverse carpal (anterior annular) ligament upon which it rests. It here lies immediately to the radial side of the pisiform bone, and to the ulnar side of the hook of the hamate (unciform), the two bones forming for the vessel a protecting channel, which is further converted into a short canal by the expansion of the flexor carpi ulnaris passing from the pisiform to the hook of the hamate (unciform). The ulnar nerve in this situation is immediately to the ulnar side of the artery.

The Ulnar Artery in the Palm (Superficial Volar Arch)

The ulnar artery, on entering the palm, divides into two branches, the superficial and deep.

The **superficial branch** (fig. 472), the direct continuation of the vessel, anastomoses with the superficial volar, a branch of the radial, forming what is then known as the **superficial volar arch.** After descending a short distance toward the cleft between the fourth and fifth fingers, it turns toward the thumb, forming a curve with its convexity toward the fingers and its concavity toward the muscles of the thumb, and anastomoses opposite the cleft between the index and middle fingers, at the junction of the upper with the middle third of the palm, with the superficial volar branch of the radial artery to complete the arch. A line drawn transversely across the palm on a level with the metacarpo-phalangeal joint of the thumb will roughly indicate the situation of the arch.

Relations.—In front: in addition to the skin and superficial fascia, the vessel is crossed successively, by the palmaris bevis, the palmar branch of the ulnar nerve, the palmar aponeurosis and the palmar branch of the median nerve.

Behind, it rests successively upon the short muscles of the little finger, the digital branches of the ulnar nerve, the flexor tendons, and the digital branches of the median nerve.

The **branches of the superficial volar arch.** In addition to small muscular and cutaneous branches the superficial volar supplies:—

The **common digital** arteries [aa. digitales volares communes]. These, usually four in number, arise from the convexity of the superficial arch and, running downward through the palm, give off the digital arteries proper to both sides of the little, ring, and middle fingers, and the ulnar side of the index finger. The radial side of the index finger and the thumb are supplied by the first volar metacarpal branch of the radial artery.

The most ulnar of the common digital arteries passes distally over the muscles in the ulnar border of the palm, and thence along the ulnar border of the little finger. The remaining arteries pass distally in the three ulnar intermetacarpal spaces to within about 6 mm. ($\frac{1}{4}$ in.) of the clefts between the fingers, where they divide into branches, the **digital arteries proper** [aa. digitales volares propriæ], which supply the sides of contiguous fingers.

As the common digital arteries pass through the palm, they lie between the flexor tendons, on the digital nerves and lumbrical muscles, and beneath the palmar aponeurosis. Just before bifurcating they pass under the transverse fasciculi, and are joined by the volar metacarpal branches from the deep volar arch (fig. 472). At this spot they also receive the volar perforating branches from the dorsal metacarpal vessels. On the sides of the fingers the proper digital arteries lie between the palmar and dorsal digital nerves. They anastomose by small branches, forming an arch across the front of the bones on the proximal side of each interphalangeal joint. They supply the flexor tendons and the integuments, and terminate in a plexiform manner beneath the pulp of the finger and around the matrix of the nail. A dorsal digital branch is given off to the back of the fingers about the level of the middle of the first phalanx, and a second but smaller dorsal digital branch about the level of the middle of the second phalanx.

The **deep branch** of the ulnar artery, also called the communicating artery, sinks deeply into the palm between the abductor and flexor quinti digiti brevis, and joins the radial to form the deep volar arch. (See The Radial Artery.)

THE RADIAL ARTERY

The **radial** artery—the smaller of the two arteries into which the brachial divides at the bend of the elbow—appears as the direct continuation of the brachial. It runs, at first curving laterally, along the radial side of the forearm as far as the styloid process, then, coiling over the radial collateral ligament and the lateral and back part of the wrist, enters the palm of the hand from behind between the first and second metacarpal bones, and ends by anastomosing with the deep branch of the ulnar to form the deep volar arch. Hence the artery is divisible into three parts: that in the forearm, that at the wrist, and that in the palm of the hand. The course of the artery is indicated by a line drawn from a point 2.5 cm. (1 in.) below the centre of the elbow to a point situated just medial to the styloid process of the radius.

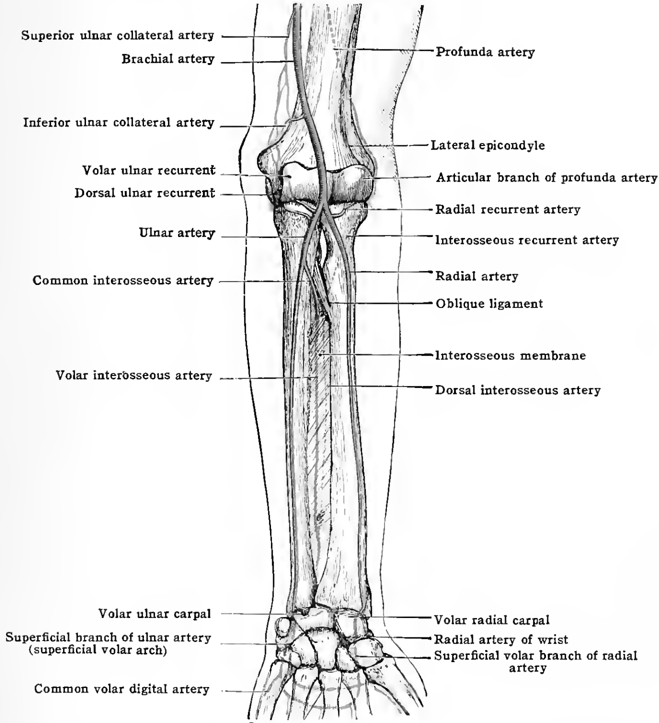
I. The Radial Artery in the Forearm

In its course through the forearm (fig. 470) the radial artery is found in the most lateral of the intermuscular spaces, and it is only necessary to divide the skin, superficial and deep fascia, to expose the vessel, and in addition in the upper third to separate the brachio-radialis from the pronator teres.

Relations.—In front, the artery is at first overlapped by the brachio-radialis, but for the rest of its course it is merely covered by the skin, superficial and deep fasciæ, by some cutaneous veins, and by cutaneous branches of the musculo-cutaneous nerve.

Behind, it lies successively from above downward on the tendon of the biceps, the supinator, from which it is separated by a layer of fat, the insertion of the pronator teres, the radial origin of the flexor digitorum sublimis, the flexor pollicis longus, the pronator quadratus, and the volar surface of the lower end of the radius. It is in this last situation, where the artery lies upon the bone and can therefore be easily pressed against it, that the pulse is usually felt.

Fig. 474.—Diagram of the Relation of the Arteries of the Left Forearm to the Bones. (Walsham.)



On its lateral side it has, throughout the whole of its course, the brachio-radialis muscle, the guide to the artery in ligature, and the lateral vena comitans; in its middle third, the superficial radial nerve as well. In its lower third the superficial radial nerve is to its lateral side, but separated from it by the brachio-radialis and fascia.

On its **medial side,** in the upper third is the pronator teres, in the lower third the tendon of the flexor carpi radialis, and throughout the whole of its course the medial vena comitans.

The **branches of the radial artery in the forearm** are:—(1) The radial recurrent; (2) the muscular; (3) the volar radial carpal; (4) the superficial volar.

(1) The **radial recurrent** [*a.* recurrens radialis] usually arises from the lateral side of the radial just below its origin from the brachial. It at first runs laterally on the supinator and then divides into three chief branches (fig. 475). One of these continues laterally through the fibres of the radial (musculo-spiral) nerve, or between the superficial (radial) and deep radial (posterior interosseous) nerves when the radial (musculo-spiral) divides higher than usual, into the brachio-radialis and extensor carpi radialis longus and brevis, and anastomoses with the interosseous recurrent. A second ascends between the brachialis and brachio-radialis, with the radial

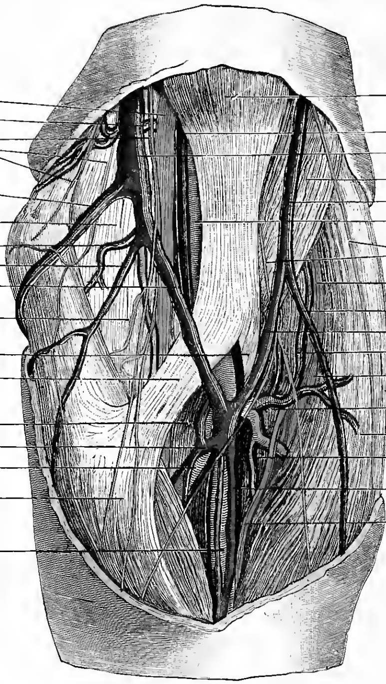
(musculo-spiral) nerve, and anastomoses with the profunda artery. A third descends with the superficial radial nerve under cover of the brachio-radialis, supplying that muscle. The radial recurrent also gives off branches to the elbow-joint.

(2) The **muscular branches** [rami musculares] come off irregularly to supply the contiguous muscles on the lateral side of the forearm.

(3) The **volar radial carpal** branch [ramus carpeus volaris] arises from the medial side of the radial artery about the level of the lower border of the pronator quadratus. It crosses the front of the radius beneath the flexor muscles, and anastomoses with the volar carpal branch of the ulnar, forming the volar carpal rete. This plexus is joined above by terminal twigs from the volar interosseous artery, and below by recurrent branches from the deep volar arch. It supplies branches to the lower end of the radius, and to the wrist and carpal joints.

(4) The **superficial volar** branch [ramus volaris superficialis] leaves the radial artery as the latter vessel is about to turn over the radial collateral ligament to the back of the wrist. It courses forward over the short muscles of the ball of the thumb, and anastomoses with the superficial.

Fig. 475.—The Bend of the Elbow, Left Side.
(From a dissection by Dr. Alder Smith in the Museum of St. Bartholomew's Hospital.)



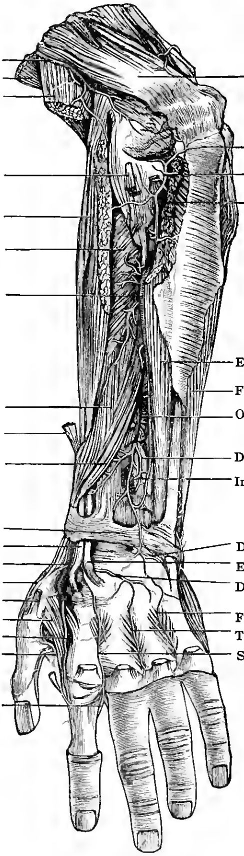
branch of the ulnar artery to complete the superficial volar arch. It supplies small branches to the muscles of the ball of the thumb, and frequently terminates in these muscles without joining the arch. Occasionally it passes beneath the abductor pollicis brevis.

II. The Radial Artery at the Wrist

The radial artery at the wrist winds over the radial side of the carpus, under the extensor tendons of the thumb, from a spot a little below and medial to the styloid process of the radius to the base of the first interosseous space, where it sinks between the two heads of the first dorsal interosseous muscle into the palm, to form, by anastomosing with the deep branch of the ulnar artery, the deep volar arch. A line drawn from 1.2 cm. ($\frac{1}{2}$ in.) medial to the styloid process to the base of the first interosseous space, which can be distinctly felt on the back of the hand, will roughly indicate the course of the artery (fig. 476).

Relations.—The artery is covered successively by the abductor pollicis longus and extensor pollicis brevis, by branches of the superficial radial nerve and veins, and, just before it sinks between the two heads of the interosseous muscle, by the tendon of the extensor pollicis longus. The branches of the superficial radial nerve to the thumb and index finger cross it. It is at first somewhat deeply placed beneath the first-mentioned extensor muscles of the thumb; but subsequently it lies quite superficial, and can be felt pulsating in a little triangular depression bounded on either side by the extensores pollicis longus and brevis, and above by the lower end of the radius. The artery lies successively on the radial collateral ligament of the wrist, on the navicular (scaphoid), the greater multangular (trapezium), the base of the first metacarpal bone, and on the dorsal ligaments uniting these bones. It has usually with it two companion veins, and a few branches of the musculo-cutaneous nerve.

FIG. 476.—THE RADIAL ARTERY AT THE WRIST, LEFT FOREARM.
(From a dissection in the Hunterian Museum.)



The **branches of the radial artery at the wrist** are:—(1) The dorsal radial carpal; (2) the **first dorsal** metacarpal.

(1) The **dorsal radial carpal** branch [ramus carpeus dorsalis] arises from the radial as the latter vessel passes under the abductor pollicis longus, and runs medially beneath the extensor carpi radialis longus and brevis, and the extensor pollicis longus, across the dorsal surface of the carpus, to anastomose with the dorsal ulnar carpal and with the terminal twigs of the posterior branch of the volar interosseous artery. This anastomosis is called the **dorsal carpal**

rete [rete carpi dorsale]. From this rete are given off the second, third, and fourth **dorsal metacarpal** arteries to the second, third, and fourth intermetacarpal spaces respectively. These vessels run downward on the dorsal interosseous muscles as far as the flexure of the fingers, and there divide into two branches (**dorsal digital**), which run along the sides of the contiguous fingers on their dorsal aspect. Near their proximal ends they anastomose with the dorsal **perforating branches of the deep volar arch.** Distally they are connected by **volar perforating** branches with the digital arteries or the corresponding spaces. The branches which run along the backs of the fingers anastomose with the dorsal branches of the first dorsal digital arteries derived from the volar common digital vessels (fig. 476).

(2) The **first dorsal metacarpal** (figs. 472, 476) is given off by the radial shortly before it passes between the two heads of the first dorsal interosseous muscle. It quickly divides into two branches which supply the dorsal surface of the thumb and the radial side of the index-finger toward its dorsal surface.

III. The Radial Artery in the Palm (Deep Volar Arch)

The radial artery enters the palm between the first and second metacarpal bones at the base of the first interosseous space, by passing between the two heads of the first dorsal interosseous muscle. It then runs medially between the transverse and oblique heads of the adductor pollicis muscle and continuing its course in a slight curve with the convexity forward, across the base of the metacarpal bones and interosseous muscles, it anastomoses with the deep branch of the ulnar, forming the **deep volar arch** [arcus volaris profundus]. The arch may be said to extend from the first interosseous space to the base of the metacarpal bone of the little finger, and is a finger's breadth nearer the wrist than the superficial arch. It is covered by the superficial and deep flexor tendons, by the superficial head of the flexor pollicis brevis, and by part of the flexor quinti digiti brevis. It is accompanied by the deep branch of the ulnar nerve, and two small venæ comitantes (figs. 472, 473).

The **branches of the deep volar arch** are:—(1) The princeps pollicis; (2) the radialis indicis; (5) the volar metacarpals (three in number); (4) the recurrent carpal; (3) the dorsal perforating. The first two are usually spoken of as coming off from the radial artery in the palm; the last three from the deep volar arch.

(1) The **arteria princeps pollicis** arises from the radial artery as it enters the palm between the two heads of the first dorsal interosseous muscle. It passes downward between the adductor pollicis transversus and the first dorsal interosseous muscle, parallel to the metacarpal bone, and between the two portions of the flexor pollicis brevis under cover of the flexor pollicis longus. Opposite the metacarpo-phalangeal joint it usually divides into two branches, one of which is distributed to each side of the thumb on its volar aspect. These vessels anastomose with each other at the end of the thumb, like the other digital arteries.

(2) The **arteria radialis indicis** comes off from the radial artery a little lower than the former vessel, or as a common trunk with it, and passes forward between the first dorsal interosseous and adductor pollicis transversus, parallel to the radial side of the second metacarpal bone. After emerging from beneath the adductor pollicis transversus it continues its course along the radial side of the index-finger, on its volar aspect, as far as the tip, anastomosing in this course with the digital artery on the opposite side of the finger in a way similar to that of the other digital arteries. It frequently communicates, at the lower border of the adductor pollicis, with the superficial volar arch and princeps pollicis. It gives off a dorsal branch, which anastomoses with the branch fron the first dorsal metacarpal to the index finger.

(3) The **volar metacarpal** arteries [aa. metacarpeæ volares], three in number, come off from the convexity of the deep arch, and, coursing downward in the centre of the second, third, and fourth interosseous spaces on the interosseous muscles, terminate near the cleft of the fingers by anastomosing with the digital arteries from the superficial arch. These vessels supply the interosseous muscles and the bones, and the second, third, and fourth lumbricales.

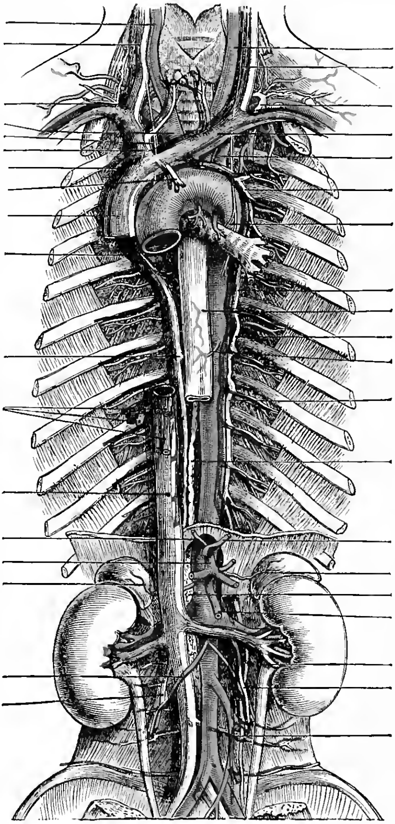
(4) The **recurrent branches** come off from the concavity of the arch, and consist of two or three small vessels which run upward toward the wrist, and anastomose with the volar branch of the volar interosseous, and the volar radial and ulnar carpal arteries.

(5) The **dorsal perforating** branches (rr. perforantes), which are usually three in number, pass from the arch directly through the second, third, and fourth interosseous spaces between the two heads of the corresponding dorsal interosseous muscle, and join the proximal ends of the first dorsal interosseous, and the second, third, and fourth dorsal metacarpal arteries respectively.

THE THORACIC AORTA

The **thoracic aorta** [aorta thoracalis] (fig. 477) is the thoracic portion of the aorta descendens. It extends from the termination of the aortic arch at the lower border of the body of the fourth thoracic vertebra to the lower border of the body of the twelfth thoracic vertebra, where it passes between the medial crura of the diaphragm, and is thence continued under the name of the abdominal aorta. It is at first situated a little to the left of the vertebral column, but as it descends, approaches the front of the column, at the same time following the backward curve of the spine, and at the diaphragm is almost in the middle line. It lies in the posterior mediastinum, having the œsophagus at first a little to the right of it, then in front of it, and just above the tenth thoracic vertebra, where this tube pierces the diaphragm, a little to its left side.

Fig. 477.—The Arch of the Aorta, the Thoracic Aorta, and the Abdominal Aorta, with the Superior and Inferior Vena Cava and the Innominate and Azygos Veins.



Relations.—**In front** it is crossed from above downward by the root of the left lung, by the œsophagus, which separates it from the pericardium and heart, and by the diaphragm.

Behind, it lies upon the lower seven thoracic vertebræ, and is crossed obliquely opposite the seventh or eighth thoracic vertebra by the the vena hemiazygos (azygos minor) and opposite the fifth or sixth vertebra by the accessory hemiazygos vein, or by one or more of the intercostal veins.

On the **right side** it has, above, the œsophagus and vertebral column; lower down the right pleura and lung. The vena azygos and thoracic duct also lie to the right, but on a somewhat posterior plane.

On the **left side** it has the left lung and pleura above, and the œsophagus below. The vena hemiazygos and the accessory hemiazygos vein are also to the left, but on a posterior plane.

Branches of the Thoracic Aorta

The **branches of the thoracic aorta** may be divided into the visceral and the parietal. The **visceral** are:—(1) The pericardiac; (2) the bronchial; and (3) the œsophageal. The **parietal** are:—(1) The intercostal; (2) the superior phrenic; and (3) the arteria aberrans.

A. Visceral Branches

(1) The **pericardiac** branches [rami pericardiaci]—two or three small branches, irregular in their origin, course, and distribution—pass to the posterior surface of the pericardium to supply that structure, and anastomose with the other pericardiac branches. They give small twigs to the posterior mediastinal glands.

(2) The **bronchial** arteries [aa. bronchiales] supply the bronchi and the lung substance. They vary considerably in their origin, course, and distribution; they are usually three in number—one on the right side, and two on the left.

(*a*) The **right bronchial** generally arises either from the first right aortic intercostal, or else as a common trunk with the left upper bronchial from the front of the aorta just below the level of the bifurcation of the trachea. It passes laterally on the back of the right bronchus, and is distributed to the bronchi and lung substance. (*b*) The **left upper bronchial** arises from the front of the aorta just below the bifurcation of the trachea, or as a common trunk with the right bronchial. (*c*) The **left lower bronchial** arises from the front of the aorta just below the level of the left bronchus. Like the corresponding artery on the right side, the left bronchial arteries run laterally on the left bronchus, and, after dividing and subdividing on the back of the bronchi, supply the bronchi themselves and the lung substance. Small twigs are given off from the bronchial arteries to the bronchial glands and to the œsophagus.

(3) The **œsophageal** arteries [aa. œsophageæ], four or sometimes five in number, arise at intervals from the front of the descending thoracic aorta, the first coming off just below the left lower bronchial. They usually increase in size from above downward, the upper coming off more toward the right side of the aorta, the lower more toward the left side. They pass forward to the œsophagus, supplying that tube and anastomosing with each other and with the descending œsophageal branches of the inferior thyreoid above, and with the ascending œsophageal branches of the phrenic and gastric arteries below, thus forming a chain of anastomoses along the whole length of the tube.

B. Parietal Branches

(1) The **intercostal** arteries [aa. intercostales], usually ten in number on each side, supply the lower intercostal spaces, the two upper spaces (occasionally the first only) being supplied from the costo-cervical trunk of the subclavian artery. The lowest artery accompanies the twelfth thoracic nerve below the last rib and is therefore called the **subcostal artery.** Its distribution is similar to that of the lumbar arteries (p. 593) except that it commonly crosses the anterior surface, rather than the posterior, of the quadratus lumborum.

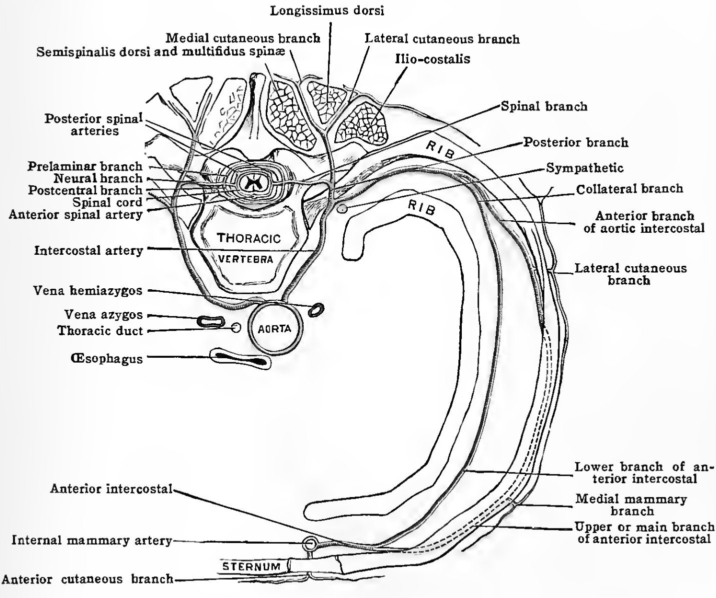
The intercostals arise in pairs from the back part of the aorta, and at once turning, the one to the right, the other to the left, wind backward over the front and sides of the vertebral bodies to reach the intercostal spaces. In fœtal life these arteries run almost transversely backward, or even with a slight inclination downward, to the intercostal spaces; but after the first year, in consequence of the disproportionate growth of the aorta and vertebral column, the upper intercostals have to ascend to reach their respective spaces.

The arteries in their course around the vertebræ differ on the two sides of the body. On the **right side** the arteries—and especially the upper, in consequence of the aorta lying a little to the left side of the spine in the upper part of its course—are longer than the left. They wind over the front and right side of the vertebræ, being crossed by the thoracic duct and vena azygos (major), and covered by the right pleura and lung. The upper are also crossed by the œsophagus. They give off small branches to the bodies of the vertebræ and anterior longitudinal ligament. On the **left side,** as the intercostals wind around the sides of the bodies of the vertebræ, the lower are crossed by the vena hemiazygos (azygos minor), the two upper by the left superior intercostal vein, and the two next by the accessory hemiazygos vein when this is present. They are all covered by the left pleura and lung (fig. 478).

The **branches of the intercostal arteries** are:—(a) anterior, (b) posterior.

(*a*) The **anterior** branches [rami anteriores] at first cross the intercostal space obliquely, in consequence of the downward direction of the ribs, toward the angle of the rib above, and thence are continued forward in the costal groove, and anastomose with the superior branches of the anterior intercostals from the internal mammary in the upper spaces, and from the musculo-phrenic in the lower spaces. They lie at first on the external intercostal muscles, being covered in front by the pleura and lung, the endothoracic fascia, and the subcostal muscles. Opposite the heads of the ribs they are crossed by the sympathetic nerve. At the angle of the ribs they pass under cover of the internal intercostal muscles, and thence to their termination lie between the two intercostal muscles. Their situation in the midspace as far as the angle of the rib should be remembered in performing paracentesis thoracis. To avoid the risk of injuring the vessels, the puncture should not be made further back than the angle of the ribs. They are accompanied by a nerve and vein, the vein lying above and the nerve below, except in the upper spaces, where the artery, having to ascend to reach the space, at first lies below the nerve which runs more horizontally. The uppermost branch anastomoses with the costo-cervical artery from the subclavian, and at times supplies almost entirely the second intercostal space. The arteries to the tenth and eleventh spaces on reaching the end

FIG. 478.—SCHEME OF INTERCOSTAL ARTERY. (Walsham.)



of their respective ribs pass between the abdominal muscles, and anastomose with the inf. epigastric artery from the external iliac, and with the lumbar arteries from the abdominal aorta. The artery beneath the twelfth rib anastomoses with the lumbar arteries and with the external circumflex iliac.

Each anterior branch gives off the following:—(i) The **collateral branch** which comes off near the angle of the rib and runs forward, between the external and internal intercostals, along the upper border of the lower rib enclosing the space. It is smaller than the main anterior branch and anastomoses with the lower anterior intercostal in each space. (ii) **Muscular** branches [rami musculares] supply the intercostal, pectoral and abdominal muscles. (iii) The **lateral cutaneous** branches [rami cutanei laterales], both pectoral and abdominal, run with the corresponding branches of the intercostal nerves through the external intercostal and serratus anterior muscles. They then divide into *anterior* and *posterior* branches which turn forward and backward, respectively, to supply the integument. The anterior branches from the third, fourth and fifth spaces supply *lateral mammary* branches [rr. mammarii laterales] to the lateral region of the breast. (iv) **Anterior cutaneous** branches [rami cutanei anteriores] pierce the external intercostal ligament and the pectoralis major just lateral to the sternum.

They are distributed to the skin and give *medial mammary* branches [rr. mammarii mediales] to the medial region of the breast.

(*b*) The **posterior branches** [rami posteriores].—These large branches are given off from the intercostals opposite the quadrilateral space bounded by the transverse process of the vertebra above, the neck of the rib below, the body of the vertebra medially, and the anterior costo-transverse ligament laterally. Passing backward toward this space with the dorsal branch of the corresponding intercostal nerve, they divide opposite the intervertebral foramen into a muscular and a spinal branch. (i) The **muscular** branch [r. muscularis] passes backward through the quadrilateral space, and soon subdivides into a medial and a lateral branch. The former passes between the longissimus dorsi and ilio-costalis, and, after supplying these muscles, gives off **medial cutaneous** branches [rr. cutanei mediales]. The latter branch pierces the multifidus spinæ, and, emerging between the longissimus dorsi and semispinalis dorsi near the spinous processes, gives off **lateral cutaneous** branches [rr. cutanei laterales]. It supplies the muscles in its course.

(ii) The **spinal** branch [r. spinalis] enters the intervertebral foramen with the spinal nerve of the corresponding segment. The disposition of the spinal branch is similar to that of the spinal branches entering the canalis vertebralis in other regions and may be described here:—

ARTERIES OF THE VERTEBRAL CANAL

Spinal arteries are derived from the vertebral, ascending cervical and costo-cervical arteries, from the dorsal rami of the intercostal (fig. 478) and lumbar arteries, and from the ilio-lumbar and lateral sacral arteries. The spinal branch in each case divides into three branches, post-central, prelaminar and neural.

Each *post-central* branch divides on the lateral part of the posterior longitudinal ligament into an ascending and a descending branch by which means a bilateral series of anastomosing arches are formed throughout the length of the canal. From the concavities of the opposite arches transverse connecting stems are formed which are again connected by a median longitudinal channel.

The *pre-laminar* branches also divide and form an anastomosis in front of the laminæ and ligamenta flava. This is similar in character to the post-central, but much less regular.

The *neural* branches enter the dura mater and are usually small and end by supplying the nerve roots. A variable number of these (5–10 on a side) are larger than the others and reinforce the longitudinal anterior and posterior spinal arteries given off from the vertebrals within the cranium. (For arteries of the spinal cord, see Section VII.)

(2) The **superior phrenic** arteries [aa. phrenicæ superiores], are small twigs coming off from the thoracic aorta immediately above the diaphragm. They are distributed to the vertebral portion of the diaphragm on its upper surface.

(3) The **arteria aberrans** is a small twig which, arising from the thoracic aorta near the right bronchial artery, passes upward and to the right behind the œsophagus and trachea, and is occasionally found to anastomose on the œsophagus with the arteria aberrans of the superior intercostal artery (see p. 568). It is regarded as the remains of the right aortic dorsal stem (fig. 506).

(4) The **mediastinal** branches [rami mediastinales], numerous, but small, are distributed to the pleura, and the vessels, nerves and lymph-nodes of the posterior mediastinum.

THE ABDOMINAL AORTA

The **abdominal aorta** [aorta abdominalis] (fig. 479), the abdominal portion of the descending aorta, begins at the aortic opening in the diaphragm opposite the lower broder of the twelfth thoracic vertebra, and ends usually opposite the middle of the body of the fourth lumbar vertebra by dividing into the right and left common iliac arteries. It is at first centrally placed between the medial crura of the diaphragm, but as it descends in front of the lumbar vertebræ it leaves the middle line, and, at its bifurcation, lies a little to the left side of the spine.

The place at which the aorta bifurcates may be somewhat roughly indicated on the surface of the abdomen by a point about 2.5 cm. (1 in.) below and a little to the left of the umbilicus. The level of its bifurcation may be more accurately determined by drawing a straight line across the front of the abdomen joining the highest points of the iliac crests.

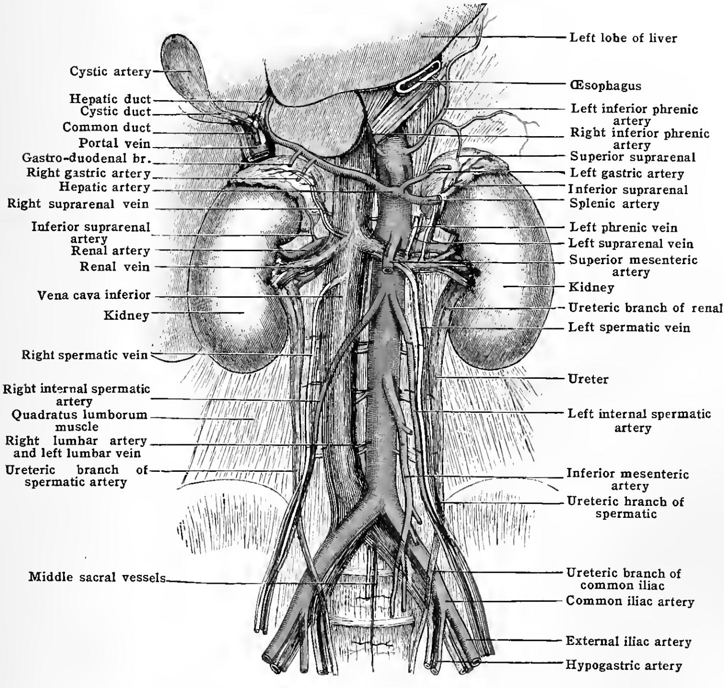
The inferior vena cava, which accompanies the abdominal aorta, lies to its right side. Below, the vein is in contact with the artery and on a somewhat posterior plane; but above, it is separated from the aorta by the right medial crus of the diaphragm, and, in consequence of the caval opening in the diaphragm being placed further forward than the opening for the aorta, is on an anterior plane.

Relations.—**In front,** the aorta is successively crossed from above downward by the right lobe of the liver, the cœliac (solar) plexus, the lesser omentum, the termination of the œsophagus in the stomach, the ascending layer of the transverse meso-colon, the splenic vein or commencement of the portal vein, the pancreas, the left renal vein, the third portion of the duodenum, the mesentery, the aortic plexus of the sympathetic nerve, the internal spermatic or ovarian arteries, the inferior mesenteric artery, the median lumbar lymphatic nodes and lymphatic vessels, and the small intestines.

Of these structures the cœliac (solar) plexus, the aortic plexus, the splenic vein or the commencement of the portal vein, the pancreas, the left renal vein, the duodenum, the lymphatics, the spermatic or ovarian arteries, and the peritoneal reflexions are in contact with the aorta.

Behind, the aorta lies upon the bodies of the lumbar vertebræ and intervening intervertebral cartilages, the anterior longitudinal ligament, the origin of the left medial crus of the diaphragm, and the left lumbar veins.

Fig. 479.—The Abdominal Aorta and its Branches, with the Inferior Vena Cava and its Tributaries.



On the **right side** from above downward are the right medial crus of the diaphragm, the great splanchnic nerve, the caudate lobe of the liver, the receptaculum chyli and beginning of the thoracic duct (the two latter structures are on a posterior plane), the right cœliac (semilunar) ganglion, and the inferior vena cava.

On the **left side** are the left medial crus of the diaphragm, the left splanchnic nerve, and the left cœliac (semilunar) ganglion. The pancreas is also in contact with the aorta on the left side, and the small intestines are separated from it only by peritoneum.

Branches of the Abdominal Aorta

The **branches of the abdominal aorta** usually arise in the following order from above downward (figs. 479, 480):—

(1) Right and left inferior phrenic; (2) cœliac; (3) right and left middle suprarenal; (4) right and left first lumbar; (5) superior mesenteric; (6) right and

left renal; (7) right and left internal spermatic; (8) right and left second lumbar; (9) inferior mesenteric; (10) right and left third lumbar; (11) right and left fourth lumbar; (12) right and left common iliac; (13) middle sacral.

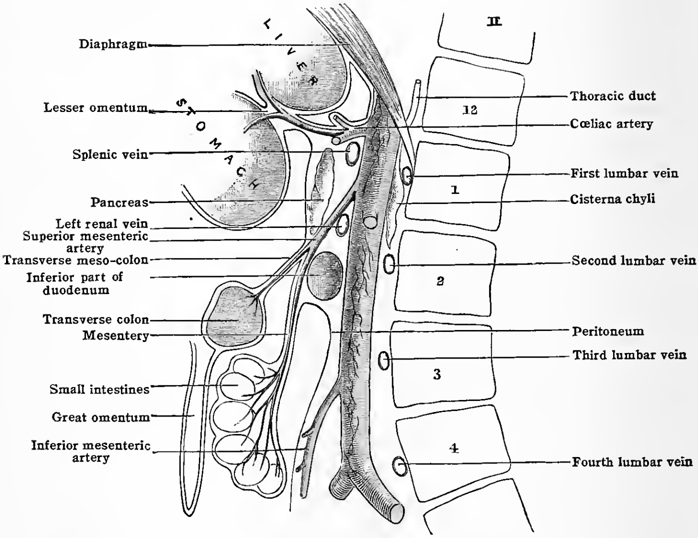
The above branches may be divided into the parietal, the visceral, and the terminal.

The **parietal branches** are distributed to the abdominal walls. They are the right and left phrenics, and the four right and left lumbars.

The **visceral branches** supply the viscera. Three of these are given off singly from the front of the aorta, namely, the cœliac, the superior mesenteric, and the inferior mesenteric; and three are given off in pairs, namely, the two suprarenals, the two renals, and the two spermatics.

The **terminal branches** are the middle sacral and the right and left common iliac arteries.

Fig. 480.—Scheme of the Abdominal Aorta. (Walsham.)



A. The Parietal Branches of the Abdominal Aorta

1. THE INFERIOR PHRENIC ARTERIES

The **inferior phrenic** artery [a. phrenica inferior] usually arises from the aorta as it passes between the medial crura of the diaphragm. At times it comes off from the cœliac artery; or when it arises as two separate vessels, either the right or left vessel may come from this artery, or from other of the upper branches of the abdominal aorta.

The **right phrenic** passes (fig. 480) over the right medial crus of the diaphragm behind the vena cava, and then upward and to the right between the central and right leaflets of the central tendon of the muscle, where it divides into an **anterior** and a **posterior** branch. The former courses anteriorly and medially and anastomoses with the anterior branch of the left phrenic, with the musculo-phrenic branches of the internal mammary, and with the pericardio-phrenic arteries; the latter passes posteriorly and laterally toward the ribs, and anastomoses with the intercostal arteries. Besides the two terminal branches and branches for the supply of the diaphragm itself the right phrenic gives off the **right superior suprarenal** [ramus suprarenalis superior], to the right suprarenal gland, as well as branches to the vena cava, to the liver, and to the pericardium.

The **left phrenic** crosses the left medial crus of the diaphragm behind the œsophagus, and, like the right artery, divides into an anterior and posterior branch and gives off a left suprarenal branch. The distribution and anastamoses are similar on the two sides.

2. THE LUMBAR ARTERIES

The **lumbar** arteries [aa. lumbales] (fig. 479), usually eight in number, four on each side, come off in pairs from the posterior aspect of the abdominal aorta, opposite the bodies of the four upper lumbar vertebræ. A fifth pair of lumbar arteries, generally of small size, frequently arises from the middle sacral artery opposite the fifth lumbar vertebra. The lumbar arteries, which are rather longer on the right than on the left side, in consequence of the aorta lying a little to the left of the median line, wind more or less transversely around the bodies of the vertebræ to the space between the transverse processes, where they give off each a dorsal branch, and then, coursing forward between the abdominal muscles, terminate, by anastomosing with the other arteries of the abdominal wall.

Relations.—As they wind around the bodies of the vertebræ they pass beneath the chain of the sympathetic nerve trunk, and the upper two beneath the crura of the diaphragm. The right arteries also pass beneath the vena cava inferior, and the two upper on that side beneath the receptaculum chyli. The arteries on both sides then dip beneath the tendinous arch thrown across the sides of the bodies of the vertebræ by the psoas, and continue beneath this muscle until they arrive at the interval between the transverse processes of the vertebræ and the medial edge of the quadratus lumborum. While under cover of the psoas tbey are accompanied by two slender filaments of the sympathetic nerve and by the lumbar veins. A little anterior to the transverse processes they are crossed by branches of the lumbar plexus, and here usually cross in front of the ascending lumbar vein. They now pass behind the quadratus lumborum, with the exception sometimes of the last, which may pass in front of the muscle. At the lateral edge of the quadratus they run between the transversus and the internal oblique, and then, after perforating the internal oblique between the internal and external oblique. Finally, much diminished in size, they enter the rectus, and give off one or more anterior cutaneous branches, which accompany the last thoracic and the ilio-hypogastric nerves to the skin. They anastomose with the lower intercostals, ilio-lumbar, deep circumflex iliac, and inf. epigastric arteries.

The **branches of the lumbar arteries** are:—

(*a*) **Vertebral** branches which supply the bodies of the vertebræ and their connecting ligaments.

(*b*) **Muscular** branches to the psoas, quadratus lumborum, and oblique muscles of the abdomen.

(*c*) The **dorsal** branch [r. dorsalis]. This is of large size, and passes backward in company with the dorsal nerve between the transverse processes above and below, the intertransversalis medially and the quadratus lumborum laterally, to the muscles of the back. On reaching the interval between the longissimus dorsi and multifidus spinæ, it divides into a lateral and a medial branch. The former ends in the multifidus, the latter and larger supplies the sacrospinalis, and gives branches which accompany the termination of the dorsal nerves to the skin. Just before the artery passes between the transverse processes it gives off a **spinal** branch [r. spinalis], which accompanies the lumbar nerve through the intervertebral foramen into the vertebral canal (see p. 590).

(*d*) **Renal** branches of small size pass forward in front of the quadratus lumborum to the capsule of the kidney. They anastomose with the renal artery. A communication is thus established between the renal arteries and the arteries supplying the lumbar region.

B. The Visceral Branches of the Abdominal Aorta

THE CŒLIAC ARTERY

The **cœliac** artery [a. cœliaca]—or **cœliac axis**, as it is commonly called, because it breaks up simultaneously into three branches which radiate from it like the spokes of a wheel from the axle—is a short thick trunk given off from the front of the aorta between the medial crura of the diaphragm a little below the aortic opening. It passes horizontally forward above the upper margin of the pancreas for about half an inch, and then breaks up into three branches for the supply of the stomach, duodenum, spleen, pancreas, liver, and gall-bladder (fig. 481).

Relations.—**In front** is the lesser omentum; **behind,** the aorta; **above,** the right lobe of the liver; **below,** the pancreas; to the **right,** the right cœliac (semilunar) ganglion and caudate lobe of the liver; to the **left,** the left cœliac (semilunar) ganglion and the cardiac end of the stomach. It is closely surrounded by the dense cœliac (solar) plexus of sympathetic nerves.

Branches of the cœliac artery.—The cœliac artery divides into the left gastric, the hepatic, and the splenic arteries.

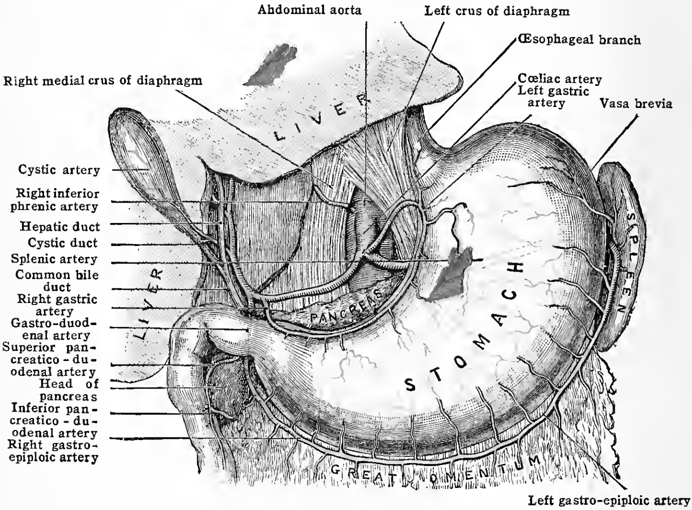
1. The Left Gastric Artery

The **left gastric** [a. gastrica sinistra] (fig. 481), the smallest of the three branches into which the cœliac artery divides, courses at first upward and to the left toward the cardiac end of the stomach, where it turns sharply round, and then, following the lesser curvature of the stomach, descends from left to right toward the pylorus. It anastomoses with the right gastric branch of the hepatic artery, which has proceeded from the opposite direction, the two branches thus forming a continuous arterial arch corresponding to the lesser curvature of the stomach.

The artery at first lies behind the posterior layer of the omental bursa of peritoneum (fig. 480), but on reaching the cardiac end of the stomach it passes, between the layers of peritoneum reflected from the diaphragm onto the œsophagus, into the lesser omentum in which it then runs to its terminal anastomosis with the pyloric. It is surrounded by a plexus of sympathetic nerves.

It supplies both surfaces of the stomach around the lesser curvature and gives off small **œsophageal** branches [rami œsophagei] which anastomose with the œsophageal branches from the thoracic aorta.

Fig. 481.—The Cœliac Artery and its Branches.



2. The Hepatic Artery

The **hepatic** artery [a. hepatica], the largest branch of the cœliac artery in the fœtus, but intermediate in the adult between the left gastric and the splenic, comes off on the right side of the cœliac artery, and, winding upward and to the right to the porta (portal fissure) of the liver, there breaks up into two chief branches for the supply of the right and left lobes of that organ. It at first courses forward and to the right along the upper border of the head of the pancreas, behind the posterior layer of the peritoneal omental bursa, to the upper margin of the duodenum, where it passes forward beneath the layer of peritoneum forming the floor of the epiploic foramen (of Winslow). It thus runs between the two layers of the lesser omentum, and ascends along with the hepatic duct which lies to its right, and with the portal vein which lies behind it (figs. 480, 481).

The **branches of the hepatic artery** are:—(1) The right gastric; (2) the gastro-duodenal; (3) the hepatic proper.

(1) The **right gastric** artery [a. gastrica dextra] comes off from the hepatic just as the latter vessel enters the lesser omentum, and, descending between the two layers of that fold of peritoneum to the pylorus, there turns to the left, and, ascending from right to left, anastomoses along the lesser curvature of the stomach, as already mentioned, with the left gastric artery, which descends from the opposite direction.

(2) The **gastro-duodenal** artery [a. gastroduodenalis] arises from the hepatic

a little beyond the pyloric. It descends behind the superior portion of the duodenum to the lower border of the pylorus, where it divides into the **right gastro-epiploic** and the **superior pancreatico-duodenal.** It varies from 1.2 to 2.5 cm. ($\frac{1}{2}$ to 1 in.) in length.

(*a*) The **right gastro-epiploic** artery [a. gastroepiploica dextra] passes from right to left along the greater curvature of the stomach between the layers of the great omentum, and anastomoses with the left gastro-epiploic branch of the splenic. From this anastomotic arch are given off:—(i) **Ascending** or **gastric** branches, which supply the anterior and posterior surfaces of the stomach, and anastomose with the descending gastric branches of the arteries along the lesser curvature. (ii) **Epiploic** [rami epiploici] or **omental branches**—long slender vessels which descend between the two anterior layers of the great omentum, and then, looping upward, anastomose with similar slender branches given off from the middle and left colic, and passing down in like manner between the two posterior layers of the great omentum.

(*b*) The **superior pancreatico-duodenal** [a. pancreaticoduodenalis superior]—the smaller division of the gastro-duodenal—arises from that vessel as it passes behind the first portion of the duodenum, and courses downward behind the peritoneum, in the anterior groove between the second portion of the duodenum and the pancreas, to anastomose with the inferior pancreatico-duodenal, a branch of the superior mesenteric. Both the inferior and superior pancreatico-duodenal give off **duodenal** [rami duodenales] and **pancreatic** branches [rami pancreatici] to supply these organs.

(3) The **hepatic artery proper** [a. hepatica propria] is the continuation of the hepatic after the gastro-duodenal has arisen. It ascends between the layers of the lesser omentum, preserving the relations of the main artery to the portal vein and common bile (and hepatic) duct, and divides, near the porta hepatis, into **right** and **left** branches.

(*a*) The **right** branch [r. dexter], given off at the porta (portal fissure) of the liver, runs to the right either behind the hepatic and cystic ducts, or between these strucures. At the right end of the porta it divides into or more branches, which again subdivided as they enter the liver substance for the supply of the right lobe. As it crosses the cystic duct it gives off the cystic artery.

The **cystic** artery [a. cystica] courses forward and downward through the angle formed by the union of the hepatic and cystic ducts, and just before it reaches the gall-bladder divides into a superficial and deep branch. The former breaks up into a number of small vessels, which ramify over the free surface of the gall-bladder beneath the peritoneal covering, and furnish branches to the muscular and mucous coats. The deep branch ramifies between the gall-bladder and the liver-substance, supplying each, and anastomosing with the superficial branch.

(*b*) The **left** branch [r. sinister], the smaller division of the hepatic artery, runs medialward toward the left end of the porta hepatis, and, after giving off a distinct branch to the caudate (Spigelian) lobe, enters the left lobe of the liver.

3. The Splenic Artery

The **splenic** artery [a. lienalis]—the largest branch of the cœliac artery—arises from the left side of the termination of that vessel below the left gastric, and passes along the upper border of the pancreas in a tortuous manner to the spleen. It at first lies behind the ascending layer of the transverse meso-colon, but on nearing the spleen enters the lieno-renal ligament, and there breaks up into numerous branches, which enter the hilus and supply the organ. In this course it crosses in front of the left medial crus of the diaphragm and the upper end of the left kidney and is placed above the splenic vein.

The **branches of the splenic artery** are:—(1) The pancreatic; (2) the left gastro-epiploic; (3) the vasa brevia; and (4) the terminal.

(1) The **pancreatic** branches (rami pancreatici) come off from the splenic at varying intervals as that vessel courses along the upper margin of the pancreas. They enter and supply the organ. One larger branch usually arises from the splenic about the junction of its middle with its left third. Entering the pancreas obliquely, it runs from left to right, commonly above, and a little behind, the pancreatic duct, which it supplies together with the substance of the organ.

(2) The **left gastro-epiploic** [a. gastroepiploica sinistra] arises from the splenic near the greater curvature and below the fundus of the stomach, and, passing between the anterior layers of the great omentum, descends along the greater curvature of the stomach from left to right, and anastomoses with the right gastro-epiploic. Like that vessel, it gives off **ascending** or **gastric** branches to the anterior and posterior surfaces of the stomach respectively, and long slender descending **epiploic** or **omental** branches to the great omentum which anastomose with like branches from the right and left colic arteries.

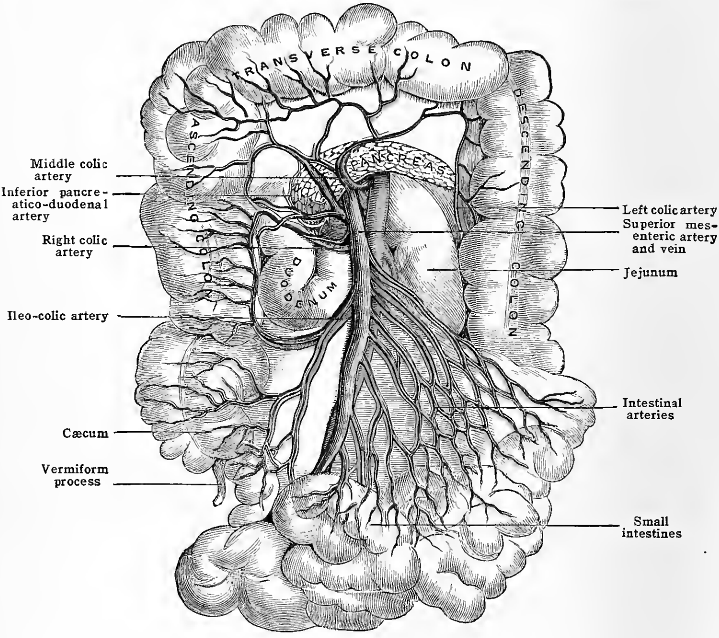
(3) The **vasa brevia** [aa. gastricæ breves] come off from the splenic just before it divides into its terminal branches, oftentimes from some of these terminal branches themselves. Passing from between the folds of the lieno-renal ligament into those of the gastro-lienal, they thus reach the fundus of the stomach, where, ramifying over both its anterior and posterior surfaces, they anastomose with the left gastric and left gastro-epiploic arteries.

(4) The **splenic** or **terminal** branches, five to eight or more in number, are given off from the splenic as it lies in the lieno-renal ligament, and, entering the spleen at the hilum, are distributed in the way mentioned in the description of that organ.

THE SUPERIOR MESENTERIC ARTERY

The **superior mesenteric artery** [a. mesenterica superior] is given off from the front of the aorta a little below the cœliac, which it nearly equals in size; sometimes it forms a common trunk with the cœliac. Lying at first behind the pancreas and splenic vein, it soon passes forward between the lower border of that gland and the upper border of the inferior portion of the duodenum, and, crossing in front of the duodenum, enters the mesentery, in which it runs from left to right, in the form of a curve with its convexity to the left, to the cæcum, where it anastomoses with its ileo-colic branch. Its vein lies to its right side above, having

Fig. 482.—The Superior Mesenteric Artery and Vein.
(The colon is turned up, and the small intestines are drawn over to the left side.)



previously crossed obliquely in front of the artery from left to right. It is surrounded by the mesenteric plexus of nerves. The accessory portion of the head of the pancreas dips in behind the vessel.

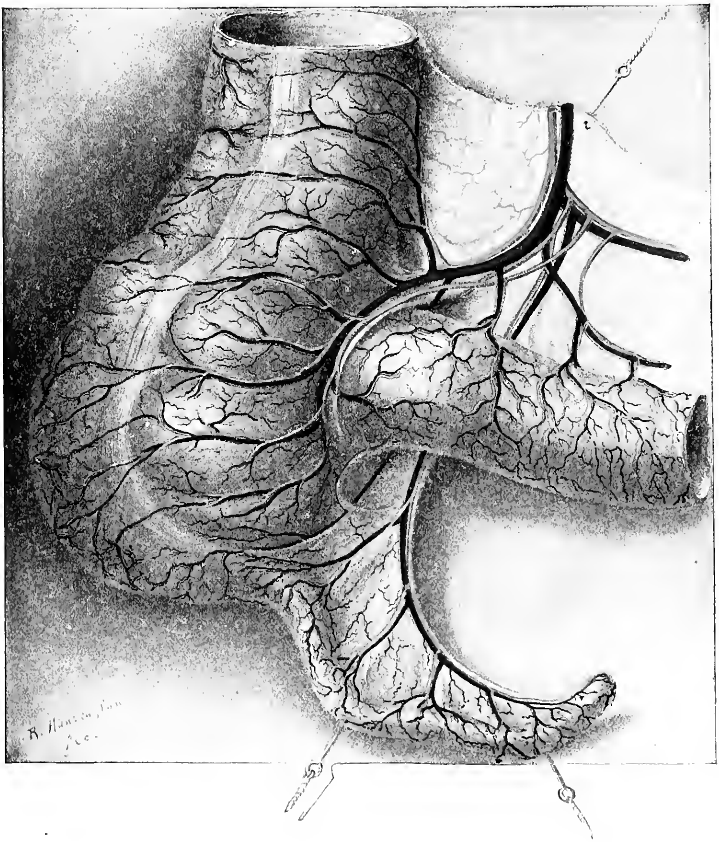
The **branches of the superior mesenteric** are, in their *primitive* order:—(1) the inferior pancreatico-duodenal; (2) the intestinal arteries; (3) the ileo-colic; (4) the right colic; and (5) the middle colic.

(1) The **inferior pancreatico-duodenal** [a. pancreatico duodenalis inferior] arises either from the superior mesenteric as that vessel emerges from the contiguous margins of the pancreas and inferior part of the duodenum or from its first intestinal branch. Crossing behind the superior mesenteric vein, it courses upward and to the right between the head of the pancreas and the duodenum, and beneath the ascending layer of the transverse meso-colon, to anastomose with the superior pancreatico-duodenal.

(2) The **intestinal arteries** [aa. intestinales] arise from the convex side of the superior mesenteric, and, varying from twelve to sixteen in number, radiate in the mesentery, where

Fig. 483.—The Blood-vessels of the Ileo-cæcal Region. (From Kelly.)

(Arteries red, veins blue.) The peritoneal covering is removed so as to show the vessels more clearly. Above and to the right are seen the cut ends of the ileo-colic artery and vein. This artery gives off a branch to the ascending colon and a posterior and anterior cæcal artery, the latter descending through the ileo-colic fold. A short anastomosis connects the ileo-colic with the mesenteric. The artery of the vermiform process (appendix) is seen to arise from the posterior cæcal artery, 2 cm. above the ileum. It passes behind the ileum in the free border of the mesappendix and gives off five branches (long appendices have 8–12, short appendices, 2–3), which traverse the mesappendix at fairly regular intervals in the direction of the hilus of the appendix, where they divide into anterior and posterior branches. The branches in the mesappendix are sometimes seen to anastomose, forming loops of varying size. The terminal branch curves around the tip. The cæco-appendicular junction is supplied by a separate branch arising likewise from the posterior ileo-cæcal trunk. This branch may or may not anastomose with the proximal appendicular twig and while in some cases it supplies only the cæcum, in others, as in the present case, it sends a few delicate branches into the appendix. At the place where this cæco-appendicular artery crosses the ileo-cæcal fold it is seen to give off a delicate recurrent twig to this structure. Throughout their entire course the arteries are accompanied by veins.



each divides into two branches, which inosculate with similar branches given off from the branch above and below. From the primary loops thus formed, secondary loops are derived in like manner, and from these tertiary, and at times quaternary, or even quinary loops. From the ultimate loops terminal **jejunal and iliac** branches [aa. jejunales et ilieæ] pass on to the muscular coat of the gut. These terminal vessels bifurcate, the two branches encircling the intestine, and thus forming with those above and below a series of vascular rings surrounding the small intestine throughout its whole length. The first intestial artery anastomoses with the pancreatico-duodenal arteries, and the last (the continuation of the main artery) with the ileo-colic. These branches of the superior mesenteric in their course to the intestine also supply the mesentery and the mesenteric glands.

(3) The **ileo-colic** [a. ileocolica] descends behind the peritoneum toward the cæcum, where it divides into a colic branch which tracks upward beneath the peritoneum to anastomose with the descending branch of the right colic; and into an iliac branch which passes between the layers of the mesentery and anastomoses with the termination of the superior mesenteric artery. Near the site of division the ileo-colic gives off anterior and posterior cæcal branches. From the latter of these arises a cæco-appendicular artery, to the cæcum and root of the vermiform process, and a main **appendicular** artery [a. appendicularis] (fig. 483).

(4) The **right colic** [a. colica dextra]—sometimes given off as a common trunk either with the middle colic or with the ileo-colic—passes to the right behind the peritoneum to the back of the ascending colon, where it divides into an ascending branch, which anastomoses with the descending branch of the middle colic, and a descending branch which anastomoses with the ascending or colic branch of the ileo-colic.

(5) The **middle colic** [a. colica media], arising from the concavity of the superior mesenteric a little below the pancreas, enters the transverse meso-colon, and divides into two branches—one of which passes to the left and anastomoses with the ascending branch of the left colic; the other, winding downward and to the right, anastomoses with the ascending branch of the right colic.

THE RENAL ARTERIES

The **renal** arteries [aa. renales] come off one on each side of the abdominal aorta, a little below the superior mesenteric and first lumbar arteries, on a level with the first lumbar vertebra. They pass laterally across the crura of the diaphragm to the kidneys, the right being on a slightly lower plane and somewhat longer than the left, and passing behind the inferior vena cava. In front of each is the corresponding renal vein, and behind, at the hilus of the kidney, is the commencement of the ureter. Each artery as it enters the hilus usually divides into three main stems, one of which passes toward the upper part of the pelvis, a second to its middle portion, and a third to its lower. Each of these primary stems then divides so that there result from seven to nine secondary branches, the majority of which pass anterior to the pelvis, while the remainder are posterior to it (fig. 484). No anastomoses take place between the branches of the anterior and posterior secondary stems and hence a longitudinal incision into the kidney along its curved border, half way between the anterior and posterior calices, will cut only terminal arteries.

The **branches of the renal arteries** are:—

(1) The **inferior suprarenal** [a. suprarenalis inferior] which ascends to the suprarenal body.
(2) The **capsular** or **peri-renal** branches to the capsule of the kidney and peri-renal fat.
(3) The **ureteral** branch to the upper end of the ureter.

THE MIDDLE SUPRARENAL ARTERIES

The **middle suprarenal** artery [a. suprarenalis media] comes off, one on each side from the aorta, just above the first lumbar artery, and passes laterally to the suprarenal body, across the medial crura of the diaphragm a little above the renal arteries. In the fœtus they equal the renals in size. In the adult they are much smaller.

They anastomose with the superior and inferior suprarenal arteries from the inferior phrenic and renal arteries respectively. For the distribution of the suprarenal vessels within the suprarenal bodies, see Section XII.

THE INTERNAL SPERMATIC ARTERIES

The **internal spermatic** arteries [a. spermatica interna], (fig. 479), right and left, come off from the front of the abdominal aorta. They diverge from each other as they descend over the aorta and psoas muscle to the abdominal inguinal (internal abdominal) ring, where they are joined by the ductus deferens, and, passing with it through the inguinal canal and out of the subcutaneous inguinal (external abdominal) ring, run downward into the scrotum in a tortuous course to the testes. They terminate in branches to the epididymis and body of those organs. Within the abdomen they lie beneath the peritoneum, and cross in their descent over the ureters and distal ends of the external iliac arteries; the right being super-

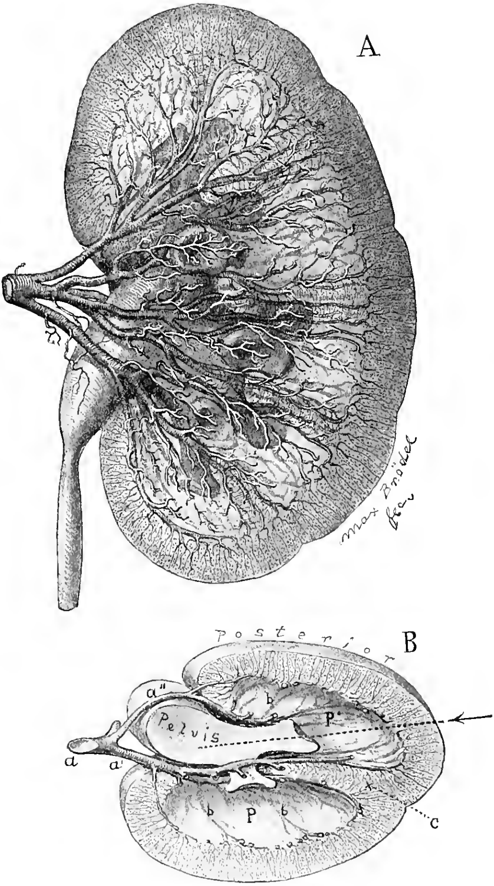
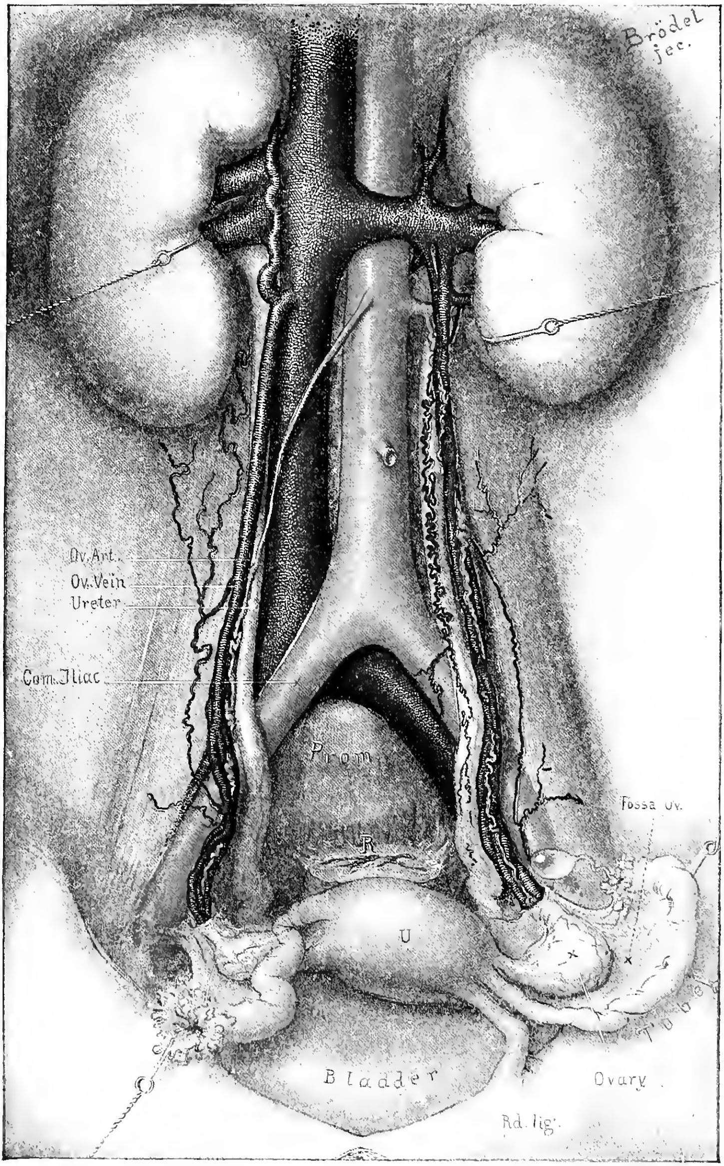
a, renal artery; *a'* and *a''*, its anterior and posterior branches; *b*, branches to pyramids; *c*, line of division between anterior and posterior pyramids. The arrow and dotted line indicate the line of separation between the terminals of the anterior and posterior branches.



ficial to the vena cava, and behind the termination of the ileum; and the left beneath the sigmoid colon. In the inguinal canal and in the scrotum the spermatic veins lie in front of the artery, and the ductus deferens lies behind it.

In the fœtus these vessels pass in a transversely lateral direction to the testis, which in early fœtal life lies in the loin in front of the kidney; but as the testes

FIG. 485.—THE VASCULAR TRUNKS OF THE LOWER ABDOMEN. (From Kelly, by Brödel.)



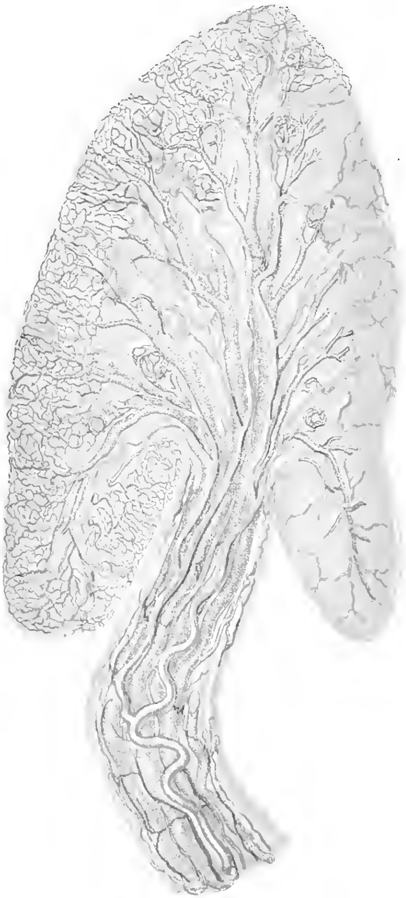
descend to the scrotum, the vessels become elongated, and are drawn with the testis into the scrotum.

The **branches of the internal spermatic artery** are:—(1) Ureteral; (2) cremasteric; (3) epididymal; and (4) testicular.

(1) The **ureteral** are small branches given off to the ureter as the spermatic artery crosses it. They anastomose with the other ureteral branches derived from the renal, common iliac, and vesical arteries.

(2) The **cremasteric** are small branches given off to the cremaster muscle; they anastomose with the cremasteric branch of the inf. epigastric.

Fig. 486.—The Ovarian Vessels. (After Clark.)



(3) The **epididynal** are distributed to the epididymic, and anastomose with the deferential artery.

(4) The **testicular** arteries [aa. testiculares] are the terminal branches of the spermatic; they perforate the tunica albuginea posteriorly, and are distributed to the body of the organ in the way mentioned in the section on the Testis.

The external spermatic artery is a branch of the inferior epigastric artery (p. 614).

THE OVARIAN ARTERIES

The **ovarian** arteries [aa. ovaricæ], are the homologues of the internal spermatic arteries in the male, and correspond in their relations in the upper part of their course. They diverge somewhat less, however, and, on reaching the level of the common iliac artery, turn medialward over that vessel and descend tortuously into the pelvis between the folds of the broad ligament to the ovaries. In the broad ligament the ovarian artery lies below the Fallopian tube, and on reaching the ovary turns backward and supplies that organ. In fig. 486 is shown how the artery enters the hilus of the ovary and breaks up into branches which determine the lobules of the organ.

The **branches of the ovarian arteries** are:—(1) Ureteral; (2) tubal; (3) uterine; and (4) ligamentous.

(1) The ureteral is distributed, as in the male, to the ureter.

(2) The **tubal** supplies the isthmus and ampulla of the tuba uterina (Fallopian tube) and its fimbriated extremity.

(3) The **uterine** runs beneath the tuba uterina (Fallopian tube) to the uterus, supplying the upper part of the fundus, and anastomosing with the uterine arteries from the hypogastric.

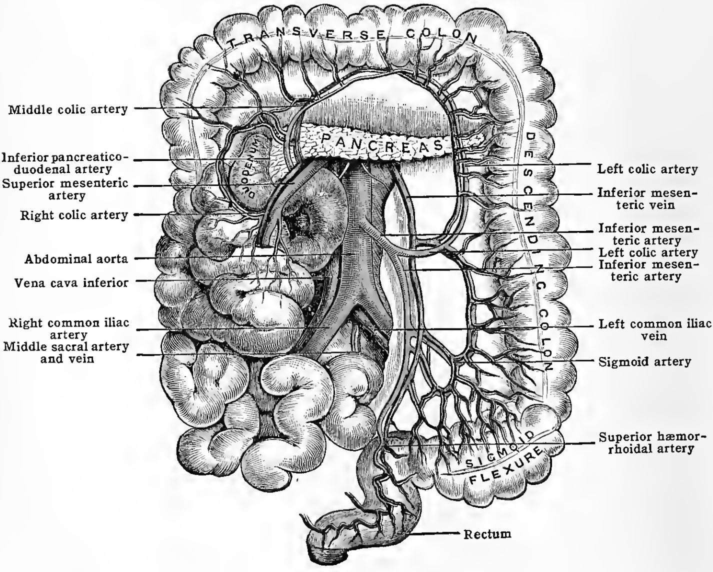
(4) The **ligamentous** is distributed to the round ligament, passing with that structure through the inguinal canal, and anastomosing with the superficial external pudendal artery.

Like the spermatic, the ovarian arteries in the fœtus come off at right angles to the aorta, and pass transversely lateralward to the ovaries, which are formed, as are the testes, in the right and left loin in front of the kidneys. They elongate as the ovaries descend into the pelvis. During pregnancy these arteries undergo great enlargement.

THE INFERIOR MESENTERIC ARTERY

The **inferior mesenteric** artery [a. mesenterica inferior], smaller than the superior, arises from the front of the abdominal aorta about 3.7 cm. ($1\frac{1}{2}$ in.)

Fig. 487.—The Inferior Mesenteric Artery and Vein.
(The colon is turned up, and the small intestines are drawn to the right side.)



above the bifurcation of that vessel. It runs obliquely downward and to the left, behind the peritoneum, across the lower part of the abdominal aorta and then over the left psoas muscle and left common iliac artery. It descends into the pelvis between the layers of the sigmoid meso-colon, and terminates on the rectum in the superior hæmorrhoidal artery. It supplies the lower half of the large intestine. Its vein lies at first close to the left side, but soon passes upward on the psoas, away from the artery, to end in the splenic vein (fig. 487).

The **branches of the inferior mesenteric** are:—(1) The left colic; (2) the sigmoid; and (3) the superior hæmorrhoidal.

(1) The **left colic** artery [a. colica sinistra] runs transversely to the left, beneath the peritoneum, and divides into two branches, one of which, entering the transverse meso-colon, ascends upward and to the right, to anastomose with the middle colic. The other descends, and, entering the sigmoid meso-colon anastomoses with the ascending branch of the sigmoid artery.

The distribution of this artery, and of the next, to the colon is similar to that of the colic branches of the superior mesenteric, and does not require a separate description. (See pp. 597, 598.)

(2) The **sigmoid artery** [a. sigmoidea] runs downward and to the left over the psoas muscle and, entering the sigmoid meso-colon, divides into two branches; the upper anastomosing with the left colic, the lower with the superior hæmorrhoidal.

(3) The **superior hæmorrhoidal** artery [a. hæmorrhoidalis superior] is the continued trunk of the inferior mesenteric. It descends into the pelvis, behind the rectum, between the layers of the sigmoid meso-colon. On reaching the wall of the bowel it bifurcates, one branch proceeding on either side of the gut, to within 10 or 12 cm. (4 or 5 in.) of the anus. Here each again divides, and the branches, piercing the muscular coat, descend between that coat and the mucous membrane, forming with each other, and with the middle hæmorrhoidal arteries—derived from the hypogastric (internal iliac)—a series of small vessels, running longitudinally to the rectum, and parallel to each other as far as the level of the internal sphincter, where, by their anastomosis, they form a series of loops around the lower part of the rectum.

C. The Terminal Branches of the Abdominal Aorta

THE MIDDLE SACRAL ARTERY

The **middle sacral** artery [a. sacralis media], is, anatomically, the continuation of the aorta. The coccygeal glomerulus [glomus coccygeum], in which it terminates, is believed to contain the rudiments of the caudal aorta. The artery extends from the bifurcation of the aorta to the tip of the coccyx. As it passes downward into the pelvis, it runs behind the left common iliac vein, the hypogastric plexus of the sympathetic nerve, and the peritoneum. It lies successively upon the intervertebral disc between the fourth and fifth lumbar vertebræ, the fifth lumbar vertebra, the intervertebral disc between that vertebra and the sacrum, and lower down upon the anterior surface of the sacrum and coccyx.

Branches.—The **branches of the middle sacral artery** are:—

(1) The **lowest lumbar** artery [a. lumbalis ima], which, when present, usually comes off from the middle sacral artery. Each vessel of this pair runs laterally beneath the common iliac artery and vein; and, after giving off a dorsal branch, ramifies over the lateral part of the sacrum, and ends in the iliacus muscle by anastomosing with the circumflex iliac artery. The **dorsal branch** passes to the back between the last lumbar vertebra and the sacrum and ramifies in the gluteus maximus, anastomosing with the lumbar arteries above, and the superior gluteal artery below.

(2) **Lateral sacral** branches, are usually four in number. They are serially homologous with the intercostal and lumbar arteries given off by the aorta. They run laterally, and anastomose with the lateral sacral branches of the hypogastric (internal iliac) artery. They give off small spinal branches, which pass through the sacral foramina, and supply the sacral canal and back of the sacrum.

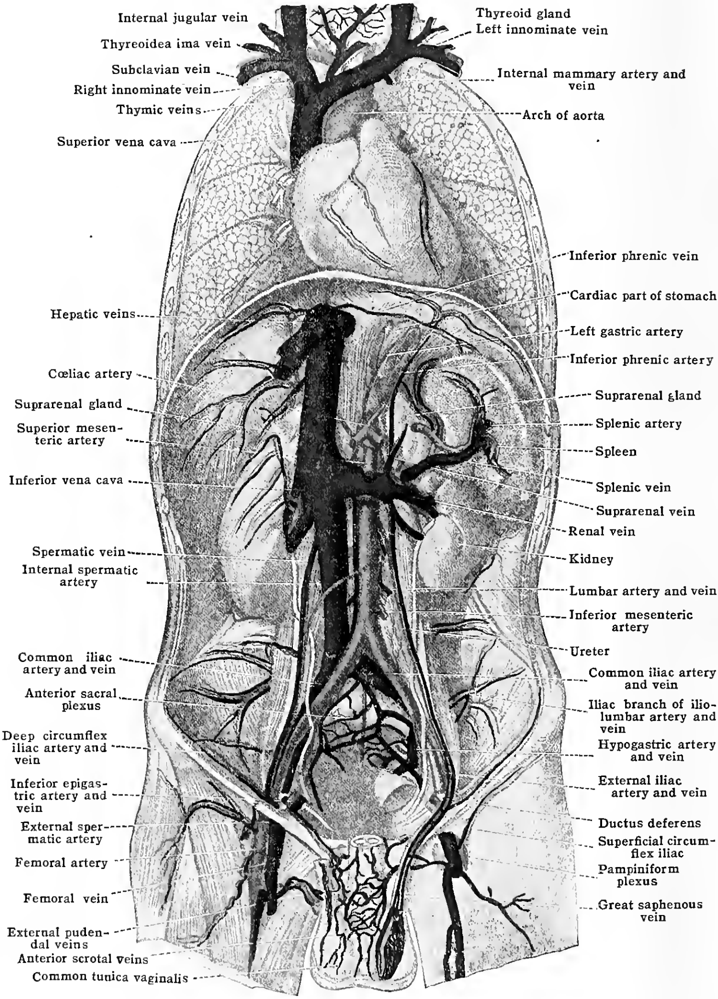
(3) **Rectal** or **hæmorrhoidal** branches pass forward beneath the peritoneum or in the sigmoid meso-colon to the rectum, which they help to supply, and anastomose with the other hæmorrhoidal or rectal arteries.

THE COMMON ILIAC ARTERIES

The **common iliac** arteries [aa. iliacæ communes] arise opposite the left side of the middle of the body of the fourth lumbar vertebra, at the bifurcation of the abdominal aorta, and, diverging from each other in the male at about an angle of 60°, and in the female at an angle of 68°, terminate opposite the lumbo-sacral articulation by bifurcating into the external iliac, which is continued along the brim of the pelvis to the lower limb, and into the hypogastric (internal iliac), which passes through the superior aperture of the pelvis and descends into that cavity (fig. 488).

The relations differ slightly on the two sides, and may be considered separately.

Fig. 488.—The Relations of the Common Iliac Arteries. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The Right Common Iliac Artery

The **right common iliac** measures about 5 cm. (2 in.) in length, and is rather longer than the left, in consequence of the aorta bifurcating a little to the left of the median line.

Relations.—In front it is covered by the peritoneum, and is crossed by the right ureter a little before its bifurcation, by the ovarian artery in the female, by the termination of the ileum, by the terminal branches of the superior mesenteric artery, and by branches of the sympathetic nerve descending to the hypogastric plexus.

Behind, it lies on the right common iliac vein, the end of the left common iliac vein, and the commencement of the inferior vena cava, which separate it from the fourth and fifth lumbar vertebræ and their intervening disc, the psoas muscle, and the sympathetic nerve; whilst still deeper in the groove between the fifth vertebra and the psoas are the lumbo-sacral trunk, the obturator nerve, and the ilio-lumbar artery.

To the **right side** are the beginning of the inferior vena cava, the end of the right common iliac vein, and the psoas muscle, which, however, is separated from the artery by the vena cava inferior at its upper part.

To the **left side** are the right common iliac vein, the termination of the left common iliac vein, and the hypogastric plexus.

The Left Common Iliac Artery

The **left common iliac** artery, 4 cm. (14 in.) in length, is a little shorter and thicker than the right.

Relations.—In front it is covered by the peritoneum, which separates it from the intestines, and is crossed by the ureter, the ovarian artery in the female, branches of the sympathetic nerve descending to the hypogastric plexus, the termination of the inferior mesenteric artery, the sigmoid colon, and the sigmoid mesocolon.

Behind are the lower border of the body of the fourth lumbar vertebra, the disc between the fourth and fifth lumbar vertebra, the body of the fifth lumbar vertebra, and the disc between it and the sacrum. Crossing deeply behind the artery between the fifth lumbar vertebra and the psoas, is the obturator nerve, the lumbo-sacral trunk, and the ilio-lumbar artery.

To the **left side** is the psoas muscle.

To the **right side** are the left common iliac vein, the hypogastric plexus, and the middle sacral artery.

Collateral Circulation

The **collateral circulation** after obstruction or ligature of the common iliac artery is carried on chiefly (fig. 497) by the anastomosis of the middle sacral with the lateral sacral; the internal mammary with the epigastric; the lumbar arteries of the aorta with the ilio-lumbar and deep circumflex iliac; the pubic branch of the epigastric with the pubic branch of the obturator; the posterior branches of the sacral arteries with the superior gluteal (gluteal); the superior hæmorrhoidal from the inferior mesenteric, with the hæmorrhoidal branches of the hypogastric (internal iliac) and pudic; the ovarian arteries from the aorta with the uterine branches of the hypogastric (internal iliac); and by the anastomosis across the middle line of the pubic branch of the obturator with the like vessel of the opposite side; the lateral sacral with the opposite lateral sacral; and the vesical, hæmorrhoidal, uterine, and vaginal branches of the hypogastric with the corresponding branches of the opposite hypogastric (internal iliac).

Branches of the Common Iliac Artery

The **branches of the common iliac artery** are:—(1) The hypogastric (internal iliac); and (2) external iliac.

There are a few small, unimportant branches distributed to the peritoneum and subperitoneal fat. They anastomose with vessels given off from the lumbar, inferior phrenic, and renal arteries, forming a subperitoneal arterial anastomosis. The ureter receives small insignificant twigs as it crosses the artery. They anastomose with the ureteral arteries given off from the internal spermatic above, and with those derived from the vesical arteries below.

THE HYPOGASTRIC ARTERY

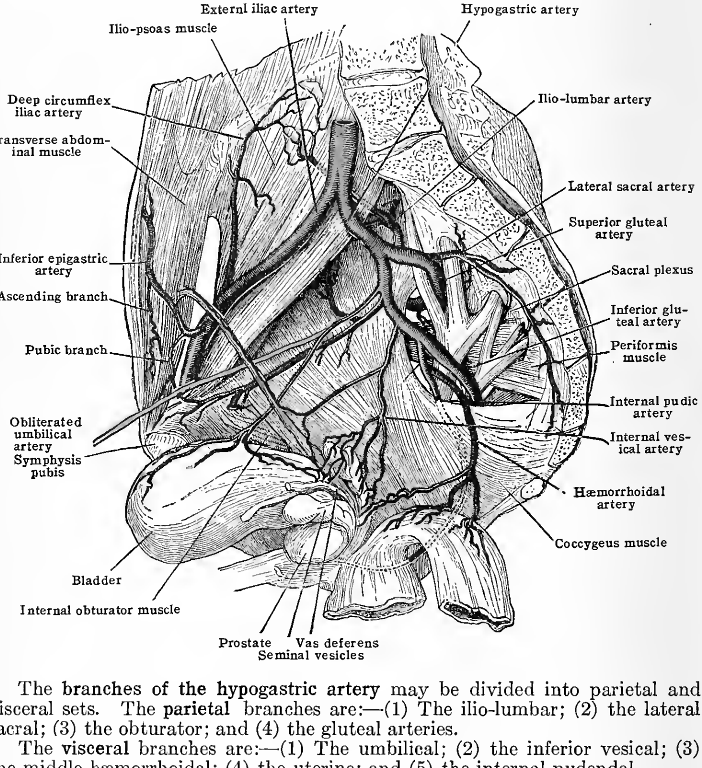
The **hypogastric** or **internal iliac** artery [a. hypogastrica], arises at the bifurcation of the common iliac opposite the lumbo-sacral articulation. It descends into the pelvis for about 3 cm. ($1\frac{1}{4}$ in.) and then divides, opposite the upper margin of the great sciatic foramen, into an anterior and a posterior division. The *anterior division* commonly gives off the obturator, inferior gluteal, umbilical, inferior vesical, deferential, middle hæmorrhoidal, uterine (in the female), and internal pudendal arteries. From the *posterior division* the ilio-lumbar, lateral sacral, and superior gluteal arteries arise. These vessels are classified, for description, as parietal and visceral.

In the adult the hypogastric is smaller than the external iliac; in the fœtus it is much larger and through it the fœtal blood is returned to the placenta. The adult hypogastric and common iliac arteries of either side represent the proximal portion of each of the embryonic umbilical arteries. The remainder of the umbilical artery within the body is represented by the umbilical branch of the hypogastric which runs to the navel. At birth, when the circulation in the umbilical cord ceases, the lumen of the umbilical branch of the hypogastric becomes obliterated except a small channel which remains pervious as the superior vesical of the adult.

Relations.—Behind, the hypogastric artery rests on the termination of the external iliac vein, the hypogastric vein, the medial margin of the psoas muscle, the lumbo-sacral trunk, the obturator nerve, and the sacrum.

In front, it is covered by the peritoneum, and is crossed by the ureter.

Fig. 489.—The Hypogastric Artery. (After Henle.)



The **branches of the hypogastric artery** may be divided into parietal and visceral sets. The **parietal** branches are:—(1) The ilio-lumbar; (2) the lateral sacral; (3) the obturator; and (4) the gluteal arteries.

The **visceral** branches are:—(1) The umbilical; (2) the inferior vesical; (3) the middle hæmorrhoidal; (4) the uterine; and (5) the internal pudendal.

Parietal Branches of the Hypogastric Artery

1. THE ILIO-LUMBAR ARTERY

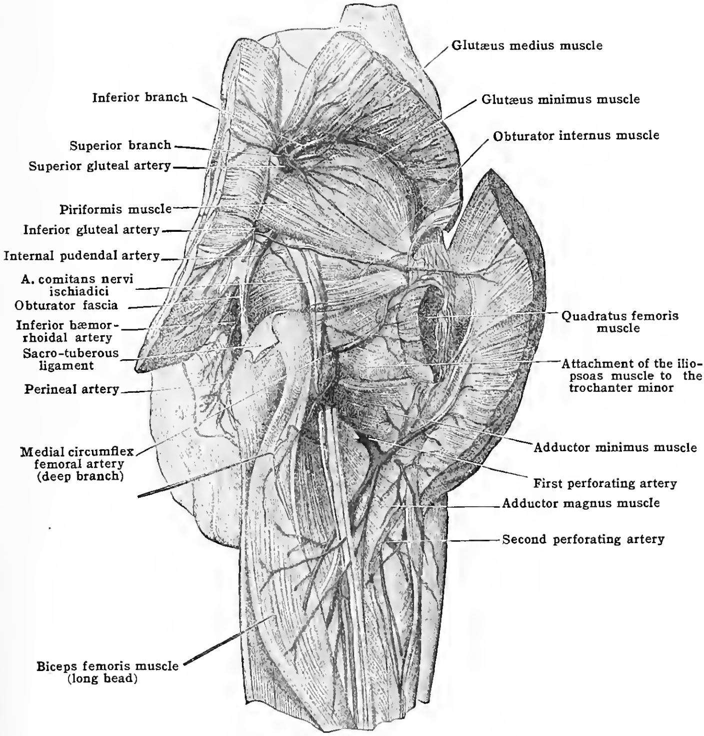
The **ilio-lumbar** artery [a. iliolumbalis]—a short vessel coming off from the posterior part of the hypogastric artery—runs upward and laterally beneath the common iliac artery, first between the lumbo-sacral trunk and obturator nerve, and then between the psoas muscles and the vertebral column. On reaching the superior aperture of the pelvis it divides into two branches, an iliac and a lumbar (fig. 489).

The **iliac** branch [ramus iliacus] passes laterally beneath the psoas and the femoral (anterior crural) nerve and, perforating the iliacus, ramifies in the iliac fossa between that muscle and the bone. It supplies a nutrient artery to the bone, and then breaks up into several branches which radiate from the parent trunk, upward toward the sacro-iliac synchondrosis, laterally toward the crest of the ilium, downward toward the anterior superior spine, and medially toward the pelvic cavity. The first anastomoses with the last lumbar; the second with the external circumflex and gluteal; the third with the deep circumflex iliac from the external iliac; the fourth with the iliac branch of the obturator. The **lumbar** branch [ramus lumbalis] ascends beneath the psoas, and, supplying that muscle and the quadratus lumborum, anastomoses with the last lumbar artery. It sends a **spinal** branch (ramus spinalis) into the vertebral canal through the intervertebral foramen between the last lumbar vertebra and the sacrum; this branch anastomoses with the other spinal arteries. The ilio-lumbar artery is serially homologous with the lumbar arteries. Hence the similarity in its course and distribution.

2. THE LATERAL SACRAL ARTERIES

The **lateral sacral** artery [a. sacralis lateralis], commonly arises as two vessels from the posterior division of the hypogastric. The **superior** artery, when two

Fig. 490.—The Gluteal Arteries. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



are present, runs downward and medially to the first anterior sacral foramen, through which it passes; and, after supplying the spinal membranes and anastomosing with the other spinal arteries, passes through the first posterior sacral foramen, and is distributed to the skin over the back of the sacrum, there anastomosing with branches of the superior and inferior gluteal arteries. The **inferior lateral sacral** descends on the side of the sacrum, lateral to the sacral chain of the sympathetic, and medial to the anterior sacral foramina, crossing in its course the slips of origin of the piriformis muscle and the first anterior sacral nerve. On reaching the coccyx it anastomoses in front of that bone with the middle sacral artery, and with the inferior lateral sacral of the opposite side (fig. 489).

In this course it gives off:—**Spinal branches** [rami spinales], which enter the second, third and fourth anterior sacral foramina, and, after supplying the spinal membranes and anastomosing with each other, leave the spinal canal by the corresponding posterior sacral foramina, and are distributed to the muscle and skin over the back of the sacrum; and **rectal branches** which run forward to the rectum.

At times the lateral sacral arteries are exceedingly small, the spinal branches then coming chiefly from the middle sacral. The anastomosing branches between the lateral sacral and middle sacral are usually regarded as sacral arteries diminished in size, and serially homologous with the lumbar and intercostal arteries.

3. THE OBTURATOR ARTERY

The **obturator** artery [a. obturatoria], usually arises from the anterior division of the hypogastric. It runs forward and downward a little below the brim of the pelvis, having the obturator nerve above and the obturator vein below. It here lies between the peritoneum and the endo-pelvic fascia, but later it passes through the obturator canal, the aperture in the upper part of the obturator membrane. In this course it is crossed by the ductus deferens. On emerging from the obturator canal the artery divides into two branches, anterior and posterior, which wind around the margin of the obturator foramen beneath the obturator externus muscle.

The **branches of the obturator artery** are:—(1) The iliac or nutrient branch; (2) a vesical branch; (3) the pubic branch; (4) the anterior, and (5) posterior terminal branches.

(1) The **iliac** or **nutrient branch** ascends to the iliac fossa, passing between the iliacus muscle and the bone. It supplies a nutrient vessel to the ilium, and anastomoses with the medial branch of the iliac division of the ilio-lumbar artery.

(2) The **vesical branch** or branches are small vessels which run in the lateral false ligament of the bladder to that organ, where they anastomose with the other vesical arteries.

(3) The **pubic branch** [ramus pubicus] comes off from the obturator as that vessel is leaving the pelvis by the obturator canal. It runs upward and medially behind the pubis, anastomosing with its fellow of the opposite side of the body, and with the pubic branch of the inferior epigastric artery. One of the anastomosing channels between the pubic branch of the obturator and pubic branch of the inferior epigastric arteries is sometimes of large size, a fact of surgical interest in that the enlarged vessel may then run around the medial side of the femoral ring (pp. 615 and 636).

(4) The **anterior** branch [ramus anterior] runs around the medial margin of the obturator foramen, and anastomoses with the posterior branch and with the medial circumflex artery. It supplies branches to the obturator and adductor muscles.

(5) The **posterior** branch [ramus posterior] skirts the lateral margin of the obturator foramen, lying between the obturator externus and the obturator membrane. At the lower margin of the foramen it divides into two branches. One branch continues its course around the lower margin of the foramen, and anastomoses with the anterior branch of the obturator and with the medial circumflex. The other branch turns laterally below the acetabulum, and ends in the muscles arising from the tuberosity of the ischium. It anastomoses with the inferior gluteal artery. This branch gives off a small twig, the **acetabular artery** [a. acetabuli], which passes under the transverse ligament into the hip-joint, where it supplies the synovial membrane, the ligamentum teres, and the fat in the fossa at the bottom of the acetabulum.

4. THE GLUTEAL ARTERIES

There are two gluteal arteries, the **superior** and **inferior.** The **superior gluteal** artery [a. glutea superior], the largest branch of the posterior division of the hypogastric comes off as a short, thick trunk from the lateral and back part of that vessel, of which indeed it may be regarded as the continuation. Passing backward between the first sacral nerve and the lumbo-sacral trunk through an osseo-tendinous arch formed by the margin of the bone and the upper edge of the endo-pelvic fascia, it leaves the pelvis through the great sciatic foramen above the piriformis muscle in company with its vein and the superior gluteal nerve. At its exit posteriorly from the great sciatic foramen it lies under cover of the gluteus maximus and beneath the superior gluteal vein, and in front of the superior gluteal nerve. It here breaks up into two chief branches, a superficial and a deep. Its emergence from the pelvis is indicated on the surface by a point situated at the junction of the posterior with the middle third of a line drawn from the anterior superior to the posterior superior spine of the ilium.

The **branches of the superior gluteal artery** are:—

(*a*) **Within the pelvis,** branches are distributed to the obturator internus, the piriformis, the levator ani, the coccygeus, and the pelvic bones.

(*b*) **External to the pelvis,** the artery divides into a superior and an inferior branch.

(i) The **superior** branch [ramus superior] breaks up into a number of large vessels for the supply of the upper portion of the gluteus maximus, some of them piercing the muscle and supplying the skin over it, and anastomosing with the posterior branches of the lateral sacral arteries; whilst one of larger size, emerging from the muscle near the iliac crest, anastomoses with the deep circumflex iliac artery. The lower branches to the muscle anastomose with branches of the inferior gluteal (sciatic).

(ii) The **inferior** branch [ramus inferior] subdivides into two branches—One skirts along the line of origin of the gluteus minimus (fig. 490), between the gluteus medius and the bone, and, emerging in front from beneath these muscles under cover of the tensor fasciæ latæ, anastomoses with the ascending branch of the lateral circumflex and the deep circumflex iliac arteries. The other passes forward between the gluteus medius and minimus, accompanied by the branch to the tensor fasciæ latæ of the inferior division of the superior gluteal nerve, toward the greater trochanter, where it anastomoses with the ascending branch of the lateral circumflex. It supplies branches to the contiguous muscles and to the hip-joint. The inferior branch before its division gives off the external nutrient artery of the ilium.

The **inferior gluteal** [a. glutea inferior], is one of the terminal branches of the anterior division of the hypogastric artery. It leaves the pelvis below the piriformis muscle, and immediately breaks up into a number of diverging branches. The largest enter the gluteus maximus muscle, where they anastomose with the superior gluteal branches. Others pass to the hip-joint and the deep muscles around it; a third group passes downward to the hamstring muscles and anastomoses with the medial and lateral circumflex and first perforating; a fourth slender branch, the **sciatic** artery [a. comitans n. ischiadici], accompanies the sciatic nerve (fig. 490).

Visceral Branches of the Hypogastric Artery

1. THE UMBILICAL ARTERY

The **umbilical** artery in the fœtus is the continuation of the hypogastric. Passing forward along the side of the pelvis, it runs beneath the lateral reflexion of peritoneum from the bladder, where, after giving off one or more vesical branches, it ceases to be pervious and passes on to the side and upper part of the bladder. Thence it ascends in the lateral umbilical fold, as a fibrous cord [ligamentum umbilicale laterale], to the umbilicus, where it is joined by its fellow of the opposite side. As it lies lateral to the bladder it is crossed by the ductus deferens.

The **branches of the umbilical artery** are:—(1) Superior vesical arteries, the lowest of which is sometimes called (2) the middle vesical artery (fig. 489).

The **superior vesical** arteries [aa. vesicales superiores] ramify over the upper surface of the bladder, anastomosing with the artery of the opposite side and with the middle and inferior vesical below. They give off the following branches:—(*a*) The **urachal** branches which pass upward along the urachus. (*b*) The **ureteric** branches pass to the lower end of the ureter, and anastomose with the other ureteric arteries. (*c*) The **middle vesical** may come off from one of the superior vesicals or from the umbilical. It is distributed to the sides and base of the bladder, and anastomoses with the other vesical arteries.

2. THE INFERIOR VESICAL ARTERY

The **inferior vesical** artery [a. vesicalis inferior] arises from the anterior division of the hypogastric, frequently in common with the middle hæmorrhoidal, and passes downward and medially to the fundus of the bladder, where it breaks up into branches which ramify over the lower part of the viscus. It gives off branches to the prostate, which supply that organ and anastomose with the arteries of the opposite side by means of descending arteries which pass through the prostatic plexus of veins, but outside the capsule of the prostate, and with the inferior hæmorrhoidal branches of the internal pudic. At times one of these prostatic branches is of large size, and supplies certain of the parts normally supplied by the int. pudendal. It is then known as the **accessory pudendal** and most commonly terminates as the dorsal artery of the penis.

The inferior vesical usually gives off the **deferential, or artery of the ductus deferens** [a. deferentialis]. This vessel, which may come off from the superior vesical, divides, on the ductus deferens, into an ascending and a descending branch. The ascending branch follows the ductus through the inguinal canal to the testis, where it anastomoses with the internal spermatic artery. The descending branch passes downward to the dilated portion of the ductus and vesiculæ seminales.

3. THE MIDDLE HÆMORRHOIDAL ARTERY

The **middle hæmorrhoidal** artery [a. hæmorrhoidals media], variable in origin, perhaps most commonly arises from the anterior division of the hypogastric along with the inferior vesical. It runs medially to the side of the middle portion of the rectum, dividing into branches which anastomose above with the superior hæmorrhoidal derived from the inferior mesenteric, and below with the inferior hæmorrhoidal derived from branches of the internal pudendal. Its corresponding vein terminates in the inferior mesenteric vein. In the female it also sends branches to the vagina.

4. THE UTERINE ARTERY

The **uterine** artery [a. uterina], arises from the anterior division of the hypogastric close to or in conjunction with the middle hæmorrhoidal or inferior vesical. It runs downward and medially through the pelvic connective tissue, crossing the ureter about 12 mm. ($\frac{1}{2}$ in.) from the cervix uteri. It then turns upward and ascends in the parametrium between the layers of the broad ligament at the side of the uterus in a coiled and tortuous manner, and, after giving off a number of tortuous branches which ramify horizontally over the front and back of the uterus, supplying its substance, anastomoses with the uterine branch of the ovarian artery.

In addition to the branches to the uterus the **branches of the uterine artery** are:—(1) **Cervical.**—This branch comes off from the uterine as the latter artery crosses the ureter to turn upward on to the uterus. It is directed medially, and divides into three or four branches which pass on to the cervix at right angles to it; one branch anastomosing with its fellow of the opposite side in front and behind the neck, forming the so-called coronary artery of the cervix. (2) **Tubal** [ramus tubarius].—This courses along the lower surface of the tuba uterina (Fallopian tube) as far as its fimbriated extremity, and may also send a branch to the ligamentum teres. (3) **Ovarian** [ramus ovarii].—This runs along the attached border of the ovary, sending branches to that structure, and terminates by anastomosing widely with the ovarian artery. Usually the vaginal artery also arises from the uterine. (4) The **vaginal** artery [a. vaginalis] corresponds to the inferior vesical artery of the male, and may arise directly from the hypogastric artery, close to the origin of the uterine, or from the superior vesical. It passes medially, behind the ureter, to the upper part of the vagina, and sends numerous branches to that structure and also some to the posterior part of the fundus of the bladder.

The branches to the vagina tend to anastomose with one another and with the cervical branch of the uterine, to form a more or less perfect vertical stem in the median line of the vagina, both back and front. This stem is sometimes termed the **azygos artery of the vagina.** Branches also pass to the vagina from the middle hæmorrhoidal artery.

5. THE INTERNAL PUDENDAL ARTERY

The **internal pudendal** (pudic) artery [a. pudenda interna] (figs. 492, 493, 494) is one of the terminal branches of the anterior division of the hypogastric artery (the inferior gluteal being the other). It arises opposite the piriformis muscle and accompanies the inferior gluteal downward to the lower border of the great sciatic foramen. It leaves the pelvis between the piriformis and coccygeus and winds over the ischial spine to enter the ischio-rectal fossa through the small sciatic foramen. Running forward in the ischio-rectal fossa medial to the lower part of the obturator internus it ends by dividing into the **perineal artery** and the **artery of the penis** (or clitoris).

Relations.—*Within the pelvis,* the artery is anterior to the piriformis muscle and the sacral plexus of nerves, and lateral to the inferior gluteal artery. It passes between the piriformis and coccygeus, with the gluteal artery and pudendal nerve medial to it, and the nerve to the obturator internus lateral. The sciatic and posterior femoral cutaneous (lesser sciatic) nerves are still more lateral. *On the ischial spine* the artery retains its relations to the pudendal nerve (which often divides in this situation into its two terminal branches) and the nerve to the obturator internus. It is accompanied by venæ comitantes and covered by the gluteus maximus

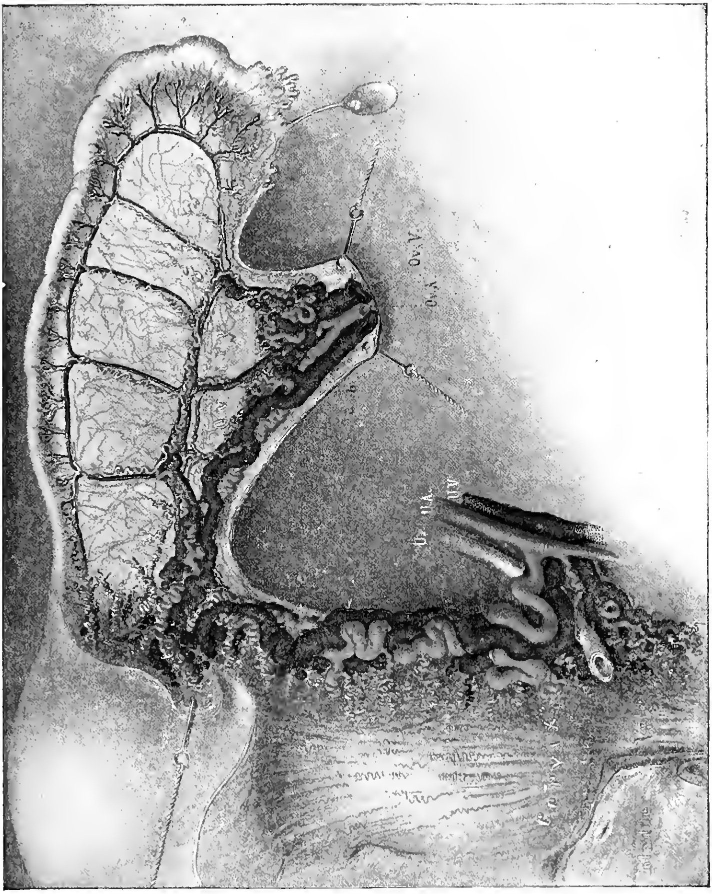


Fig. 491.—Scheme of the Ovarian and Uterine and Vaginal Arteries. (From Kelly, by Brödel.)

muscle. *In the ischio-rectal fossa* the artery is placed on the lateral wall about 3.5 cm. (1½ in.) above the tuberosity of the ischium. It is accompanied in a canal in the obturator fascia (Alcock's canal) by the dorsal nerve of the penis and the perineal nerve, which are respectively above and below the artery.

The **branches of the internal pudendal artery** are:—(1) Small branches to the gluteal region; (2) the inferior hæmorrhoidal arteries; and the terminal branches (3) perineal; and (4) artery to the penis or clitoris.

FIG. 492.—THE INTERNAL PUDENDAL ARTERY. (From Kelly, by Brödel.)

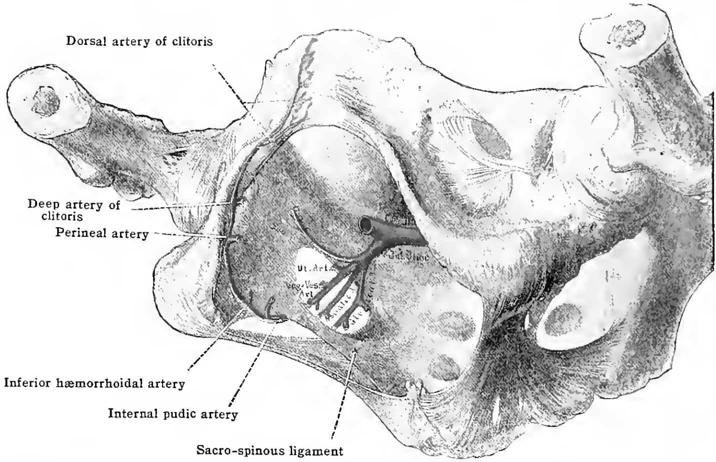

FIG. 493.—THE PERINEAL AND HÆMORRHOIDAL BRANCHES OF THE INTERNAL PUDENDAL ARTERIES. (From Kelly, by Brödel.)

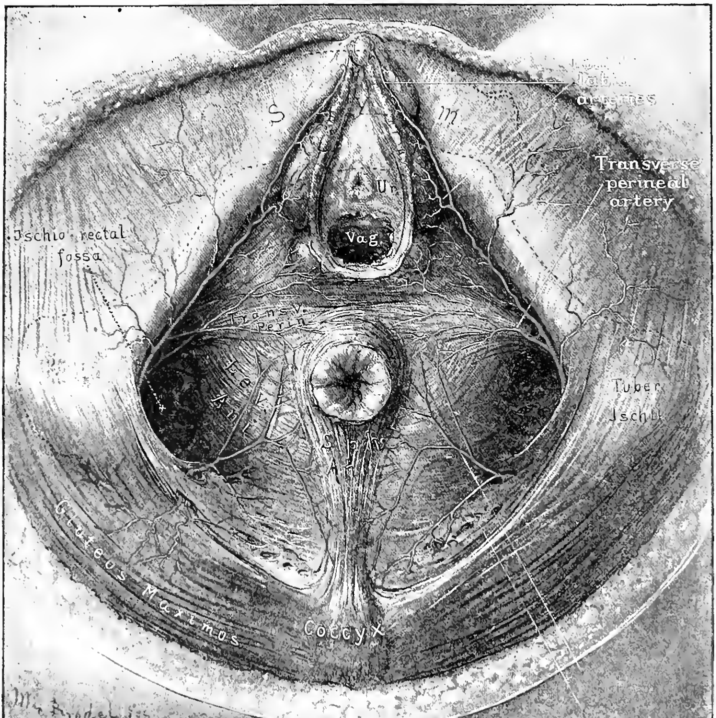


(1) The **branches of the gluteal region** are: (*a*) twigs to the gluteus maximus; (*b*) branches accompanying the nerve to the obturator internus; (*c*) a sacral branch which pierces the sacrotuberous ligament, and anastomoses with the inferior gluteal artery.

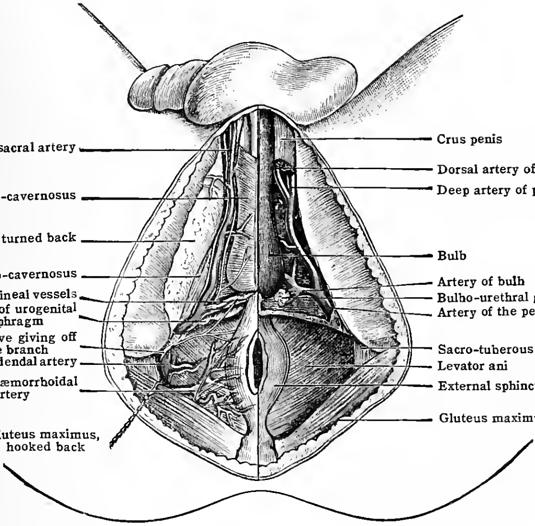
(2) The **inferior hemorrhoidal** artery (a. hæmorrhoidalis inferior] (figs, 493, 494) arises at the posterior part of the ischio-rectal fossa and, perforating the obturator fascia, at once breaks up into several branches. These, running medially toward the anus, traverse the ischio-rectal fat and supply the fascia, skin and the levator ani and external sphincter muscles. The inferior hæmorrhoidal branches anastomose with those from the middle and superior hæmorrhoidal, and from the gluteal and perineal arteries.

(3) The **perineal** artery [a. perinei] (figs. 493, 494), one of the terminal arteries of the internal pudendal, arises at the anterior part of the ischio-rectal fossa. It pierces the base of the urogenital diaphragm (triangular ligament) anterior or posterior to the superficial transverse perineal muscle, and enters the space deep to Colles's fascia. Here it runs forward between the ischio- and bulbo-cavernosus muscles to the scrotum or labium majus and divides into numerous terminal branches. Immediately after piercing the diaphragm, the perineal artery gives off a constant **transverse perineal** branch which runs toward the median line along the superficial transverse perineal muscle. The terminal branches of the perineal are the **posterior scrotal or labial** arteries [aa. scrotales, or labiales posteriores] which ramify on the scrotum or labia majora (according to sex) and anastomose with external pudendal arteries.

(4) The **artery of the penis, or clitoris** [a. penis or clitoridis] (figs. 493, 494) pierces the free border of the urogenital diaphragm and runs forward between the layers of the diaphragm with the dorsal nerve of the penis along the inferior ramus of the pubis. It traverses the fibres of the deep transverse perineal muscle and of the sphincter of the membranous urethra and

Fig. 494.—The Arteries of the Male Perinæum.

On the right side Colles's fascia has been turned back to show the perineal artery. On the left side the perineal vessels have been cut away with the inferior layer of the urogenital diaphragm to show the artery of the penis.



ends by dividing into deep and dorsal arteries of the penis, or clitoris, according to sex.

The **branches of the artery of the penis (or clitoris)** are: (*a*) The artery to the bulb; (*b*) the urethral artery; and (*c*) the terminal, deep artery of the penis or clitoris.

(*a*) The **artery of the bulb** [a. bulbi urethræ or vestibuli vaginæ] takes a medial direction through the fibres of the m. transversus perinei profundus. It then pierces the inferior fascia of the urogenital diaphragm to reach the bulb, the erectile tissue of which it supplies, in either sex. This vessel also supplies branches to the bulbo-urethral gland (Cowperi) or the gland of the vestibule (Bartholini).

The situation of the artery to the bulb should be remembered in performing the operation of lateral lithotomy, particularly as it may arise far back. When the artery arises, as it occasionally does, from the accessory pudendal it pierces the urogenital diaphragm further forward and is out of danger in the ordinary low operation.

(*b*) The **urethral** artery [a. urethralis] is a small branch which passes into the corpus spongiosum and anastomoses with branches from the artery of the bulb.

(*c*) The **deep artery of the penis or clitoris** [a. profunda penis or clitoridis], larger in the male sex, pierces the inferior layer of the urogenital diaphragm near the inferior ramus of the pubis. It enters the crus of the penis (fig. 494) or clitoris, and is distributed in the corpus cavernosum urethræ.

(*d*) The **dorsal artery of the penis or clitoris** [a. dorsalis penis or clitoridis] (figs. 492, 494), perforates the inferior fascia of the urogenital diaphragm near its apex. The dorsal nerve is lateral to the artery and both join the dorsal vein (which lies between the arteries of either side) on the dorsum of the penis or clitoris. The artery is much larger in the male than the female; in either sex it supplies the glans, corona, and prepuce and anastomoses with the external pudendal artery.

THE EXTERNAL ILIAC ARTERY

The **external iliac** artery [a. iliaca externa]—the larger in the adult of the two vessels into which the common iliac divides opposite the lumbo-sacral articulation—extends along the superior aperture of the pelvis, lying upon the medial border of the psoas muscle, to the lower margin of the inguinal ligament, where, midway between the anterior superior spine of the ilium and the symphysis pubis, it passes into the thigh, and takes the name of the femoral.

It measures 8.5 to 10 cm. ($3\frac{1}{2}$ to 4 in.) in length. The course of the vessel is indicated by a line drawn from 2.5 cm. (1 in.) below and a little to the left of the umbilicus to a spot midway between the symphysis pubis and the anterior superior spine of the ilium. If this line is divided into thirds, the lower two-thirds indicate the situation of the external iliac, the upper third the common iliac. The external iliac vein, the continuation upward of the femoral vein from the thigh, lies to the medial side of the artery, but on a slightly lower plane, and, just before its termination, gets a little behind the artery on the right side.

Relations.—In front, the artery together with the vein is covered by the parietal peritoneum descending from the abdomen into the pelvis, and by a layer of condensed subperitoneal tissue (Abernethy's fascia). It is crossed by the termination of the ileum on the right side, and by the sigmoid colon on the left. The external spermatic (genital) branch of the genito-femoral (genito-crural) nerve runs obliquely over its lower third, and just before its termination it is crossed transversely by the deep circumflex iliac vein. The internal spermatic or ovarian vessels lie for a short distance on the lower part of the artery, and the ductus deferens in the male curves over it to descend to the pelvis. It is sometimes crossed at its origin by the ureter. The external iliac lymphatic nodes lie along the course of the artery. The commencement of its inferior epigastric branch is also in front.

Behind.—At first the artery lies partly upon its own vein; lower down upon the medial border of the psoas; and just before it passes through the lacuna vasorum, beneath Poupart's ligament, upon the tendon of the psoas. The continuation of the iliac into the endo-pelvic fascia is also below it.

To its **medial side** is the external iliac vein, the peritoneum, and the ductus deferens in the male, or the ovarian vessels in the female.

To its **lateral side** is the psoas muscle and the iliac fascia.

The **collateral circulation** is carried on (fig. 497) when the external iliac is tied, by the anastomosis of the ilio-lumbar and lumbar arteries with the circumflex iliac; the internal mammary with the inferior epigastric; the obturator with the medial circumflex; the inferior gluteal with the medial circumflex and superior perforating; the gluteal with the lateral circumflex; the arteria comitans nervi ischiadici from the inferior gluteal, with the perforating branches of the profunda; the external pudenal with the internal pudendal; the pubic branch of the obturator with the pubic branch of the epigastric.

The **branches of the external iliac artery** are:—(1) The inferior epigastric; (2) the deep circumflex iliac; and (3) several small and insignificant twigs to the neighbouring psoas muscles and lymphatic gland.

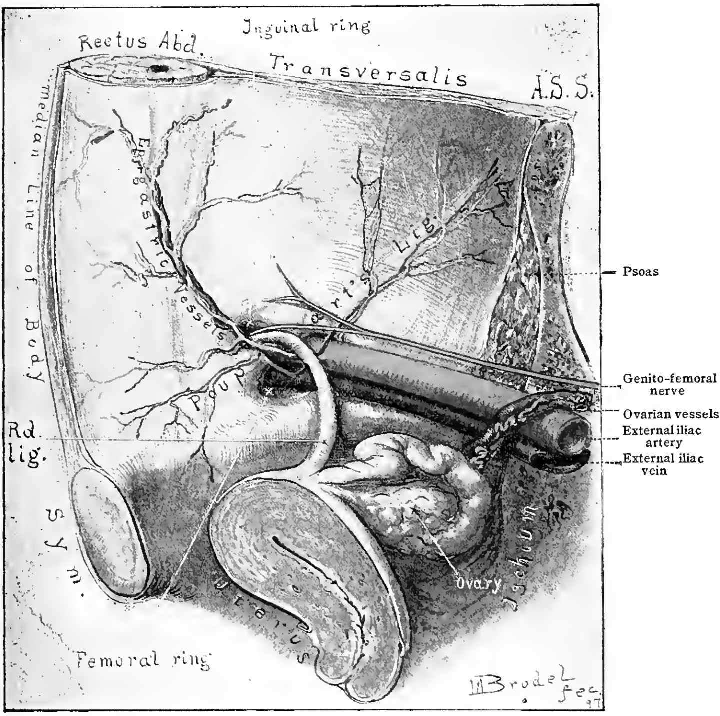
(1) The Inferior Epigastric Artery

The **inferior** or **deep epigastric** artery [a. epigastrica inferior] (fig. 495) usually comes off from the external iliac just above the inguinal (Poupart's) ligament. Immediately after its origin, the ductus deferens in the male, and the round ligament in the female, loop around it on their way to the pelvis. It here lies medial to the abdominal inguinal (internal abdominal) ring, behind the inguinal canal, and a little above and lateral tc the femoral ring. Thence it ascends with a slightly medial direction passing above and to the lateral side of the subcutaneous inguinal (external abdominal) ring, lying between the fascia transversalis and the peritoneum. Having pierced the fascia transversalis at this point, it passes in front of the linea semicircularis (Douglas' fold) and turns upward between the rectus and its sheath. Higher, it enters the substance of the muscle, and anastomoses with the superior epigastric, descending in the rectus from the internal mammary.

The situation of the artery between the two inguinal rings should be borne in mind in the operation for strangulated inguinal hernia, and its near proximity to the upper and lateral side of the femoral ring should not be forgotten in the operation for femoral hernia. The artery is accompanied by two veins which end in a siugle trunk before opening into the external iliac vein.

The **branches of the inferior epigastric** are small and include:—(*a*) The **external spermatic** [a. spermatica externa], which runs with the ductus through the inguinal canal, supplies the cremaster muscle, and anastomoses with the internal spermatic, external pudendal, and perineal arteries. In the female a corresponding artery [a. lig. teretis uteri] accompanies the round liga-

Fig. 495.—The Inferior (Deep) Epigastric Artery. (From Kelly, by Brödel).



ment of the uterus through the inguinal canal and anastomoses in a similar manner. (*b*) The **pubic** [ramus pubicus], which passes below, or sometimes above, the femoral ring to the back of the pubis, where it anastomoses with the pubic branch of the obturator. This branch, though usually small, is occasionally considerably enlarged, when its exact course becomes of great interest to the surgeon. Thus it may descend immediately medial to the vein, and therefore lateral to the femoral ring, or it may course medially in front of the femoral ring and turn downward either behind the os pubis or immediately behind the free edge of the lacunar (Gimbernat's) ligament, in which situation it would be exposed to injury in the operation for the relief of a strangulated femoral hernia. In such cases the obturator may lose its connection with the hypogastric and actually arise from the inferior epigastric. Very rarely the inferior epigastric loses its connection with the external iliac and arises from the obturator. This abnormal origin of the obturator is said to occur once in every three subjects and a half; but the abnormal artery only courses around the medial side of the ring—in which situation it is liable to injury in the operation for femoral hernia—in exceptional cases. According to Langton (Holden's 'Anatomy'), the chances are about seventy to one against this occurring. But even when it takes the abnormal course, it lies 3 mm. or so from the margin of the ring, and will probably escape injury in the division of the stricture if several short notches are made in place of a single and longer incision.

(2) The Deep Circumflex Iliac Artery

The **deep circumflex iliac** artery [a. circumflexa ilium profunda], arises from the lateral side of the external iliac artery either opposite the epigastric or a little below the origin of that vessel. It courses laterally just above the lower margin of Poupart's ligament, lying between the fascia transversalis and the peritoneum, or at times in a fibrous canal formed by the union of the fascia transversalis with the iliac fascia. Near the anterior superior spine of the ilium, it perforates the transversus, and then courses between that muscle and the internal oblique, along and a little above the crest of the ilium. It finally gives off an ascending branch, which anastomoses with the lumbar and lower intercostal arteries, and runs backward to anastomose with the ilio-lumbar artery. It is accompanied by two veins. These unite into one trunk, which then crosses the external iliac artery to join the external iliac vein.

The **branches of the deep circumflex iliac artery** are as follows:—(*a*) **Muscular** branches which supply the psoas, iliacus, sartorius, tensor fasciæ latæ, and the oblique and transverse muscles of the abdomen. One of these branches, larger than the rest, usually arises about 2.5 cm. (1 in.) behind the anterior superior spine of the ilium and ascends perpendicularly between the transversus muscle and the internal oblique. It has received no name but is important to the surgeon, as it indicates the intermuscular plane between the two muscles. (*b*) **Cutaneous** branches, which supply the skin over the course of the vessel, and anastomose with the superficial circumflex iliac, the superior gluteal, and the ascending branch of the lateral circumflex.

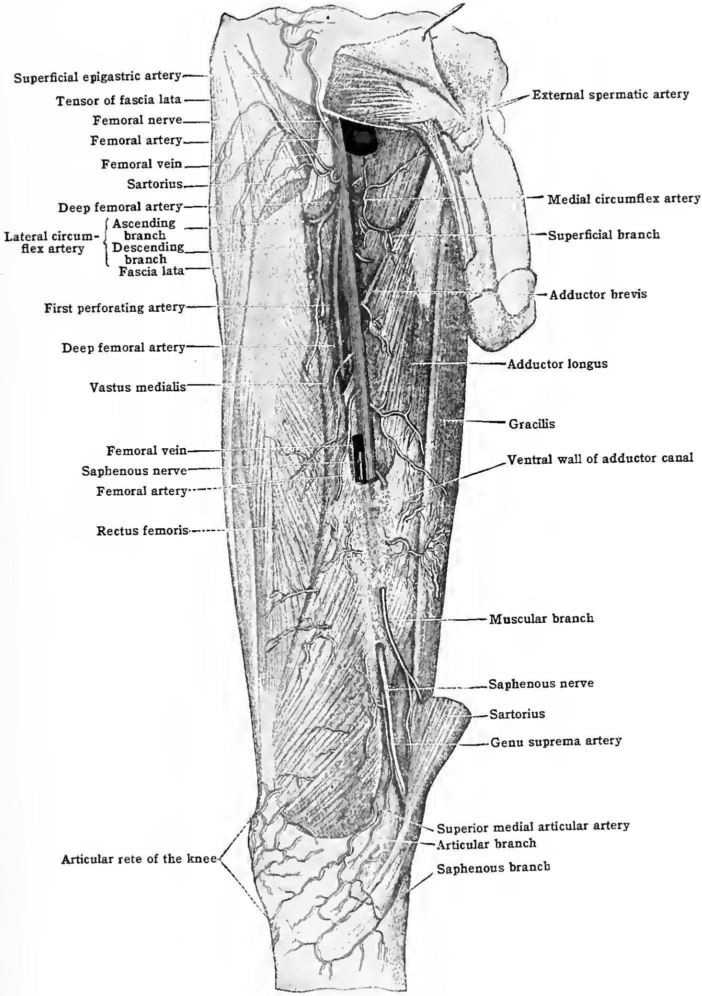
THE FEMORAL ARTERY

The **femoral** artery (fig. 496) is the continuation of the external iliac, and extends from the lower border of Poupart's ligament, down the anterior and medial aspect of the thigh, to the tendinous opening in the adductor magnus, through which it passes into the popliteal space, and is then known as the popliteal. The femoral artery is at first quite superficial, being merely covered by the skin, and superficial and deep fascia; but, after thus passing about 13 cm. (5 in.) downward through the space known as the femoral trigone (Scarpa's triangle), it sinks at the apex of that triangle beneath the sartorius muscle, and thence to its termination continues beneath the sartorius, coursing deeply between the vastus medialis and adductor muscles in the space known as the adductor (Hunter's) canal. It at first rests upon the brim of the pelvis and head of the thigh bone, from which it is merely separated by the capsule of the hip-joint and the tendon of the psoas. Here it can be readily compressed. Owing to the obliquity of the neck of the femur and the direct course taken by the artery, it lies lower down on muscles only, at some little distance from the bone. At its termination, in consequence of the shaft of the femur inclining toward the middle line of the body, the artery lies close to the bone, but to the medial side. The course of the vessel when the thigh is slightly flexed and abducted—the position in which the limb is placed when the vessel is ligatured—is indicated by a line drawn from a spot midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle. When the thigh is in the extended position and parallel to its fellow, the course of the artery will correspond to a line drawn from the spot above mentioned to the medial border of the patella.

About 4–5 cm. ($1\frac{1}{2}$–2 in.) below the inguinal ligament the femoral artery gives off a large branch called the profunda femoris. The portion of the artery proximal to the origin of the profunda is sometimes called the *common femoral*, and the continuation of the vessel the *superficial femoral.*

The superficial femoral varies in length according to the distance that the profunda is given off from the common femoral below Poupart's ligament. As a rule, it measures 9 cm. ($3\frac{1}{2}$ in.), the common 4 cm. ($1\frac{1}{2}$ in.). But the profunda may come off 5 cm. (2 in.) or more below Poupart's ligament, in which case the superficial femoral will be shorter to this extent; or it may come off less than 3.7 cm. (1½ in.) below Poupart's ligament, or even from the external iliac above Poupart's ligament, when the superficial will be longer than normal. The practical point to remember is that it is more usual to meet with a short than with a long common femoral and that if the superficial femoral is tied at the apex of the femoral trigone—i. e., the spot where the sartorius comes into contact with the adductor longus—there is nearly always a sufficient

Fig. 496.—The Femoral Artery. (After Toldt, "Atlas of Human Anatomy," Rebman London and New York.)



length of that vessel above the ligature to ensure a firm internal clot and consequently, as far as this point is concerned, a successful result.

The relations of the femoral artery in the femoral trigone.—In front, the femoral artery (fig. 496) is covered by the skin, the superficial fascia, the iliac portion of the fascia lata, and the lumbo-inguinal (crural) branch of the genito-femoral nerve. The superficial circumflex iliac vein, and sometimes the superficial epigastric vein, descend over the artery from the medial to the lateral side. Just above the sartorius, the artery is crossed by the most medial of the anterior cutaneous branches of the femoral nerve. The fascia transversalis, which is continued downward into the thigh beneath the inguinal ligament, is also in anterior relation, but it soons becomes indistinguishable from the sheath of the vessel.

Behind, the artery rests from above upon the tendon of the psoas muscle, which separates it from the brim of the pelvis and capsule of the hip-joint; the pectineus, and adductor longus. The artery is partially separated from the pectiueus by the femoral vein and the profunda vein and artery, and from the adductor longus by the femoral vein which is almost directly behind the artery near the apex of the femoral trigone. The small nerve to the pectineus crosses behind the artery to reach its medial side.

A similar prolongation to that derived from the fascia transversalis in front, descends behind the vessel from the iliac fascia; but this, like the anterior prolongation or fascia, soon blends with the sheath of the vessels.

To the **medial side** is the femoral vein. This is separated above from the artery, where the two vessels lie in the femoral sheath, by a thin fascial septum. Below, the vein is somewhat behind the artery.

To the **lateral side**.—Above, the common stem of the femoral (anterior crural) nerve is about 1 cm. ($\frac{1}{3}$ in.) lateral to the artery. When the femoral nerve gives off its branches, the saphenous nerve and the nerve to the vastus medialis accompany the artery on the lateral side.

The **adductor canal** is the somewhat triangularly shaped space bounded by the vastus medialis on the lateral side, the adductors longus and magnus posteriorly, and by an aponeurosis thrown across from the adductors to the vastus medially and in front. Below, the canal terminates at the tendinous opening in the adductor magnus; above, its limit is less well defined, as here the aponeurosis between the muscles becomes less tendinous, and gradually fades away into the perimuscular fascia. The transverse direction of the fibres of the aponeurotic covering at the lower two-thirds of the canal is characteristic, and serves as a rallying-point in tying the artery in this part of its course. Lying superficial to the aponeurosis is the sartorius muscle. The femoral artery, in the adductor (Hunter's) canal, has the **following relations**:—

In front, in addition to the skin, superficial and deep fascia, are the sartorius muscle and the aponeurotic fibres of the canal. The saphenous nerve crosses in front of the artery from the lateral to the medial side, lying in the wall of the canal.

Behind, the artery is in contact with the adductor longus, and just above the opening in the adductor magnus, usually with the latter muscle.

The femoral vein lies behind the artery, but gets a little lateral to it at the lower part of the canal. It is here very firmly and closely attached to the artery, embracing it as it were on its posterior and lateral aspect. Hence it is very liable to be punctured on ligaturing the artery in this part of its course. Such an accident is best avoided by opening the sheath of the vessels well to the medial side of the front of the artery, and by keeping the point of the aneurysm needle closely applied to the vessel in passing it between the vein and the artery. There are sometimes two veins, which then more or less surround the artery.

To the lateral side are the vastus medialis, the nerve to the vastus medialis, and at the lower part of the canal, the femoral vein.

Branches of the Femoral Artery

The **branches of the femoral artery** are:—

(1) The superficial epigastric; (2) the superficial circumflex iliac; (3) the external pudendal; (4) the inguinal; (5) the profunda; (6) muscular branches; and (7) the suprema genu (anastomotica magna).

(1) the **superficial epigastric** artery [a. epigastrica superficialis], comes off from the femoral about 1.2 cm. ($\frac{1}{2}$ in.) below the inguinal ligament. At its origin it is beneath the fascia lata, but almost at once passes through this fascia, or else through the fossa ovalis, and courses in an upward and slightly medial direction in front of the external oblique muscle almost as far as the umbilicus.

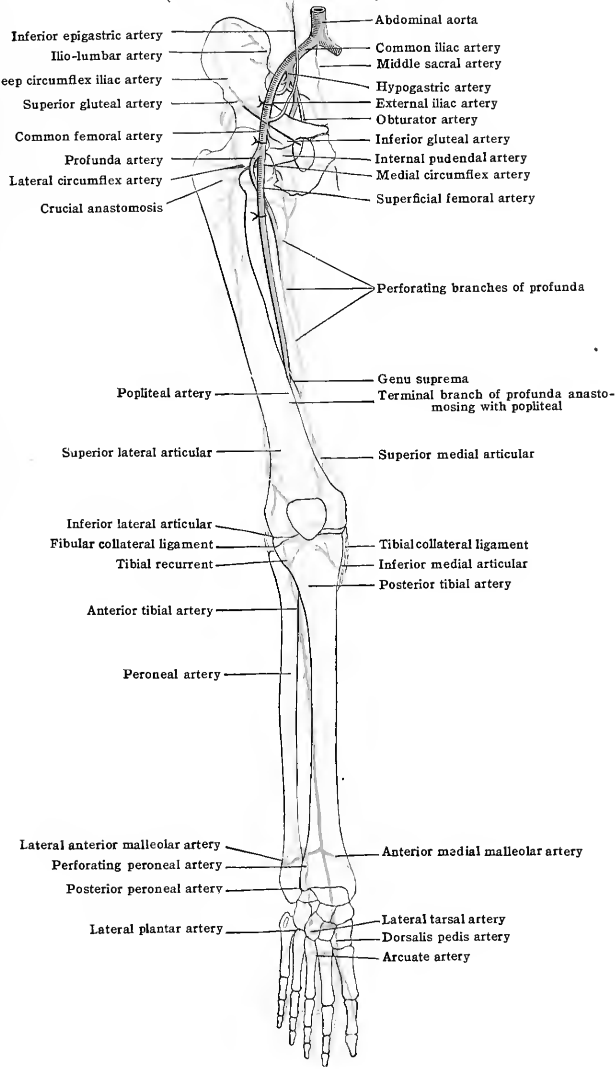
It ends in numerous small twigs, which anastomose with the cutaneous branches from the inferior epigastric and internal mammary. In its course it gives off small branches to the inguinal glands and to the skin and superficial fasciæ. Running with it is the superficial epigastric vein, which ends in the great saphenous just before the latter passes through the fossa ovalis (saphenous opening).

(2) The **superficial circumflex iliac** artery [a. circumflexa ilium superficialis], (fig. 496), usually smaller than the superficial epigastric, arises either in common with that vessel, or else as a separate branch from the femoral. It passes laterally over the iliacus, and, soon perforating the fascia lata a little to the lateral side of the fossa ovalis, runs more or less parallel to the inguinal ligament about as far as the crest of the ilium, where it ends in branches which anastomose with the deep circumflex iliac artery.

In its course it gives off branches to the iliacus and sartorius muscles, to the inguinal glands, and to the fascia and skin. Its companion vein ends in the great saphenous vein just before the latter passes through the fossa ovalis (saphenous opening).

(3) the **external pudendal** arteries [aa. pudendæ externæ], arise from the medial side of the femoral. Some of them pass either through the fascia lata, or

Fig. 497.—To show the Anastomoses of the Arteries of the Lower Extremity. (After Smith and Walsham.)



through the fascia covering the fossa ovalis (saphenous opening) and cross the spermatic cord in the male, or round ligament in the female, to reach and supply the integument above the pubes. One branch descends along the penis lateral to the dorsal artery, with which, and with the corresponding artery of the opposite side, it anastomoses at the corona. In the female, this branch terminates in the preputium clitoridis, anastomosing with the dorsal artery of the clitoris.

Other branches run medially beneath the deep fascia, across the pectineus and adductor longus muscles, and, perforating the fascia close to the ramus of the pubis, supply the skin of the *scrotum* or the *labium majus*, in the female [aa. scrotales or labiales anteriores] anastomosing with the posterior scrotal or labial branches of the perineal artery. The external pudendal supplies small twigs to the pectineus and adductor muscles. Its companion veins terminate as a single trunk in the great saphenous.

(4) The **inguinal** branches [rami inguinales], a series of five or six small branches arise a short distance below the inguinal ligament. They supply the subinguinal lymph-nodes, and the skin and muscles in this region.

(5) The **profunda** artery [a. profunda femoris] (figs. 496, 497), is the chief nutrient vessel of the thigh. It is usually given off from the back and lateral part of the common femoral, about 4 cm. ($1\frac{1}{2}$ in.) below the inguinal (Poupart's) ligament. At first it is a little lateral to the femoral, but as it runs downward and backward it gets behind that artery and closer to the bone. On reaching the upper border of the adductor longus muscle, it leaves the femoral, and, passing beneath the muscle, pierces the adductor magnus. Finally, much reduced in size, it ends in the hamstraing muscles, anastomosing with the third perforating and muscular and articular branches of the popliteal.

Relations.—Behind, the artery lies successively upon the iliacus, the pectineus, the adductor brevis, and adductor magnus muscles. **In front,** at first it is superficial, being merely covered by the skin, superficial and deep fasciæ, and branches of the femoral (anterior crural) nerve; but as it sinks behind the femoral artery, it has in front of it both the femoral and the profunda veins and lower down the adductor longus muscle. **Laterally** is the femur at the angle of union of the adductors longus and brevis. **Medially** is the pectineus at the upper part of its course.

Branches of the profunda.—The profunda gives off the following branches:—(*a*) The lateral circumflex; (*b*) the medial circumflex; and (*c*) the three perforating. The termination of the artery is sometimes called the fourth perforating branch.

(*a*) The **lateral circumflex** [a circumflexa femoris lateralis] a short trunk, but the largest in diameter of the branches of the artery, arises from the lateral side of the profunda as it lies on the iliacus muscle, about 2 cm. ($\frac{3}{4}$ in.) below the origin of that vessel from the femoral. It passes in a transversely lateral direction over the iliacus, under the sartorius and rectus, and between the branches of the femoral (anterior crural) nerve. In this course it gives off branches to the rectus and vastus intermedius (crureus), and then divides into two chief sets of branches—ascending and descending.

The **ascending** branch [ramus ascendeus] either breaks up at once into numerous branches or it may arise as several vessels some of which are apt to come from the profunda itself or even from the femoral. These run upward under the sartorius and tensor faciæ latæ or laterally under the rectus femoris. The highest branches reach the gluteus medius and minimus and anastomose with the gluteal and deep circumflex iliac arteries; one branch runs beneath the rectus femoris to the hip-joint, and the others cross the vastus intermedius and pierce the vastus lateralis to anastomose with the first perforating and the medial circumflex.

The **descending** branches [rami descendentes] run directly downward along with the nerve to the vastus lateralis muscle. They lie beneath the rectus muscle and on the vastus intermedius (crureus) or vastus lateralis, some of them being just under cover of the anterior edge of the latter muscle. They are distributed to the vastus lateralis, vastus intermedius, and rectus, one branch usually running along the anterior border of the vastus lateralis as far as the knee-joint, where it anastomoses with the superior lateral articular branch of the popliteal (fig. 499); another, entering the vastus intermedius, anastomoses with the termination of the profunda and with the genu suprema (anastomotica magna).

(*b*) The **medial circumflex** artery [a. circumflexa femoris medialis] comes off from the back and medial aspect of the profunda artery on about the same level as the lateral circumflex; sometimes as a common trunk with that vessel. As it winds around the medial side of the femur to reach the region of the trochanters, it lies successively, first, between the psoas and pectineus, then between the obturator externus and adductor brevis; finally, between the adductor magnus and quadratus femoris, where it anastomoses with the lateral circumflex, with the inferior gluteal (sciatic), and with the superior perforating, forming the so-called **crucial anastomosis.** While still in the femoral trgione it gives off a *superficial* branch [r. superficialis] which runs in a transversely medial direction to supply the pectineus adductor longus and brevis, and the gracilis. The remainder of the artery is designated as the *deep* branch [r. profundus]. An acetabular branch [r. acetabuli] courses upward beneath the tendon of the psoas, and enters the hip-joint beneath the transverse ligament, and, together with the articular branch of the obturator, supplies the fatty tissue in the acetabulum, and sends branches to the synovial membrane. The medial circumflex veins join the profunda vein.

(*c*) The **perforating arteries of the profunda** are so called because they perforate, in a more or less regular manner from above downward, certain of the adductor muscles. They form a series of loops by anastomosing with one another (fig. 497), and with the superior gluteal, medial circumflex, and inferior gluteal arteries above, and with the muscular and articular branches of the popliteal below. They are distributed chiefly to the hamstring muscles, but send twigs along the lateral intermuscular septum to supply the integuments at the back and lateral parts of the thigh. Other branches perforate the lateral intermuscular septum and the short head of the biceps, and, entering the vastus intermedius (crureus) and vastus lateralis, anastomose with the descending branch of the lateral circumflex. All the perforating arteries, moreover, contribute to reinforce the artery of the sciatic nerve, a branch of the inferior gluteal (sciatic) artery. They are each accompanied by two veins which terminate in the profunda.

The **first perforating** artery [a. perforans prima] is given off from the profunda as that vessel sinks beneath the adductor longus. It either pierces the adductor brevis, or else runs between the pectineus and adductor brevis, and then passes through a small aponeurotic opening in the adductor magnus close to the medial lip of the linea aspera. In this course it supplies branches to the adductors, and, after perforating the adductor magnus, is distributed to the lower part of the gluteus maximus and the hamstring muscles, one branch commonly running upward beneath the gluteus maximus to anastomose with the lateral circumflex, medial circumflex, and inferior gluteal (sciatic) arteries, forming the **crucial anastomosis** at the junction of the neck of the femur with the great trochanter (fig. 497). A second branch descends to anastomose with the ascending branch of the second perforating.

The **second perforating** artery [a. perforans secunda] which is given off from the profunda as it lies behind the adductor longus, pierces the adductor brevis, and then passes through a second aponeurotic opening in the adductor magnus a little below that for the first perforating artery, and also close to the linea aspera. It supplies the hamstring muscles, sends a branch upward to anastomose with the descending branch of the first perforating, and another downward to anastomose in like manner with the ascending branch of the third perforating.

The **third perforating** artery [a. perforans tertia] also arises from the profunda as it lies under the adductor longus, usually about the level of the lower border of the adductor brevis. It turns beneath this border, and then, like the first and second perforating, passes through an aponeurotic opening in the adductor magnus close to the linea aspera. It also supplies the hamstring muscles, and divides into two branches, which anastomose above with the second perforating, and below with the termination of the profunda.

Two **nutrient** arteries to the femur [aa. nutritiæ femoris superior et inferior] arise from the perforating arteries. The superior generally arises from the first perforating, the inferior usually from the third.

(6) The **muscular** branches [rami musculares], of the femoral artery supply the sartorius, the rectus, the vastus medialis, the vastus intermedius (crureus), and the adductor muscles.

(7) The **genu suprema** (or anastomotica magna) arises from the front and medial side of the femoral just before the latter perforates the adductor magnus muscle, and almost immediately divides into branches, (*a*) saphenous, (*b*) muscular, and (*c*) articular. These branches may sometimes come off separately from the femoral.

(*a*) The **saphenous** branch [a. saphena] pierces the aponeurotic covering of the adductor canal, passes between the sartorius and gracilis muscles along with the saphenous nerve, and, perforating the deep fascia, supplies the skin of the upper and medial side of the leg and anastomoses with the inferior medial articular branch of the popliteal and the other vessels forming the plexus or rete at the medial side of the knee. In its course it gives twigs to the lower part of the sartorius and gracilis muscles.

(*b*) The **muscular** branches [rr musculares] run downward in front of the adductor magnus tendon, burrowing amongst the fibres of the vastus medialis as far as the medial condyle. They break up into numerous twigs which supply the lower ends of the vasti muscles and adductor magnus. One branch runs laterally across the lower end of the femur to end in the vastus lateralis.

(*c*) The **articular** branches [rr. articulares] come off from the saphenous and muscular branches and enter the arterial rete on the medial and lateral sides of the knee. They anastamose with the medial and lateral superior articular branches of the popliteal and the anterior tibial recurrent and, like other vessels of the rete, supply branches to the joint.

THE POPLITEAL ARTERY

The **popliteal artery** [a. poplitea] (fig. 498) runs through the popliteal space or ham. It is a continuation of the femoral, and extends from the aponeurotic opening in the adductor magnus at the junction of the middle with the lower third of the thigh to the lower border of the popliteus muscle, where it terminates by dividing into the anterior and posterior tibial arteries. This division is on a level with the lower border of the tuberosity of the tibia. As the artery passes through the opening in the adductor magnus, it is accompanied by the popliteal vein, and at times by the branch of the obturator nerve to the knee-joint. The vein throughout is behind the artery, at first lying a little lateral to it, but as the vessels pass through the popliteal space the vein crosses obliquely over the artery, and at the termination of the artery lies a little to its medial side. The tibial (internal popliteal) nerve is superficial to both artery and vein. As it enters the space it is well to the lateral side of the vessels, but as it descends it gradually approaches them, crosses behind them, and at the lower part of the space lies to their medial side. The artery in the whole of its course is deeply placed and covered by a considerable amount of fat and cellular tissue.

Relations (fig. 498).—**In front,** the artery lies successively on the popliteal surface of the femur (from which it is separated by a little fat and sometimes one or two small glands); on the posterior ligament of the knee; on the hinder edge of the articular surface of the head of the tibia; and on the popliteus muscle. From the latter muscle it is separated by the expansion from the semi-membranosus which covers the muscle, and is attached to the popliteal line on the tibia.

Behind, the artery is covered, above by the semi-membranosus; in the centre of the space by the skin, superficial and deep fascia; and below, by the medial head of the gastrocnemius. The popliteal vein is behind it in the whole of its course. The tibial (internal popliteal) nerve crosses behind it obliquely, from the lateral to the medial side, about the centre of the space. As the artery divides into the anterior and posterior tibial, it is crossed by the aponeurotic arch of the soleus which stretches between the tibial and fibular origins of that muscle.

To the **medial side** are the semi-membranosus above, and the medial head of the gastrocnemius and the tibial (internal popliteal) nerve below.

To the **lateral side** are the biceps and the tibial (internal popliteal) nerve above, and the lateral head of the gastrocnemius and the plantaris below.

Branches of the Popliteal Artery

The **branches of the popliteal** include the following:—(1) the sural; (2) the articular; and (3) the terminal.

(1) The **sural** arteries [aa. surales] arise irregularly from the popliteal and supply the muscles of the calf, sending branches upward to the muscles bounding the upper part of the popliteal space. From the sural arteries also arise the superficial sural or cutaneous branches which pass downward between the two heads of the gastrocnemius, and, perforating the deep fascia, supply the skin and fascia of the calf. A branch, usually of moderate size, accompanies the small saphenous vein, and is sometimes called the posterior saphenous artery.

(2) The **articular,** five in number, are divided into two superior (medial and lateral), two inferior (medial and lateral), and the middle or azygos. The superior and inferior come off transversely in pairs from either side of the popliteal, the superior above, the inferior below the joint. Winding round the bones to the front of the knee, they form—by anastomosing with each other and with the genu suprema (anastomotica magna), the termination of the profunda, the descending branch of the lateral circumflex, and the anterior tibial recurrent—a superficial and deep arterial rete (fig. 499). The superficial anastomosis or rete lies between the skin and fascia round about the patella (**patellar rete**), which it supplies, the larger branches entering it from above. The deep anastomosis or **articular rete** [rete articularis genu] lies on the surface of the bones around the articular surfaces of the femur and tibia, supplying branches to the contiguous bones and to the joints. The middle articular is a single short trunk coming off from the deep surface of the popliteal artery. It at once passes through the posterior ligament into the joint.

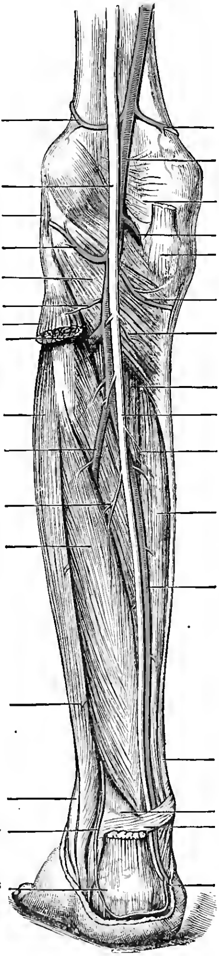
(*a*) The **superior lateral articular** artery [a. genu superior lateralis], the larger of the two superior articular branches, runs in a lateral direction above the lateral head of the gastrocnemius, and, passing beneath the biceps and through the lateral intermuscular septum and vastus lateralis, enters the substance of the vastus intermedius (crureus), and anastomoses, above with the descending branch of the lateral circumflex, below with the inferior lateral articular, and across the front of the femur with the superior medial articular, the genu suprema (anastomotica magna), and termination of the profunda, forming with them, as already described, the deep articular rete. Branches are given off to the patella, to the upper and lateral part of the joint, to the bone, and to the contiguous muscles.

(*b*) The **superior medial articular** artery [a. genu superior medialis] (fig. 499) runs medially just above the medial head of the gastrocnemius, beneath the semi-membranosus, and, after perforating the tendon of the adductor magnus, enters the substance of the vastus medialis. Here it anastomoses with the deep branch of the genu suprema (anastomotica magna) and termination of the profunda above, with the inferior medial articular below, and with the superior lateral articular across the front of the femur. It supplies small branches to the contiguous muscles, to the femur, to the patella, and to the joint.

(*c*) The **inferior medial articular** artery [a. genu inferior medialis], the larger of the two inferior articular arteries, passes in an obliquely medial direction across the popliteus, below the medial condyle (tuberosity) of the tibia and beneath the tibial collateral ligament to the front and medial side of the knee-joint. Here it anastomoses (fig. 499), above with the superior medial articular and the superficial branch of the genu suprema (anastomotica magna), and across the front of the tibia with the inferior lateral articular. It supplies branches to the lower and medial part of the joint.

(*d*) The **inferior lateral articular** artery [a. genu inferior lateralis] passes laterally above the head of the fibula, along the tendon of the popliteus muscle, beneath the lateral head of the gastrocnemius, and then under the tendon of the biceps, and between the long and short fibular

Fig. 498.—Relations of the Popliteal Artery to Bones and Muscles, Left Side.

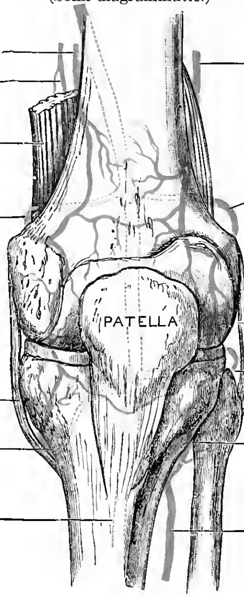


collateral ligaments. Then winding to the front of the joint, it anastomoses above with the superior lateral articular, below with the anterior tibial recurrent, and across the front of the tibia with the inferior medial articular. It also supplies branches to the lateral and lower part of the joint.

(*e*) The **middle or azygos articular** artery [a. genu media] arises from the deep surface of the popliteal artery, and passes, with the articular branch of the obturator nerve, through the popliteal ligament, directly into the knee-joint, where it supplies the crucial ligaments, and the patellar synovial and alar folds. It anastomoses with the intrinsic branches of the other articular arteries.

(3) The **terminal branches** of the popliteal are the posterior and the anterior tibial arteries.

FIG. 499.—THE ANASTOMOSIS ABOUT THE LEFT KNEE-JOINT. (Walsham.) (Semi-diagrammatic.)



THE POSTERIOR TIBIAL ARTERY

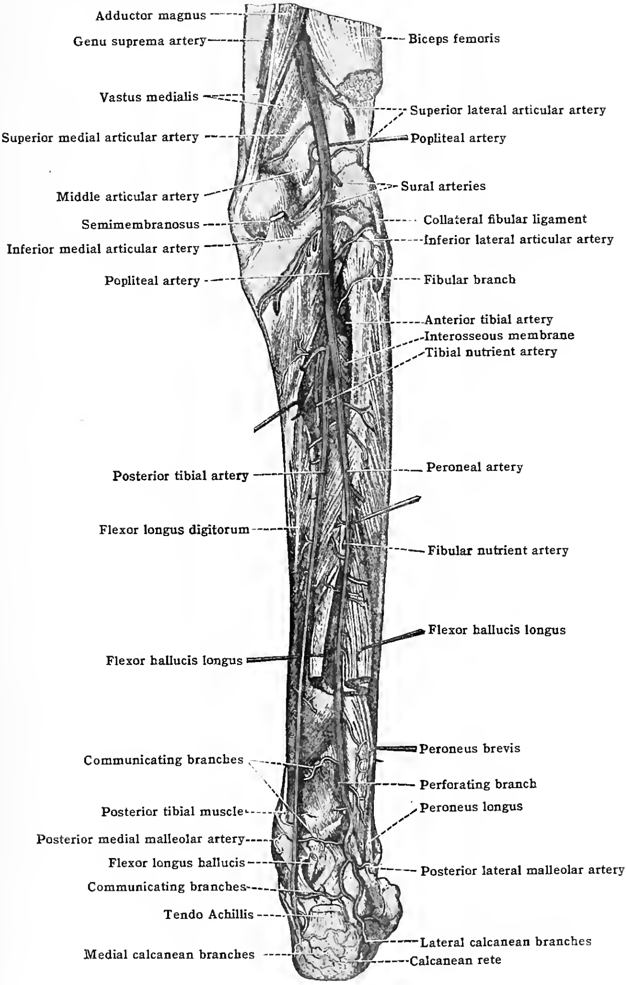
The **posterior tibial** artery [a. tibialis posterior] (fig. 500), the larger of the two branches into which the popliteal divides at the lower border of the popliteus muscle, runs downward on the flexor aspect of the leg between the superficial and deep muscles to the back of the medial malleolus. Midway between the tip of the malleolus and the calcaneus, and under cover of the origin of the abductor hallucis as it arises from the laciniate (internal annular) ligament, it divides into the medial and lateral plantar arteries.

The artery is first situated midway between the tibia and fibula, and is deeply placed beneath the muscles of the calf. As it passes downward it inclines to the medial side and at the lower third of the leg is superficial, being only covered by the skin and fasciæ. At the ankle it lies beneath the laciniate ligament, and at its bifurcation also beneath the abductor hallucis. A line drawn from the centre of the popliteal space to a spot midway between the medial malleolus and point of the heel will indicate its course. In addition to the branches named below it supplies the muscles between which it passes, and the integument of the lower medial region of the leg.

Relations.—Anteriorly, from above downward, it lies successively on the tibialis posterior, the flexor digitorum longus, the posterior surface of the tibia, and the deltoid ligament of the ankle-joint.

Posteriorly, it is covered by the skin and fascia, the gastrocnemius and soleus, and the deep or intermuscular fascia of the leg, by which it is tightly bound down to the underlying muscles. It is crossed by the tibial nerve about 4 cm. ($1\frac{3}{4}$ in.) below its origin, after it has given off its peroneal branch; the nerve first lies on the medial, and for the rest of its course on the lateral side of the vessel. It is accompanied by two veins, which send numerous anastomosing branches across it. In the lower third of the leg the artery is superficial, being covered only by the skin and by the superficial and deep fasciæ.

Fig. 500.—The Popliteal, the Posterior Tibial, and the Peroneal Arteries. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



At the **medial malleolus** it lies beneath the laciniate (internal annular) ligament and abductor hallucis upon the deltoid ligament of the ankle-joint. Here it has the tibialis posterior and flexor digitorum longus in front of it, and the tibial nerve and the flexor hallucis longus behind and to its lateral side.

At times the tibial nerve divides higher than usual, when one branch lies on the medial side of the artery and the other branch on the lateral side.

The **branches of the posterior tibial artery** are:—(1) The fibular; (2) the peroneal; (3) the tibial nutrient; (4) the communicating; (5) the posterior medial malleolar; (6) the medial calcanean, and (7) the terminal, medial and lateral plantar.

(1) The **fibular** or superior fibular branch [ramus fibularis], which frequently arises from the beginning of the anterior tibial, runs upward and laterally toward the head of the fibula. It is small and gives twigs to the soleus, peroneus longus, and extensor digitorum longus, and anastomoses with the inferior lateral articular and the lateral sural arteries.

(2) The **peroneal** artery [a. peronea] is a large vessel which (figs. 498, 500), arises from the posterior tibial about 2.5 cm. (1 in.) below the lower border of the popliteus muscle. At first forming a gentle curve convex laterally, it approaches the fibula, and continues its course downward close to that bone as far as the lower end of the interosseous membrane, where it gives off a large branch, the perforating (anterior peroneal), and then, passing over the back of the inferior tibio-fibular joint, terminates by breaking up into a network, which is distributed over the back of the lateral malleolus and lateral surface of the calcaneus (figs. 500, 504). It is accompanied by two venæ comitantes. Besides the named branches it supplies twigs to the flexor hallucis longus, tibialis posterior, tibialis anterior, peronei and soleus; also to the integument on the lateral side of the leg.

Relations.—At its upper part it is deeply placed between the tibialis posterior and soleus muscles, and beneath the deep or intermuscular fascia. For the rest of its course to the ankle it lies beneath, or sometimes in the substance of, the flexor hallucis longus in the angle between the fibula and interosseous membrane. After giving off the perforating branch, it is only covered, as it lies behind the tibio-fibular articulation, by the integuments and deep fascia, and in this part of its course is sometimes called the **posterior peroneal.**

The **branches of the peroneal artery** are:—(*a*) The perforating (anterior peroneal); (*b*) the fibular nutrient; (*c*) the communicating; (*d*) the lateral malleolar; (*e*) the lateral calcanean; and (*f*) the terminal.

(*a*) The **perforating** (or anterior peroneal) branch [ramus perforans] arises from the front of the peroneal artery at the lower part of the interosseous space, and, passing through the interosseous membrane, runs downward over the front of the inferior tibio-fibular joint, beneath the peroneus tertius, and supplies this muscle and the inferior tibio-fibular joint. It anastomoses with the tarsal, arcuate (metatarsal) and lateral malleolar branches of the anterior tibial artery, and with the lateral plantar artery on the lateral side of the foot, forming a plexus over the ankle (fig. 503).

(*b*) The **fibular nutrient** [a. nutritia fibulæ] enters the nutrient foramen of the fibula.

(*c*) The **communicating** branch [ramus communicans] passes medially in front of the tendo Achillis to anastomose with the communicating branch of the posterior tibial. The usual situation of this communication is from 2.5 to 5 cm. (1 to 2 in.) above the ankle-joint.

(*d*) The **lateral posterior malleolar** artery [a. malleolaris poster. lateralis] anastomoses on the lateral malleolus with the anterior lateral malleolar of the anterior tibial artery to form the *lateral malleolar rete.*

(*e*) The **lateral calcaneal** branches [rami calcanei laterales] come off from the peroneal below the point at which the perforating is given off, and are distributed over the lateral surface of the calcaneus.

(*f*) The **terminal** branch or posterior peroneal, the continuation of the peroneal artery, anastomoses with the other arteries distributed to the lateral malleolus and heel.

(3) The **tibial nutrient** artery [a. nutritia tibiæ], a vessel of large size, leaves the posterior tibial at its upper part, pierces the tibialis posterior, and enters the nutrient foramen in the upper third of the posterior surface of the tibia. In the interior of the bone it divides into two branches: an ascending or smaller, which runs upward toward the head of the bone; and a descending or larger, which courses downward toward the lower end. It gives off two or three muscular twigs to the tibialis posterior before it enters the foramen. The nutrient artery of the tibia is the largest nutrient artery of bone in the body, and is accompanied by a nerve given off by the nerve to the popliteus.

(4) The **communicating** branch [ramus communicans] arises from the posterior tibial about 5 cm. (2 in.) above the medial malleolus, and, passing transversely across the tibia beneath the flexor hallucis longus and tendo Achillis, anastomoses with the communicating branch of the peroneal.

Frequently an inferior communicating branch between the posterior tibial and peroneal arteries is likewise present in the loose connective tissue beneath or behind the tendo Achillis.

(5) The **posterior medial malleolar** branch [ramus malleolaris posterior medialis] divides for distribution over the medial malleolus, anastomosing with the other arteries entering into the *medial malleolar rete* [rete malleolare mediale] which is formed over the portion of bone. In its course to the malleolus it runs beneath the flexor digitorum longus and tibialis posterior muscles.

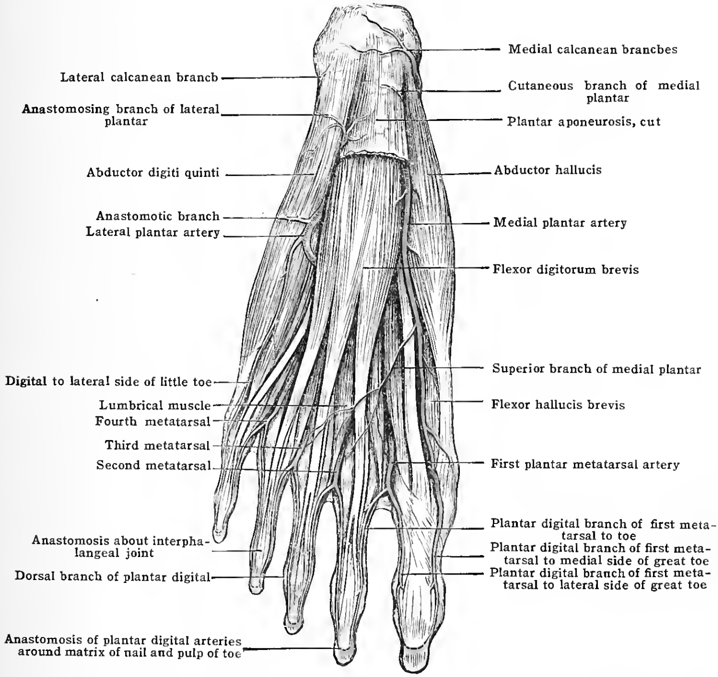
(6) The **medial calcanean** branches [rami calcanei mediales] are distributed to the soft parts over the medial side of the calcaneus. These branches come off from the posterior tibial just before its bifurcation, and anastomose with the medial malleolar and peroneal arteries.

(7) The **terminal branches** are the lateral and medial plantar arteries.

THE LATERAL PLANTAR ARTERY

The **lateral plantar** artery [a. plantaris lateralis] (figs. 501, 502)—the larger of the two branches into which the posterior tibial divides beneath the laciniate (internal annular) ligament—passes at first laterally and forward across the sole of the foot to the base of the fifth metatarsal bone, where it bends medially, and still running forward sinks deeply into the foot and terminates at the proximal end of the first interosseous space by anastomosing with the deep plantar (communicating) branch of the dorsal artery of the foot. In its course to the fifth metatarsal bone the artery runs in a more or less straight line obliquely across the foot; whilst its deep portion, extending from the fifth metatarsal bone to the proximal

FIG. 501.—THE PLANTAR ARTERIES, LEFT FOOT.
(From a dissection in the Museum of St. Bartholomew's Hospital.)

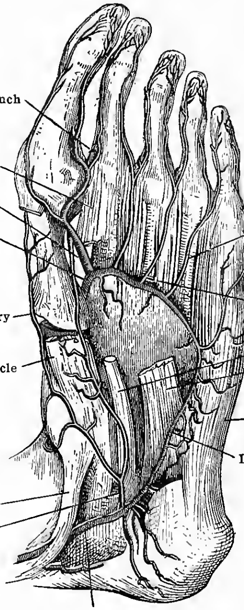


end of the first interosseous space, forms a slight curve with the convexity forward, and is known as the **plantar arch.** The plantar arch is comparable to the deep volar arch formed by the deep branch of the ulnar anastomosing with the radial through the first interosseous space. This homology is at times more complete in that the deep plantar (communicating) branch of the dorsalis pedis, the homologue of the radial in the upper limb, takes the chief share in forming the arch. The lateral plantar artery is accompanied by two veins. The course of the artery is indicated by a line drawn across the sole of the foot from a point midway between the tip of the medial malleolus and the medial tubercle of the calcaneus to the base of the fifth metatarsal bone, and thence to the lateral side of the base of the first metatarsal.

The lateral plantar artery, besides the branches named below gives twigs to supply the muscles between which it passes, and the tarsal joints. It also gives branches to the integument of the lateral side of the sole, some of which anastomose with arteries on the lateral side of the dorsum.

Relations.—In the **first part of its course** from the medial malleolus to the base of the fifth metatarsal bone, the artery is covered successively by the abductor hallucis and the flexor digitorum brevis, by which it is separated from the plantar aponeurosis, and may be slightly overlapped in muscular subjects by the abductor quinti digiti. As it approches the base of the fifth metatarsal bone it lies, as it turns medially before sinking into the foot, in the interspace between the flexor digitorum brevis and the abductor quinti digiti, and is here covered only by the skin and superficial fascia and the plantar aponeurosis. It lies upon the calcaneus, the quadratus plantæ (flexor accessorius), and the flexor digiti quinti brevis. It is accompanied by the lateral plantar nerve, the smaller of the two divisions into which the tibial nerve divides. In this part of its course it gives off small branches to the contiguous muscles and to the heel.

Fig. 502.—Plantar Arteries (Deep). (After Henle.)



In the **second part of its course** the artery, which is here known as the **plantar arch** [arcus plantaris], sinks into the sole, and is covered, in addition to the skin, superficial fascia, plantar aponeurosis, and flexor digitorum brevis by the tendons of the flexor digitorum longus, the lumbricales, branches of the medial plantar nerve, and the adductor hallucis. It lies upon the proximal ends of the second, third, and fourth metatarsal bones and the corresponding interosseous muscles.

The **branches of the lateral plantar artery** are:—(1) Perforating; and (2) plantar metatarsal (digital).

(1) The **perforating** branches [rr. perforantes], three in numbers, ascend through the proximal end of the second, third, and fourth spaces, between the two heads of the correspondingly named dorsal interosseous muscles, and communicate with the proximal ends of the first, second, and third dorsal metatarsal (interosseous) arteries (fig. 502).

(2) The **plantar metatarsal** arteries [aa. metatarseæ plantares] are usually four in number, and pass forward in the four intermetatarsal spaces, which are numbered from the medial side. They rest upon the interosseous muscles of their spaces, and are at first under cover of the lumbricals, but as they approach the clefts of the toes each divides into two branches, the **plantar digital** arteries [aa. digitales plantares], which supply the contiguous sides of the toes. The plantar digital branch for the medial side of the great toe is usually given off by the first plantar metatarsal; that for the lateral side of the little toe is usually a separate branch from the lateral end of the plantar arch.

The plantar metatarsal arteries, immediately before they bifurcate, send to the dorsum of the foot a perforating branch each to the corresponding dorsal metatarsal arteries. They anastomose by many small twigs with the dorsal metatarsal arteries, which also run along the sides of the metatarsal bones, but more toward the dorsal aspect. Immediately above each phalangeal joint the plantar digital vessels communicate by cross branches, forming a rete for the supply of the articular end of the phalanges and the contiguous joints. At the distal end of the toes they also freely anastomose with each other, forming a rete beneath the pulp and around the matrix of the nail. The metatarsal and digital arteries are each accompanied by two small veins.

THE MEDIAL PLANTAR ARTERY

The **medial plantar** artery [a. plantaris medialis] (figs. 501, 502)—much the smaller of the two divisions into which the posterior tibial divides, passes forward along the medial side of the sole of the foot usually to the first interosseous space. Here it ends by anastomosing either with the first plantar metatarsal artery derived from the plantar arch, or with the branch given off by the first plantar metatarsal to the medial side of the great toe.

Relations.—The artery is at first under cover of the abductor hallucis, but afterward lies in the interval between that muscle and the flexor digitorum brevis. It is covered by the skin and superficial fascia, but not by the plantar aponeurosis, since it lies between the central and medial portions of that structure.

The **branches of the medial plantar** are:—(1) The deep and (2) the superficial branches.

(1) The **deep** branch [ramus profundus], which at once divides—or it may come off as several branches—to supply the muscles, articulations,and integument of the medial side of the sole. Some of these branches form an anastomosis around the medial margin of the foot, with branches of the dorsalis pedis.

(2) The **superficial** branch [ramus superficialis] breaks up into very small twigs which accompany the digital branches of the medial plantar nerves, and anastomose with the plantar metatarsal arteries in the first, second, and third spaces. At times a twig from one of these branches joins the lateral plantar artery to form a superficial plantar arch.

THE ANTERIOR TIBIAL ARTERY

The **anterior tibial** artery [a. tibialis anterior] fig. 503—the smaller of the two branches into which the popliteal artery divides at the lower border of the popliteus muscle—at first courses forward between the two heads of origin of the tibialis posterior, and, after passing between the tibia and fibula above the upper part of the interosseous membrane, runs downward on the front and lateral aspect of the leg, between the anterior muscles, as far as the front of the ankle-joint. Below the joint it is known as the dorsalis pedis. The **course of the vessel** is indicated by a line drawn from the front of the head of the fibula to a point midway between the two malleoli.

The artery is accompanied by two veins which communicate with each other at frequent intervals across it. It is also accompanied in the lower three-fourths of its course by the deep peroneal nerve. The nerve, which winds round the head of the fibula, and pierces the extensor digitorum longus, first comes into contact with the lateral side of the artery about the upper third of the leg; in the middle third it is a little in front of the artery, and in the lower third again lies to its lateral side. In addition to the named branches the anterior tibial artery supplies muscular twigs to the extensors of the toes and the tibialis anterior.

Relations.—The artery at first lies in the triangle formed by the two heads of the tibialis posterior and the popliteus muscle; and, as it passes above the interosseous membrane, it has the tibia on one side and the fibula on the other. It is separated from the deep peroneal (anterior tibial) nerve at its commencement by the neck of the fibula and the extensor digitorum longus. This arrangement is homologous with that met with in the forearm in the case of the posterior interosseous artery and deep radial (posterior interosseous) nerve.

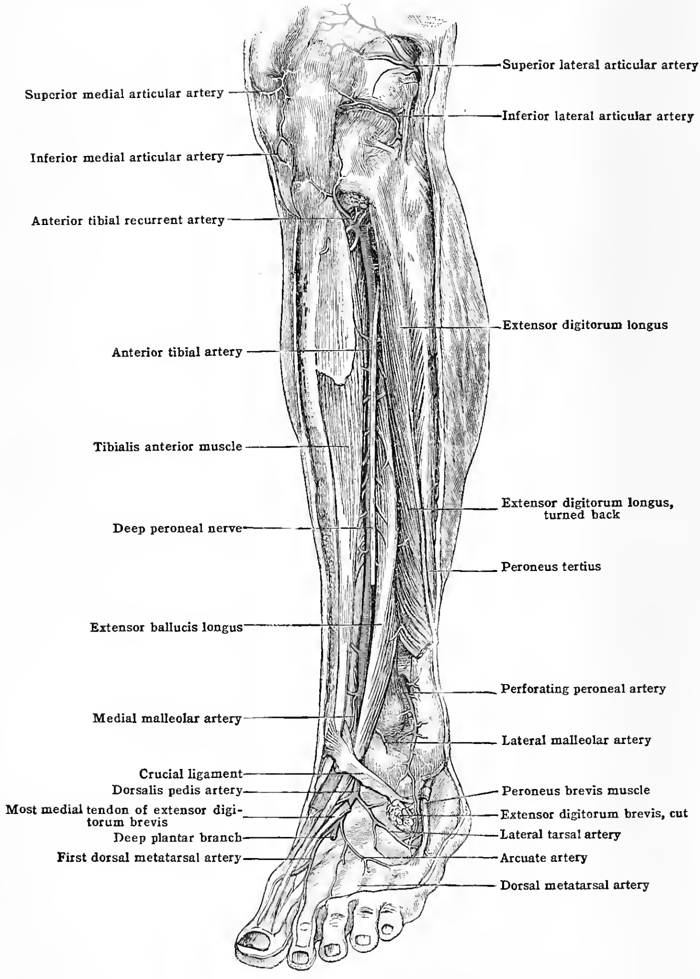
Posteriorly in its course down the leg it lies in its upper two-thirds upon the interosseous membrane, to which it is closely bound by fibrous bands; and in its lower third upon the front of the tibia and the ankle-joint.

To its **medial side** along its upper two-thirds is the tibialis anterior muscle; but at the lower third it is crossed by the tendon of the extensor hallucis longus and then for the rest of its course has this tendon overlapping it or to its medial side.

On its **lateral side** it is in contact in its upper third with the extensor digitorum longus muscle; in its middle third with the extensor hallucis longus; but, as this muscle crosses to the medial side of the artery, the vessel usually for a very short part of its course comes again into contact with the extensor digitorum longus. At the upper and lower thirds of its course on the front of the leg the artery has the deep peroneal (anterior tibial) nerve to its lateral side.

In front the artery is covered by the skin, superficial and deep fascia. In its upper two-thirds it is deeply placed in the cellular interval between the tibialis anterior on the medial side and the extensor digitorum longus and extensor hallucis longus on its lateral side; and in its lower third it is crossed in the latero-medial direction by the tendon of the extensor

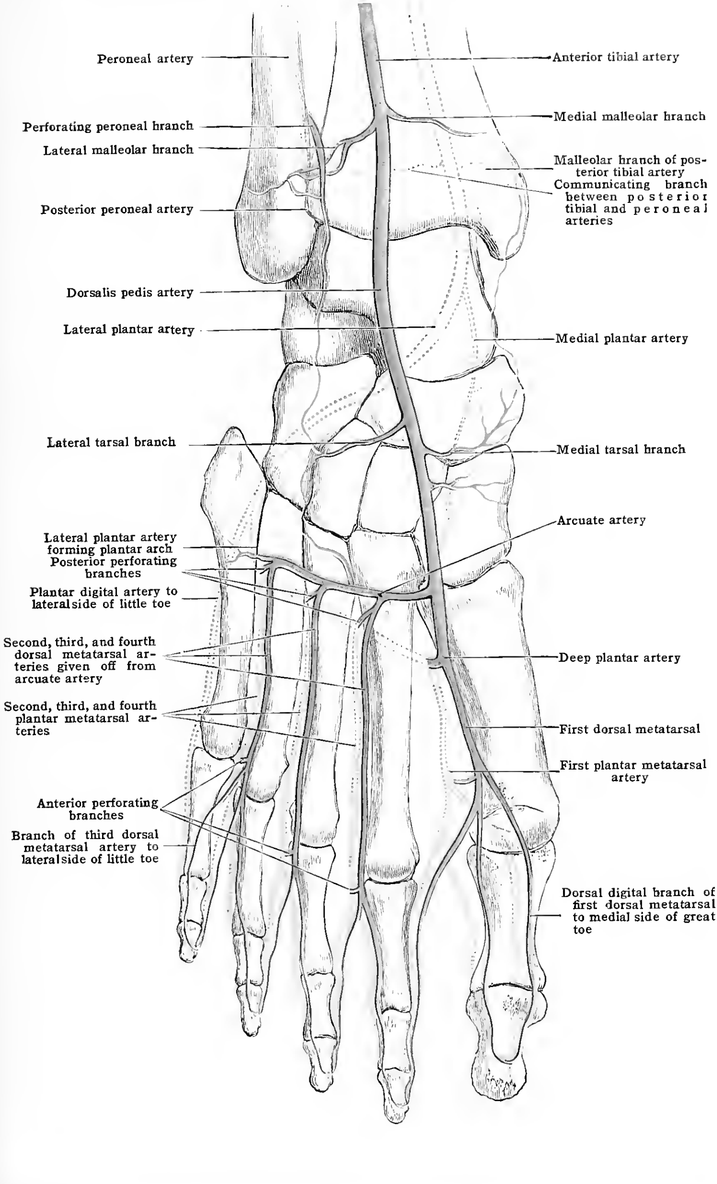
Fig. 503.—The Anterior Tibial Artery, Dorsal Artery of the Foot, and Perforating (Anterior) Peroneal Artery, and their Branches, Left Side.



hallucis longus, and lies beneath the cruciate (anterior annular) ligament of the ankle-joint The deep peroneal nerve is usually in front of the artery in the middle third of the leg.

The branches of the anterior tibial artery are:—(1) The posterior tibial recurrent; (2) the anterior tibial recurrent; (3) the medial malleolar; and (4) the

FIG. 504.—SCHEME OF THE DISTRIBUTION AND ANASTOMOSES OF THE ARTERIES OF THE RIGHT FOOT. (Walsham.)
(The plantar arteries are shown in dotted outline; the dorsal in solid red.)



lateral malleolar. In addition, ten or twelve muscular branches are given off irregularly to the adjacent muscles along the artery.

(1) The **posterior tibial recurrent** artery [a. recurrens tibialis posterior] is occasionally absent. It ascends between the popliteus muscle and the popliteal ligament of the knee-joint, supplying these structures and the superior tibio-fibular joint. It anastomoses with the inferior lateral articular branch of the popliteal, and to a less extent with the inferior medial articular branch.

(2) The **anterior tibial recurrent** [a. recurrens tibialis anterior] is given off from the anterior tibial artery immediately after that vessel has passed above the interosseous membrane. It winds tortuously through the substance of the tibialis anterior muscle, over the lateral condyle (tuberosity) of the tibia close to the bone; and, perforating the deep fascia, ramifies on the lower and lateral part of the capsule of the knee-joint. It anastomoses with the inferior and superior lateral articular branches of the popliteal, with the descending branch of the lateral circumflex, and somewhat less freely with the medial articular branches of the popliteal and with the genu suprema (anastomotica magna). It gives off small branches to the tibialis anterior, the extensor digitorum longus, the knee-joint, and the contiguous fascia and skin. It forms one of the collateral channels by which the blood is carried to the limb below in obstruction of the popliteal artery (fig. 503).

(3) The **medial malleolar** [a. malleolaris anterior medialis], the smaller of the two malleolar branches, arises from the lower part of the anterior tibial artery a little higher than the lateral, usually about the spot where the tendon of the extensor hallucis longus crosses the anterior tibial artery. It winds over the medial malleolus, passing beneath the tibialis anterior, and joins the **medial malleolar rete** anastomosing with branches from the posterior tibial artery.

(4) The **lateral malleolar** artery [a. malleolaris anterior lateralis], larger than the medial, arises from the lateral side of the anterior tibial artery, usually on a lower level than the medial malleolar. It winds downward and laterally round the lateral malleolus, passing beneath the extensor digitorum longus and peroneus tertius, and joins the **lateral malleolar rete** by anastomosing with the perforating peroneal, the termination of the peroneal, and the lateral tarsal branch of the dorsalis pedis (fig. 503).

The anastomosis between the lateral malleolar and perforating peroneal is sometimes of considerable size, supplying the blood to the dorsal artery of the foot; the anterior tibial, then much reduced in size, usually ends at the place of origin of the lateral malleolar.

THE DORSALIS PEDIS ARTERY

The **dorsalis pedis** artery [a. dorsalis pedis] (fig. 503) is a continuation of the anterior tibial. It extends from the front of the ankle-joint to the proximal end of the first interosseous space, where it ends, as the deep plantar branch, by joining the lateral plantar artery to complete the plantar arch. It is accompanied by two venæ comitantes. The course of the artery is indicated by a line drawn from a point midway between the two malleoli to the proximal end of the first metatarsal space.

Relations.—Behind, the artery from above downward lies successively on the talus (astragalus), navicular, second cuneiform, and the base of the second metatarsal bones, and the ligaments uniting these bones. At times its course is a little more lateral, lying either partly on the second cuneiform bone, or on the dorsal ligaments uniting the second cuneiform to the first cuneiform. It is more or less bound down to the bones by aponeurotic fibres derived from the deep fascia.

In front, the artery is covered by the crucial (anterior annular) ligament, sometimes by the extensor hallucis longus, by the skin, the superficial and deep fascia, and, just before its termination, by the tendon of the extensor hallucis brevis. The angle formed by this tendon with the extensor hallucis longus is the best guide to finding the artery in the process of ligature (fig. 503).

To its **lateral side** is the most medial tendon of the extensor digitorum longus, and lower down the tendon of the extensor hallucis brevis. The deep peroneal (anterior tibial) nerve is also to its lateral side.

To its **medial side** is the extensor hallucis longus, except at times for about half an inch below, where the tendon of the extensor hallucis brevis, having crossed the artery, may lie between it and this tendon.

The **branches of the dorsalis pedis artery** are:—(1) The tarsal; (2) the arcuate; and (3) the deep plantar.

(1) The **tarsal branches** may be divided into (*a*) the lateral and (*b*) the medial. (*a*) The lateral tarsal artery [a. tarsea lateralis] runs laterally over the navicular and cuboid bones beneath the extensor digitorum brevis. It supplies branches to that muscle, and to the bones and the articulations between them, and anastomoses above with the lateral malleolar and perforating (anterior) peroneal, below with the arcuate (metatarsal) and, over the lateral border of the foot, with the anastomotic branches of the lateral plantar artery. (*b*) The **medial tarsal** arteries [aa. tarseæ mediales] consists of a few small branches which run over the medial side of the foot, supplying the skin and articulations, and anastomose with the medial malleolar.

(2) The **arcuate** (**metatarsal**) artery [a. arcuata] (figs. 503, 504) runs laterally across the foot, in a slight curve with the convexity forward, over the bases of the metatarsal bones, and beneath the extensor tendons and the extensor digitorum brevis. At the lateral border of the foot it anastomoses, with the lateral tarsal, and with branches of the lateral plantar.

From the convexity of the arch it gives off four **dorsal metatarsal** (interosseous) arteries, which run forward on the dorsal interosseous muscles in the centre of the four interosseous spaces to the cleft of the toes, where they bifurcate for the supply of the contiguous sides of the toes. The artery to the first space is large, and gives off the digital artery to the medial side of the great toe. This vessel continues the direction of the dorsalis pedis and is commonly known as the **dorsalis hallucis** artery. The most lateral of the interosseous branches gives off a small vessel for the supply of the lateral side of the little toe. At the proximal end of the second, third, and fourth interosseous spaces each artery receives a perforating branch from the lateral plantar artery, and immediately before they bifurcate a second perforating artery through the distal end of the interosseous space from the corresponding digital.

The **dorsal digital** arteries [aa. digitales dorsales], into which the dorsal metatarsal arteries divide at the cleft of the toes, run along the side of each toe toward the dorsal aspect, anastomosing with each other across the dorsum of the toes and by frequent branches with the digital branches of the plantar metatarsal arteries, which also run along the sides of the toes, but nearer the plantar surface. At the end of the toes they anastomose with each other around the quick of the nail.

(3) The **deep plantar** branch [ramus plantaris profundus] comes off from the dorsalis pedis with the first dorsal metatarsal (into which arteries indeed the dorsalis pedis may be said to divide). At the back of the first interosseous space it dips into the sole between the two heads of the first dorsal interosseous muscle, aud communicates with the termination of the lateral plantar artery, completing the plantar arch, in a manner similar to that in which the radial artery, passing through the first dorsal interosseous muscle in the hand, completes by anastomosing with the ulnar the deep palmar arch.

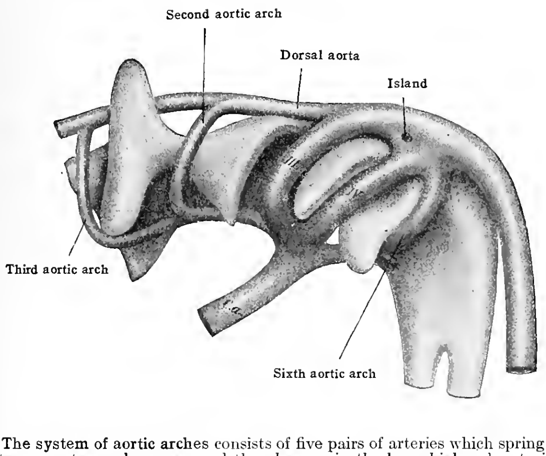
MORPHOGENESIS AND VARIATIONS OF THE ARTERIES

A. ARTERIES OF THE HEAD AND TRUNK

1. MORPHOGENESIS

In conformity with the branchiomeric and metameric development of the head and trunk (see p. 15) the arteries are developed in two sets, the branchiomeric (aortic arches) and metameric (segmental arteries).

Fig. 505.—Model of the Pharynx and Aortic Arches of a Human Embryo 5 mm. Long. (Tandler, ×75.)



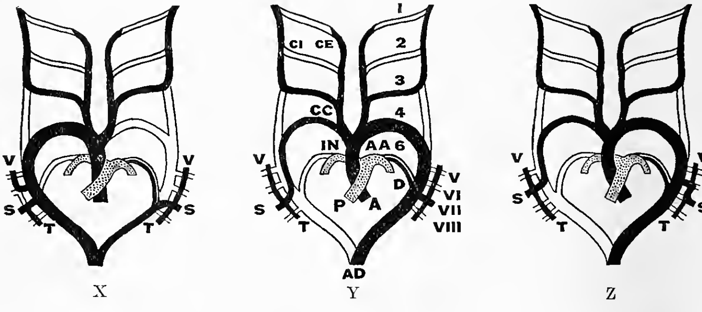
(1) **The system of aortic arches** consists of five pairs of arteries which spring from the ventral aorta, or aortæ, and pass around the pharynx in the branchial arches to join the paired dorsal aortæ. Some of the arches are very transitory, but all those that give rise to permanent vessels are present in embryos about five millimetres in length. Fig. 505 shows their distribution and rlations to the pharyngeal pouches at this stage; the arches which appear fifth in order are regarded as the sixth because (like the sixth arches in lung-fish and amphibia) they give

off the pulmonary arteries. The true fifth arches are probably not always developed, but when they occur they are later in development, imperfect, and very transitory. The dorsal aortæ, originally paired, are now united to form a single vessel as far forward as a place slightly caudal to the sixth arches.

During the separation of the heart into right and left halves (p 526.), the primitive ventral aorta is divided by the aortic septum into two vessels, the *main pulmonary artery* and the *ascending aorta* of the adult. The pulmonary trunk becomes connected with the sixth pair of arches only; the other arches then communicate, by means of the aorta, with the left ventricle. The further changes which occur in the arches to bring about the conditions found in the adult are shown diagrammatically in fig. 506. The right and left *pulmonary arteries* arise from the corresponding sixth arches. The portion of the sixth arch dorsal to the pulmonary artery disappears on the right, on the left it persists until birth as the *ductus arteriosus* (lig. arteriosum of the adult). The fourth arch, including the short ventral stem between the fourth and sixth arch, becomes the permanent *aortic arch* on the left side, and the *innominate* and proximal portion of the subclavian upon the right. The dorsal longitudinal stem disappears on both sides between the third and fourth arches, and on the right side from the sixth arch back to the unpaired dorsal aorta. A trace of the latter portion of the right dorsal stem frequently persists in the adult as a small vessel (*a. aberrans*) connecting the dorsal aorta, directly or indirectly, with the right subclavian artery (p. 590). The ventral stems between the fourth and third arches form the *common carotids;* those between the third and first become the *external carotids.* The *internal carotids* are formed by the third arches and the dorsal stems between the third and first arches. The first and second arches disappear early, contributing somewhat to the formation of the branches of the internal and external carotids.

Fig. 506.—Diagrams showing the Method of Normal Development of the Aortic (Arches, and Indicating the Mechanism of Some Variations.)

The primitive aortic arches (1–6), and some of the cervical dorsal segmentals (V–VIII) are shown in all the diagrams but numbered in Y only. X., abnormal: the aortic arch is on the right; the left subclavian takes the dorsal course; the right vertebral arises direct from the aortic arch. Y., normal; Z., abnormal: the right subclavian arises from the sixth cervical dorsal segmental; the left from the sixth and seventh. A, ascending aorta; AA, aortic arch; AD, dorsal aorta; CC, common carotid; CE, external carotid; CI, internal carotid; D, ductus arteriosus; IN, innominate; S, subclavian; T, costo-cervical; V, vertebral.



In early development the segmental arteries are caudally placed with regard to the aortic arch vessels. As the latter, however, become shifted following the migration of the heart from the neck into the thorax, the persistent seventh dorsal cervical segmental (subclavian) reaches the neighbourhood of the sixth aortic arch.

Little is known of the share taken by the first and second aortic arches in the formation of the branches of the internal and external carotid arteries. It has been shown by Tandler that the *internal maxillary* is primarily a branch of the internal carotid, (the first and second arches taking a share in its formation). The primitive vessel is known as the *stapedial* since it passes between the crura of the developing stapes. It gives off supraorbital, infraorbital, and mandibular branches; the latter two arising from the main artery by a common trunk. The common trunk is later joined by a branch from the external carotid and, together with the supraorbital, becomes the *middle meningeal.* An anastomosis between the supraorbital and the ophthalmic persists so that in the adult the anterior branch of the meningeal frequently takes a considerable share in the blood-supply of the orbit. The stapedial trunk undergoes retrogression and is represented in the adult by the *carotico-tympanic* of the internal carotid and by the *superior tympanic* of the middle meningeal. The infraorbital branch of the stapedial becomes the second and third parts of the internal maxillary and gives off branches accordingly. The mandibular branch becomes the *inferior alveolar* of the adult.

(2) The segmental system (fig. 507) consists of arteries primarily arising from the aorta in three longitudinal series, dorsal, lateral, and ventral on either side. The segmental arrangement is much less perfect in the ventral and lateral groups than in the dorsal. So much so, in fact, that the term segmental is used for the ventral and lateral groups rather as a matter

of convenience than as indicating a strict numerical correspondence between segments and vessels.

The **dorsal segmental arteries** primarily supply the central nervous system but later give off two sets of vessels to the body wall; these persist in the adult as the *anterior* and *posterior main branches of the intercostal and lumbar arteries.* The remainder of each segmental artery is represented in the adult by the *spinal ramus* which accompanies the corresponding nerve root through the intervertebral foramen. The tendency to form intersegmental anastomoses between these vessels (and their branches) gives rise to many of the important longitudinal stems of adult anatomy. Thus, the spinal ramus gives rise to a pre- and postneural anastomosing channel on either side, the (primarily paired) *anterior and posterior spinal arteries.* The anterior branches have each a longitudinal precostal anastomosis, and, as they grow forward with the developing body wall, their ends are connected to form the mammary anastomosis.

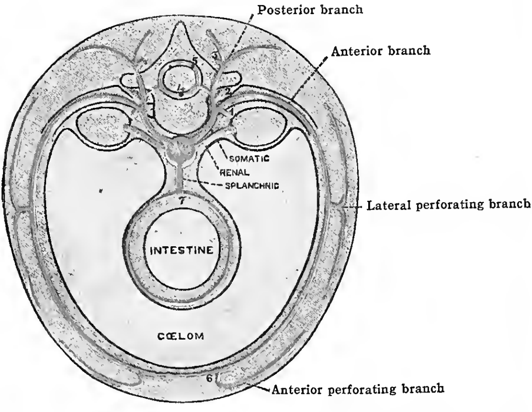
Between the posterior rami, a postcostal and a postvertebral anastomosis may be formed. In addition, the anterior rami give off lateral and anterior perforating branches (fig. 507).

Two dorsal segmental arteries have been recognized in the occipital region, the first disappears and the second, the *hypoglossus artery,* follows the hypoglossal nerve to the ventral surface of the brain where it is connected with the termination of the internal carotid of its own side by means of a longitudinal stem the *a. vertebralis cerebralis.* The hypoglossus artery, by shifting forward to the third aortic arch, itself acquires a secondary origin from the internal carotid.

In the *cervical region,* the spinal ramus of segmental cervical I forms the third, or suboccipital, part of the *vertebral artery.* Cervical segmentals I to VI lose their connection with the aorta and a postcostal anastomosis between them forms the second part of the same artery. The first part of the vertebral is formed by the posterior ramus of cervical VI and its precostal anastomosis with cervical VII (subclavian) (fig. 508).

Fig. 507.—Scheme of the Typical Arrangement of the Branches of the Aorta. (After Quain.)

Longitudinal anastomoses: 1, precostal; 2, postcostal; 3 postvertebral; 4, preneural; 5, postneural; 6, mammary.



The anterior ramus of cervical VII forms the entire first part of the subclavian on the left, and the distal portion of it upon the right (see system of aortic arches). The second part of the subclavian is formed by the lateral branch of the anterior ramus of cervical VII, while the portion of the anterior ramus ventral to this becomes the root of the internal mammary. The anterior ramus of cervical VIII disappears, but the precostal anastomosis connecting it with the subclavian (cervical VII) persists to form the *costo-cervical* of the adult. The posterior ramus of cervical VIII forms the root of the *deep cervical,* and, by a postvertebral anastomosis with the other posterior cervical rami and with the occipital, forms the remainder of the deep cervical and the *descending branch of the occipital artery.*

In the *thoracic and lumbar regions,* the embryonic conditions very largely persist (fig. 508). The anterior rami of thoracic segmentals I and II, however, lose their connection with the aorta and, by a precostal anastomosis with cervical VIII, become secondarily connected (through the costo-cervical trunk) with the subclavian. The *superior intercostal* of the adult is thus formed. The fifth lumbar segmental apparently joins the umbilical artery (of the ventral segmental series) to form the external iliac which, in the adult, provides the chief arterial supply to the lower extremity. The inferior gluteal (sciatic), which is the primitive artery of supply for the lower extremity, if it is segmental at all, belongs to the sacral region. The free ends of the anterior rami of all the thoracic and the upper four lumbar segmentals become united, as they grow out with the body wall, to form the longitudinal mammary anastomosis (fig. 508). This anastomosis, by its connection with the anterior ramus of cervical

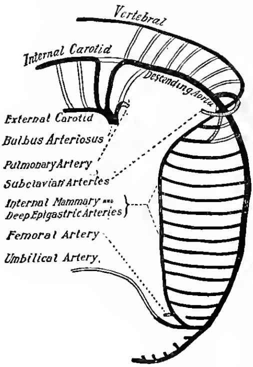
VII (subclavian) and with the anterior ramus of lumbar V (external iliac), forms the *internal mammary* (with its *superior epigastric* branch) and the *inferior* (*deep*) *epigastric* arteries of the adult.

In the sacral region, the adult shows evidence of segmental vessels in branches of the middle and lateral sacral arteries; the latter probably representing a precostal anastomosis. Whether the parietal branches may be derived directly from segmental sources, or whether they are vessels of new formation, has not been determined embryologically. The obturator would appear to be segmental, for it contributes a branch to the mammary anastomosis which persists in the adult (pubic branches of obturator and inferior epigastric). If the connecting branch with the inferior epigastric is large, the obturator may lose its connection with the hypogastric, in which case the latter is said to arise from the former, or from the external iliac.

One of the most interesting of the longitudinal anastomoses in connection with the dorsal segmentals is the primitively bilateral preneural anastomosis extending ventral to the spinal cord and connected, beyond the first spinal segment, with each internal carotid by means of the right and left aa. cerebrales vertebrales. The hypoglossus artery (p. 635) having lost its connection with the internal carotid, leaves the spinal ramus of cervical I (third part of the subclavian) to take over the major share of the cerebral supply. A process of blending by anastomosis now occurs resulting in the single *basilar* and *anterior spinal* arteries of the adult. The *posterior communicating*, proximal portions of the *posterior cerebrals*, the fourth part of the vertebrals, and the right and left roots in the anterior spinals of the adult alone retain the primitive arrangement and testify to the double nature of the original anastomosis. Asymmetry in the vertebrals and other irregularities in the adult can usually be explained on developmental grounds. The postneural anastomosis, which joins the preneural at about the first cervical segment, retains its bilaterality throughout to form the paired *posterior spinal arteries* of the adult.

Fig. 508.—Diagram to Show the Development of the Arteries of the Trunk from the Aortic Arches and Segmental Arteries.

The arteries which persist are black; those which degenerate are in outline; those newly formed are shaded. (After Mall.)



The lateral segmental arteries take origin from the aorta in series, intermediate in position between the dorsal and ventral segmentals. They reach their fullest development in embryos of about 8 mm., when they extend from the seventh cervical to the twelfth thoracic segment and supply the mesonephros. At this stage Broman found twenty arteries on each side, many of which were non-segmental. As the suprarenals and gonads develop, they each receive branches from several mesonephric arteries. The latter arteries now undergo rapid retrogression and the suprarenal and gonadic branches are shifted caudally through the mesonephric series to newly formed (non-segmental) arteries opposite the upper lumbar segments. Finally there remain three suprarenal arteries opposite the twelfth thoracic and first and second lumbar segments and a gonadic artery (*ovarian or internal spermatic* of the adult) opposite the third lumbar segment. All of these vessels now appear to be direct branches from the aorta. Of the three suprarenal branches, the upper and lower each gives a large branch to the diaphragm and kidney respectively and become the *inferior phrenic* and *renal arteries* of the adult. The middle becomes the *middle suprarenal* of the adult. Felix puts a somewhat different interpretation upon the origin of the vessels persisting in the lumbar region after the disappearance of the thoracic mesonephric arteries. He finds in an embryo of 18 mm. nine arteries on either side, extending from the ninth thoracic to the third lumbar segment, all of which he looks upon as mesonephric. These he classifies into three groups:—Cranial, which reach the mesonephros by passing dorsal to the suprarenal; caudal which pass ventral to the suprarenal, and middle which pass through it. Inasmuch as the arteries anastomose in the mesonephros there is great liability to variation in the number and position of the stems which persist in the adult. The suprarenal arteries are usually derived from the caudal group, the renals from the caudal or middle and the spermatics from the middle. When accessory renals or spermatics occur in the adult their place of origin and course will generally indicate the group from which they are derived.

The **ventral segmental arteries** appear very early. In an embryo of seven somites (ca. 2 mm.) described by Dandy* there was a right and a left series of twelve arteries, each arising from the still ununited dorsal aortæ, the artery at the caudal end of each series being the umbilical, and the remainder vitelline arteries. In an embryo of 4.9 mm. (35 somites) described by Ingalls† the originally paired vitelline arteries had united (as had the dorsal aortæ in part) to form unpaired vessels. There were unpaired vessels as follows: one opposite the seventh cervical segment (cœliac); five opposite the first four thoracic (omphalo-mesenterics, united by a longitudinal anastomosis), and one vessel of doubtful significance opposite the fifth and sixth thoracic segments. The paired umbilical arteries were opposite the first lumbar segment. No other ventral arteries were present.

It has been found from more fully developed stages that the inferior mesenteric artery is distinguishable at a stage of 8 mm. opposite the second lumbar segment. Also that the ventral segmental vessels undergo a process of migration until they reach their definitive positions, i. e., the *cœliac* opposite the twelfth thoracic segment, the *superior mesenteric* opposite the first, the *inferior mesenteric* opposite the third, and the umbilicals opposite the fourth lumbar segments, respectively. The œsophageal arteries of the adult do not belong to this series; but seem to be vessels of later formation.

The *umbilical arteries*, by means of secondary anastomosis, move laterally upon the aorta so as to pass lateral to the Wolffian ducts instead of medial. The proximal portion of each umbilical artery becomes the *common iliac* of the adult; its continuation is represented by the *hypogastric* and its umbilical branch. The *external iliac* appears to be derived from the dorsal segmental artery of the fifth lumbar segment, and the parietal branches of the hypogastric from corresponding sacral segmentals acquired by anastomosis. How such anastomoses between the umbilicals and the dorsal segmentals come about has not been ascertained.

2. VARIATIONS

Aorta and pulmonary artery.—The variations met with in the arch of the aorta are usually to be explained as persistent fœtal conditions, and are often associated with abnormalities of the heart. Many of the variations are due to different modes of transformation of the primitive system of aortic arches. Since the aorta and pulmonary artery develop from a common conus and truncus arteriosus, irregular and imperfect development of the aortic septum may also produce numerous variations.

It has been seen that at one stage of development two fourth arches, a right and a left, are present, and such a condition is occasionally persistent in the adult. In such cases, owing to the portion of the aorta derived from the bulbus arteriosus being directed upward and to the right and the descending aorta lying in the left side of the vertebral column, the right arch passes from right to left behind the œsophagus, which thus seems to perforate the aortic arch.

Another variation occasionally seen is the occurrence of an aortic arch curving to the right instead of the left. This may be due to a persistence of the lower portion of the right dorsal longitudinal stem and the disappearance of the left, as shown in fig. 506; or it may be associated with a complete inversion of all the viscera, a *situs inversus*.

If the lower portion of the right dorsal longitudinal trunk should persist, and the part of it which normally forms the proximal part of the right subclavian should disappear, the right subclavian would arise from the descending portion of the aortic arch. It is to be noted that in such cases the subclavian passes behind the œsophagus and below the right inferior laryngeal nerve. Partial persistence of the lower portion of the right dorsal longitudinal trunk is represented in the arteria aberrans (see p. 590).

Another group of variations is based on the persistence of the ductus arteriosus, which is derived from the sixth aortic arch. With this group belong the cases in which the pulmonary artery arises from the aorta; that is, where the blood of the pulmonary arteries passes from the aorta through the ductus arteriosus.

Variations in the number and the position of the vessels arising from the arch are extremely great, and many of these conditions are found normally in other mammals or birds. There may be from one to six branches. The case of one branch is the normal in the horse. It involves the fusion of the two aortic stems and the shortening of the fourth arch so that the left subclavian joins with the common stem. The avian form with two innominate arteries is extremely rare. A more common form is the one found in most apes, in which the innominate and left carotid form one branch; in rare instances the three branches are the two subclavians and a general carotid artery. When there are more than three branches the vertebral arteries are added, or the extra branch may be the thyreoidea ima (fig. 443). The commonest form with four vessels is the one in which the left vertebral arises between the left carotid and subclavian. A rarer form is to be found when the order is right subclavian, right carotid, left carotid, and left subclavian. Where there are five arteries, the extra ones are the right subclavian and left vertebral. The case of six branches is due to the separate origin of both vertebrals and both subclavians. The manner in which the vertebral artery may arise from the adult aortic arch is indicated in fig. 506.

The **innominate artery** may be absent, or may give off additional branches (see Aorta). It may be longer than usual and, bending to the left, ascend in front of the trachea (or more rarely behind the trachea and œsophagus) to turn again to the right. The *thyroidea ima* has been referred to (p. 532).

Carotid arteries.—The *common carotid* may be absent or bifurcate higher or lower than usual.

* Am. Journ. Anat., Vol. 10, 1910.
† Arch. f. mikr. Anat., Bd. 70, 1907.

It may not bifurcate at all, in which case the branches usually arising from the external carotid are derived from the common. The ascending pharyngeal and superior thyreoid occasionally arise from an otherwise normal common carotid. Unusual origin of the common carotids has been referred to (see AORTA).

Branches of the carotid arteries.—The superior thyreoid, lingual and external maxillary sometimes have a common stem of origin. The *superior thyreoid* artery varies in size inversely with the inferior. The *external maxillary* occasionally terminates in its submental branch. In such cases the main supply of the face is taken over by an abnormally large dorsal nasal branch of the ophthalmic, or transverse facial branch of the temporal artery. The *occipital* sometimes arises from the internal carotid or from the ascending cervical. The *ascending pharyngeal* is very variable in its place of origin from the external carotid, it may arise from the common or internal.

Out of 447 arteries examined, the second portion of the *internal maxillary* passed lateral to the external pterygoid muscle in 55 per cent., and medial to it in 45 per cent. of cases. When medial to this muscle the internal maxillary sometimes passes medial to the inferior alveolar and lingual nerves and occasionally between them. The variability in the course of this artery appears to depend on a tendency to reduplication of the infraorbital branch of the *stapedial artery* (p. 634) in the neighbourhood of the mandibular nerve. Such a condition was found by Thyng in a 17 mm. human embryo. When the internal maxillary passes medial to the external pterygoid there is often a parallel anastomosing channel between the posterior deep temporal and buccal branches.

The *ophthalmic artery* may arise, wholly or in part, from the middle meningeal, or *vice versa*. This is due to the anastomosis between the supraorbital branch of the stapedial and the ophthalmic in the embryo.

Subclavian artery.—Irregularities of origin have been referred to (see AORTA).

The branches of the subclavian artery are very variable in their place of origin (p. 559). The *vertebral* may arise directly from the arch of the aorta (p. 537) or take an unusual course in the neck. It may enter the foramen transversarium of the fourth or fifth cervical vertebra instead of the sixth; this arises from substitution of an embryonic precostal anastomosis in these segments for the usual postcostal. By a converse substitution it may enter the seventh. The *aa. transversa colli and scapulæ* vary inversely in size. The *arteria aberrans* connecting the right subclavian with the dorsal aorta has been referred to (p. 634).

The **thoracic aorta.**—Transposition, and the arteria aberrans have been referred to above.

Branches of the thoracic aorta.—The *intercostal arteries* are liable to numerical variation, evidently owing to the occurrence of precostal intersegmental anastomoses between the embryonic dorsal segmentals. A common longitudinal stem may even take over the vessels of both sides. The *anterior spinal artery* usually shows lack of median symmetry which indicates the bilaterality of its origin (p. 636). The arrangement of the *bronchial arteries* is liable to much variation; this has not received adequate explanation.

The abdominal aorta sometimes divides as low as the fifth lumbar vertebra, occasionally higher than usual, depending upon the definitive position taken by the umbilical arteries (p. 637). Cases are on record of accessory pulmonary arteries arising by a single stem from the abdominal aorta, which passes into the thorax along the œsophagus. The aorta and vena cava inferior may be transposed either as a part of *situs inversus* or as an abnormality of the venous system.

Branches of the abdominal aorta.—The *lumbar arteries* are subject to the same type of variation as occurs in the intercostals. There may be a loop connecting the *cœliac* and *superior mesenteric* arteries. Any or all of the branches of the cœliac may arise from the superior mesenteric (cœlio-mesenteric in the latter case) or directly from the aorta. The instability of the cœliac and superior mesenteric branches is favored by the rapid cranio-caudal migration of the two trunks; intersegmental anastomosis, in some cases, may be a factor also. There is very great variation in the number of branches given off by the superior mesenteric and in the details of their arrangement. This is a natural result of the number of possible routes which may be taken by the blood; these resemble, in their variety, those of an embryonic circulation. The region of supply of the *inferior mesenteric artery* is sometimes taken over entirely or in part (e. g., middle colic) by the superior mesenteric. An *omphalo-mesenteric* artery, in rare cases, arises from the superior mesenteric or one of its branches. It passes to the navel and anastomoses with inferior epigastric and with the small arteries accompanying the round ligament of the liver or the urachus.

Accessory renal arteries are very common; as many as six have been recorded. These may arise from the aorta, middle sacral, inferior phrenic, middle suprarenal or internal spermatic. According to Felix, these are to be regarded as persistent mesonephric arteries. Those arising above the regular renal frequently enter the kidney dorsal to the hilum. Those below it are more apt to be ventrally placed.

Nearly all possible varieties of origin are met with in the *inferior phrenic, middle suprarenal, internal spermatic* and *accessory renal* arteries which find explanation in the caudal migration of, and anastomosis between, the embryonic representatives of these vessels. The occasional origin of the inferior phrenic from the cœliac (or its branches) or from the superior mesenteric; of the internal spermatic or the middle suprarenal from the lumbar arteries, or of an accessory renal from the inferior mesenteric must be taken as indicating embryonic anastomoses between the dorsal, lateral, or ventral segmental arteries, as the case may be.

The iliac and hypogastric arteries.—The length of the *common iliac* depends upon the site of aortic bifurcation (p. 590); also upon the site of division of the common iliac into external iliac and hypogastric. If these spring directly from the aorta (as they do in rare cases) the common iliac is absent. The trunk formed by the common iliac and *hypogastric* is the proximal portion of the embryonic umbilical artery. The manner in which this takes over a dorsal segmental artery (probably the fifth lumbar) to become the *external iliac* is not sufficiently undersood to account for variations in this region.

The *branches of the hypogastric artery* show great variation in their origin, and there is frequently no separation of the hypogastric into anterior and posterior divisions. Rarely the branches all take origin from the external iliac, in which case the hypogastric (as such) is absent. The *obturator artery* may arise from the inferior epigastric, or *vice versa* (p. 615). The *arteria comitans n. ischiadici* may be larger than usual and form a very pronounced anastomosis with the popliteal. In rare cases the main blood-supply of the lower limb is thus derived from the *inferior gluteal* which is the primitive embryonic condition (p. 640). The *vesical* and *vaginal* arteries are liable to variation in their relative areas of distribution. The *internal pudendal* is sometimes small and may terminate as the *perineal artery*, in these cases the urogenital region is supplied largely by the *accessory pudendal* (p. 610).

B. ARTERIES OF THE EXTREMITIES

1. MORPHOGENESIS

The arteries of the adult extremities represent surviving channels resulting from the selection of a chosen path traversing the perineural arterial plexuses of the early embryonic limb.

At present there is little unanimity of opinion as to whether the pattern of the developing nerve trunks is specifically reproduced by the primitive arterial plexuses or whether the undoubted similarity between the two is of a more general nature. There occurs in either extremity one case in which an artery of fundamental importance follows a course practically independent of nerve distribution. The volar interosseous, in the forearm, and the peroneal, in the leg, are accompanied by insignificant nerves (n. to pronator quadratus, and n. to flexor hallucis longus respectively) which, moreover, do not extend the full length of the arteries in question.

The blood of a developing limb, having traversed the proximal segment by means of the arterial plexus around a single nerve, has the choice of several possible paths by which to reach the digits. The selected channel becomes, for the time, the principal artery of the distal segment. This presently gives way to a second favoured route, which may persist or again give way to a third. Thus, finally, the adult arrangement is established. This process of alternation is the cause of many of the commoner variations for, if it does not proceed to its usual termination, a small vessel, commonly rated as a branch, may testify to its earlier importance by appearing as one of the chief vessels of the part.

In the **upper extremity** the blood first traverses the peri-median plexus (which becomes later the axillo-brachial trunk) and flows to the digits mainly by the volar interosseous route. Next the volar interosseous dwindles in favour of the median. The median afterward relinquishes its function to the radial and ulnar.

In the **lower extremity** the main blood-flow at first follows the peri-sciatic plexus from which it is delivered to the digits chiefly by the peroneal artery. The peroneal artery passes from the sole to the dorsum of the foot through the sinus pedis, and from here supplies the digits. The anterior and posterior tibial are at first small, the latter supplying the plantar digital arteries. At a stage of 10 millimetres the femoral artery is represented by a peri-saphenous plexus which anastomoses with the peri-sciatic plexus near the knee. The peri-femoral plexus rapidly consolidates into the femoral and genu suprema arteries. The femoral later takes over the poplileal as its direct continuation, and the origin of the genu suprema marks the boundary between the femoral and ischiadic zones of the main trunk. Finally the peroneal gives place to the anterior and posterior tibial arteries. The portion of the peroneal perforating the tarsus disappears. In so doing it leaves the original termination of the peroneal artery connected with the dorsalis pedis to become the arcuate branch of the latter.

2. VARIATIONS

The variations of the arteries of the **upper extremity** may be divided into two categories, A certain number of them, particularly those occurring in the forearm and hand, are directly traceable to the unusual persistence of one or more of the embryonic channels; or, when variation involves magnitude only, to reciprocal variations in the size of the normal vessels. The commoner and more important variations of the arterial distribution, however, arise in a manner much less susceptible to ready explanation. They depend, in fact, upon variations in the course taken by the single or double route which, surviving from the intricacies of the peri-median plexus, persists to maturity. These will be referred to later.

The *volar interosseous* artery may be unusually large. It may reinforce a deficient radia or ulnar through the volar carpal artery, or its dorsal carpal branch may join the radial at the back of the wrist. In very rare cases the volar interosseous, together with a large ulnar artery, replaces the radial altogether.

A large *median artery* may participate in the palmar supply of the fingers, either by joining the superficial volar arch or (the arch being absent) by breaking directly into digital branches. The median, when large, occasionally replaces the ulnar, very rarely the radial, and frequently the superficial volar.

The *superficial volar arch* may be small, with compensation by the deep, or absent. In the latter case the digital arteries may come directly from the ulnar and radial, ulnar and median or median and radial. In the absence of the superficial volar, which is very frequent, the superficial arch is completed by the princeps pollicis or the volaris radialis indicis.

Cases are on record in which the ulnar artery, arising in the middle of the arm passes behind the medial epicondyle to follow the nerve in the forearm as usual. The ulnar artery here replaces the superior ulnar collateral and the ulnar recurrent. This anomaly is explained in a striking way by the account given by de Vriese of the development of the vessels of the upper extremity.

Several important variations in the distribution of the main vessels belong to the second category. It is not uncommon for *two arteries* to arise from the primitive peri-median plexus of the arm. In such cases one artery usually takes a course dorsal to the median nerve, i. e., it is crossed medio-laterally by the medial head of the nerve and in the contrary direction by the nerve itself. Its course corresponds to that taken by the ordinary axillo-brachial trunk; it is known as the *deep brachial* artery. The other vessel takes a course ventral to the median, nerve, and is known as the *superficial brachial.* The superficial brachial may join its companion artery, at or above the elbow, or one of the forearm vessels arising from it. In either case the superficial brachial is referred to as a "*vas aberrans.*" Persistence of the superficial brachial further operates as a frequent cause of abnormality in the forearm in that it is often continued directly into one or more of the chief arteries of the latter, the deep brachial taking the remainder. This condition is classified as a high origin of the radial, ulnar, etc., as the case may be.

There is another type of variation belonging to the same category. In this, *one large artery* only occurs above the elbow which, instead of following the normal course of the brachial, passes, entirely or in part, ventral to the median nerve. In the first case this vessel represents the superficial brachial, the deep being absent. In the second it corresponds in its upper part to the deep brachial and in its lower to the superficial, the two components varying in inverse proportion.

E. Müller*, who has made a study of the variations belonging to this category, classifies the abnormal artery occurring in cases of vas aberrans, of high origin of forearm-vessels, and of single abnormal brachial, according to the proportion of superficial brachial present in any particular example, as a. brachialis superficialis superior media, inferior, or ima. In an embryo of 11.7 millimetres he found a system of arterial channels in relation with the median nerve out of which any variation of this category might have been produced during further development.

In cases in which the superficial brachial alone persists, the branches of the axillary (and sometimes the profunda brachii and superior ulnar collateral) arise from a common (deep brachial) trunk called the *profunda axillaris.* In cases in which the deep and superficial brachial co-exist examples of continuation of the superficial brachial into the radial are rather common, continuation into the ulnar less so. Continuation of the superficial brachial into the median, interosseous, or of posterior interosseous arteries occasionally occur, but they are rare. In any case of high origin a cross branch may connect the high vessel with the deep brachial in the neighbourhood of the elbow. The ulnar artery when arising high is often superficial to the forearm flexors (a fact which has not been explained on embryological grounds), the interosseous arising from the radial.

The variations occurring in the arteries of the lower extremity are usually compensatory, or due to persistence of alternative embryonic channels. The sciatic (inferior gluteal) very rarely persists as the main artery of supply. In such cases the small femoral ends as the *genu suprema* which then appears to be a branch of the profunda.

The *profunda* is irregular; its origin may occur anywhere between the inguinal ligament and a point four inches below it. The *median* or *lateral circumflex* may arise from the femoral. The branches of the latter commonly arise separately from the profunda, or from the femoral. The *popliteal* does not vary much in its point of division. High division is commoner than low, but is never higher than the lower epiphyseal line of the femur.

The *anterior tibial* may be small and only reach the middle or lower part of the leg. In such cases an enlarged anterior peroneal may end as the dorsalis pedis, or the dorsal metatarsal arteries may be supplied from the plantar arch. Cases in which the anterior peroneal supplies the dorsum of the foot do not represent a direct inheritance of the embryonic method by which the peroneal artery performs this office. The embryonic route of the peroneal to the dorsum of the foot is transtarsal. The anterior tibial artery may reach the extensor surface of the leg by accompanying the peroneal nerve. This case, like that of the ulnar artery passing around the medial epicondyle, is interesting in connection with the work of de Vriese.

The *posterior tibial* artery may be absent or small, the peroneal replacing it, or reinforcing it by means of the ramus communicans. Absence of the *peroneal* has been recorded by Otto and W. Krause, but these cases are explained by Barkow as being suppression of the posterior tibial artery between the origin of the peroneal and the communicating branch (Quain).

The *lateral plantar* is sometimes very small, in which case the plantar arch may be supplied by a large deep plantar. In rare cases there is a superficial plantar arch as in the embryo.

3. THE SYSTEMIC VEINS

The **systemic veins** are naturally divided into three groups—(1) the veins of the heart; (2) the vena cava superior and its tributaries, namely the veins of the head, neck, upper extremity, and thorax; and (3) the vena cava inferior and its tributaries, namely, the portal system, and the veins of the abdomen, pelvis, and lower extremity.

* E. Müller, Anat. Hefte, No. 22, 1903.

I. THE VEINS OF THE HEART

The veins of the heart have already been described (p. 520).

II. THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

THE VENA CAVA SUPERIOR

The **vena cava superior** (fig. 509) carries to the heart the blood returned from the head and neck and upper extremities through the right and left innominate veins, and from the walls of the thorax, either directly through the azygos vein, or indirectly through the innominate veins. It is formed (fig. 509) by the confluence of the right and left innominate veins behind the first right sterno-chondral articulation. Descending from its origin in a gentle curve with its convexity to the right and in a direction slightly backward behind the sternal end of the first and second intercostal spaces and second costal cartilage, it terminates in the right atrium of the heart on a level with the third right costal cartilage in front and the seventh thoracic vertebra behind. It measures about 7 to 8 cm. (3 in.) in length. A little more than its lower half (4 cm.) is contained within the pericardium, the serous layer of that membrane being reflected obliquely over it immediately below the spot where it is joined by the vena azygos, and on a lower level than the reflexion of the pericardium on the aorta. The superior vena cava contains no valves.

Relations.—**In front,** in addition to the first and second intercostal spaces and the second costal cartilage, it is covered by the remains of the thymus gland, the intrathoracic fascia, and the pericardium, and is overlapped by the right pleura and lung.

Behind (fig. 509) are the vena azygos (major), the right bronchus, the right pulmonary artery, and the superior right pulmonary vein; and below, the fibrous layer of the pericardium. The serous layer is reflected over the front and sides of the vessel, but not over its posterior part.

To the **right side** are the right lung and pleura and the phrenic nerve.

To the **left side** are the innominate artery and the ascending aorta.

Tributaries.—In addition to the right and left innominate veins and the vena azygos it receives small veins from the mediastinum and pericardium.

THE INNOMINATE VEINS

The **innominate** or brachio-cephalic veins [vv. anonymæ] return the blood from the head and neck and upper extremity. They are formed on each side by the confluence of the internal jugular and subclavian veins behind the sternal end of the clavicle. They terminate behind the first costal cartilage on the right side by uniting to form the vena cava superior. The innominate veins have no valves.

The **right innominate** vein [v. anonyma dextra] (fig. 509) measures about 2 to 3 cm. (1 to $1\frac{1}{2}$ in.) in length, and descends from its origin behind the sternal end of the clavicle, very slightly forward and medially, along the right side of the subclavian and innominate arteries, to its junction with the left vein behind the first costal cartilage close to the sternum. It is superficial to the innominate artery.

Relations.—**In front** are the origins of the sterno-hyoid and sterno-thyreoid muscles, the clavicle, the first costal cartilage, and the remains of the thymus gland.

Behind are the pleura and lung.

To the **right** are the right pleura and lung and the phrenic nerve.

To the **left** (fig. 509) are the right subclavian artery, the innominate artery, the right vagus nerve, and the trachea.

The **left innominate** vein [v. anonyma sinistra] (fig. 509) measures 6 to 7.5 cm. ($2\frac{1}{2}$ to 3 in.) in length, and extends from its origin behind the sternal end of the left clavicle obliquely across the three main branches of the arch of the aorta, to unite with the right innominate vein behind the cartilage of the first rib close to the sternum to form the vena cava superior. In this course it runs from left to right with an inclination downward and slightly backward. A line drawn obliquely across the upper half of the manubrium of the sternum, from the sterno-clavicular articulation on the left side to the lower border of the first costal cartilage at its junction with the sternum on the right side, will indicate its course. The left innominate vein is on a level with the top of the sternum at birth.

Relations.—**In front,** in addition to the manubrium of the sternum, it has the origins of the sterno-hyoid and sterno-thyreoid muscles, and the remains of the thymus gland, the sternal end of the left clavicle, and the sterno-clavicular articulation.

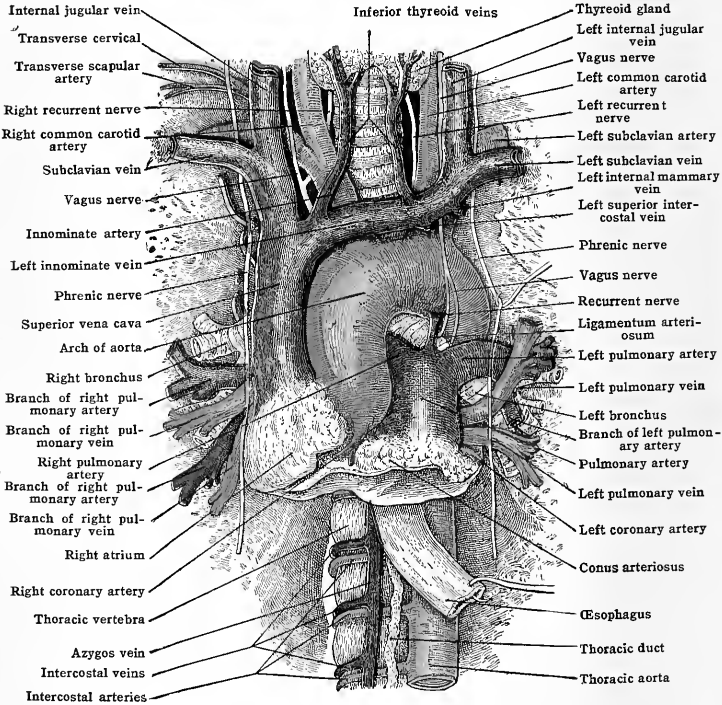
Behind are the three chief arteries arising from the arch of the aorta, the trachea, and the left phrenic and left vagus nerves.

Below it is the arch of the aorta.

Above it are the cervical fascia, the inferior thyreoid, and thyreoidea ima veins.

Tributaries.—In addition to the internal jugular and subclavian veins, by the confluence of which the innominate veins are formed, each vein receives on its upper aspect the vertebral, the deep cervical, and inferior thyreoid veins; and

FIG. 509.—THE VENA CAVA SUPERIOR AND THE INNOMINATE VEINS. (Modified from a dissection in St. Bartholomew's Hospital Museum.)



on its lower aspect the internal mammary vein. The left vein, moreover, is joined by the thyreoidea ima, the left superior intercostal, and by the thymic, tracheal, œsophageal, superior phrenic, anterior mediastinal, and pericardiac veins. At the confluence of the internal jugular and subclavian veins on the right side the three lymphatic trunks or the right lymphatic duct open; on the left side the thoracic duct.

THE VEINS OF THE HEAD AND NECK

The **veins of the head and neck** may be divided for purposes of description into the **superficial,** which return the blood from the external parts of the head and neck; and the **deep,** which return the blood from the deeper structures. All the veins, whether superficial or deep, terminate in the internal jugular or subclavian, or open directly into the innominate veins at the root of the neck. Through the latter all the blood from the head and neck ultimately passes on its way to the heart.

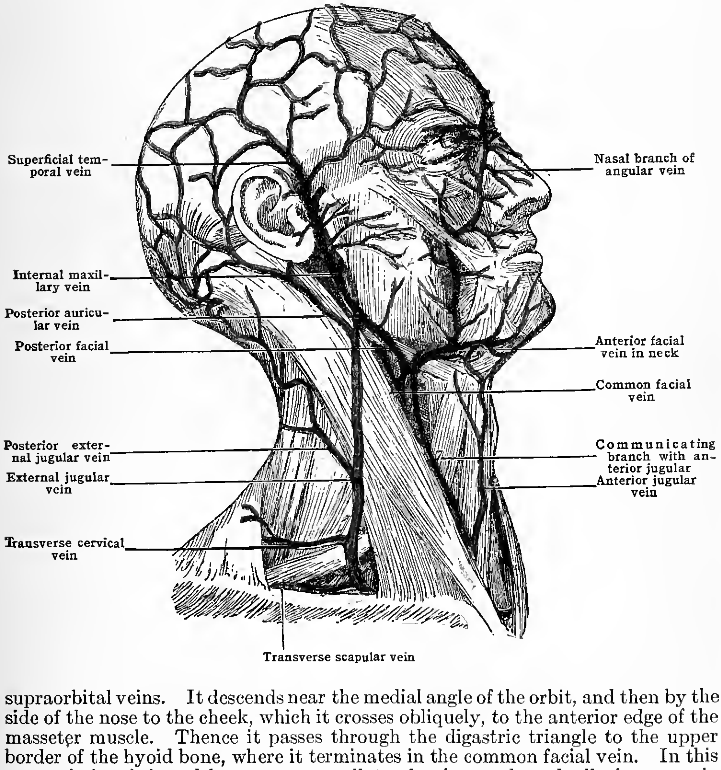
THE SUPERFICIAL VEINS OF THE HEAD AND NECK

The venous blood from the anterior part of the scalp and integument of the face is returned, through the **anterior and posterior facial** veins, to the **common facial,** a tributary of the internal jugular vein. From the posterior part of the scalp and from the integument of the neck venous blood is returned, through the **external jugular** and its tributaries, to the subclavian vein.

A. The Anterior Facial Vein

The **anterior facial** vein [v. facialis anterior] (fig. 510) begins a little below the medial end of the eyebrow where it is formed by the union of the frontal and

Fig. 510.—The Superficial Veins of the Face and Scalp. (After Quain.)



supraorbital veins. It descends near the medial angle of the orbit, and then by the side of the nose to the cheek, which it crosses obliquely, to the anterior edge of the masseter muscle. Thence it passes through the digastric triangle to the upper border of the hyoid bone, where it terminates in the common facial vein. In this course it is reinforced by numerous collateral veins, and gradually increases in size. It has, moreover, numerous communications with the deep veins. The portion of this vein above the lower margin of the orbit is called the **angular** [v.

angularis]. In the remainder of its course over the face and neck it is termed the **anterior facial** vein.

The angular vein skirts around the medial margin of the orbit, lying with the angular artery on the frontal (nasal) process of the maxillary bone slightly medial to the lacrimal sac. Branches pass from the posterior part of the angular vein into the orbit to join the ophthalmic.

The angular, the facial, and the ophthalmic veins contain no valves. The blood, therefore, can pass either forward from the ophthalmic into the angular, or backward through the facial and angular into the ophthalmic, and so on to the cavernous and other venous sinuses of the cranium. Hence in certain tumours in the orbit and cranium, the congestion of the angular and facial veins; and the danger in facial carbuncle and anthrax of septic thrombi spreading backward through the angular and ophthalmic veins to the cranial sinuses.

The anterior facial vein runs in a more or less direct line behind its corresponding artery, the external maxillary (facial), which itself pursues a tortuous course. It usually passes deep to the zygomatic muscle, the zygomatic head of the quadratus labii superioris, and the risorius, but superficial to the other muscles. At the anterior edge of the masseter it meets the external maxillary artery, lying immediately posterior to it. In the neck it lies beneath the platysma and cervical fascia, and is usually separated from the external maxillary artery by the submaxillary gland and the stylo-hyoid and posterior belly of the digastric muscles, below which it is joined by the posterior facial, to form the **common facial** vein.

Tributaries.—It receives, from above downward:—(a) the frontal vein; (b) the supraorbital vein; (c) the superior palpebral veins; (d) the external nasal veins; (e) the inferior palpebral veins; (f) the superior labial vein; (g) the inferior labial vein; (h) the masseteric veins; (i) the anterior parotid veins; (j) the palatine vein and (k) the submental vein.

(a) The **frontal** vein [v. frontalis] (fig. 510) begins about the level of the coronal suture in a venous plexus which communicates with the anterior division of the temporal vein. Soon forming a single trunk, it passes vertically downward over the frontal bone, a short distance from the middle line and parallel to its fellow of the opposite side, to the medial end of the eyebrow where it terminates in the angular vein.

(b) The **supraorbital** vein [v. supraorbitalis] begins over the frontal eminence by intercommunication with the middle temporal vein. It receives tributaries from the forehead and eyebrow, and, running obliquely, medially and downward, opens into the termination of the frontal vein to form the angular. It communicates with the ophthalmic vein, and receives the frontal vein of the diploë as the latter vein issues from the bone at the bottom of the supraorbital notch.

(c) The **superior palpebral** veins [vv. palpebrales superiores] arise in the upper eyelid and open into the lateral side of the angular vein. They communicate with the middle temporal vein.

(d) The **external nasal** veins [vv. nasales externæ] form three or four stems on either side. The upper veins run upward into the angular and the lower, from the ala, pass more horizontally into the anterior facial vein.

(e) The **inferior palpebral** veins [vv. palpebrales inferiores] arise in the lower eyelid, and, passing medially and downward over the cheek from which they receive tributaries, open into the lateral side of the anterior facial vein. They communicate with the infraorbital vein.

(f) The **superior labial** vein [v. labialis superior] and (g) the **inferior labial** vein [v. labialis inferior] arise from venous plexuses in the upper and lower lips. They run laterally to open into the medial side of the facial vein.

(h) The **masseteric** veins [vv. massetericæ] and (i) the **anterior parotid** veins [vv. parotidæ anteriores], of small size, drain the cheek over the masseteric and parotid regions.

(j) The **palatine** vein [v. palatina] accompanies the ascending palatine or tonsillar artery from the venous plexus about the tonsil and soft palate, and joins the anterior facial vein just below the body of the mandible.

(k) The **submental** vein [v. submentalis] lies on the mylo-hyoid muscle superficial to the submental artery. Running back in the submental triangle, it joins the anterior facial vein just after the latter has passed over the body of the mandible. It communicates with the anterior jugular vein.

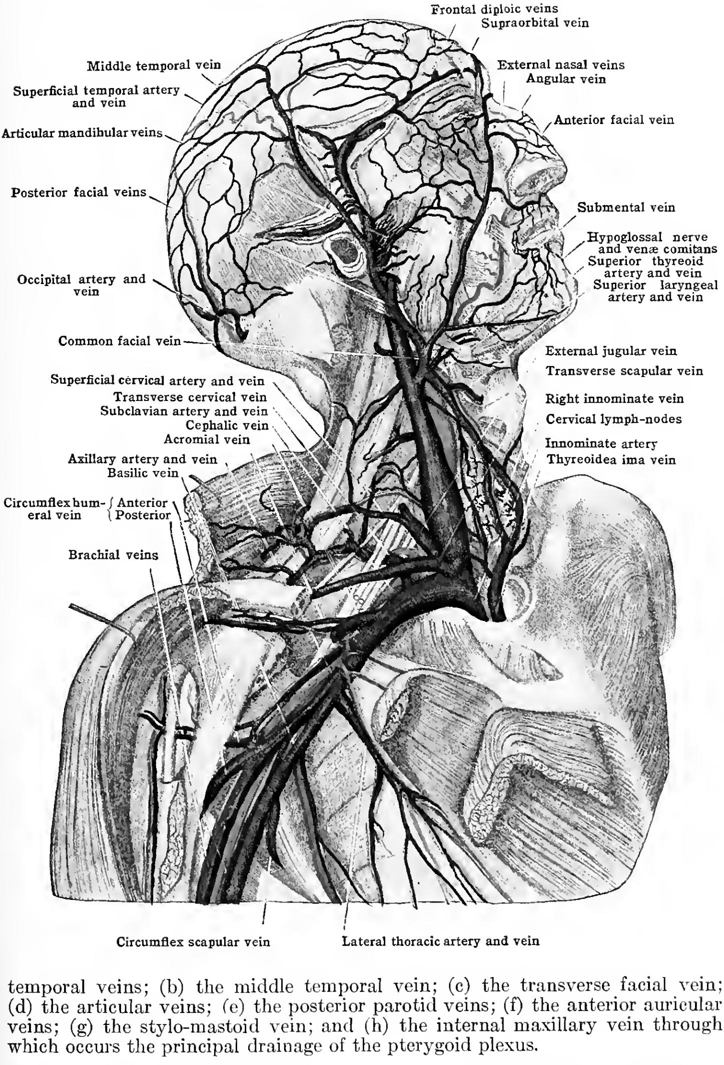
Communications.—The tributaries of the anterior facial vein communicate freely with the anterior and middle temporal, ophthalmic, infraorbital and anterior jugular veins. The main trunk has a large **communicating branch with the pterygoid plexus.** This vein, sometimes known as the deep facial, opens into the anterior facial below the zygomatic bone under cover of the zygomaticus muscle.

B. The Posterior Facial Vein

The **posterior facial** (temporo-maxillary) vein [v. facialis posterior] is formed in in the region of the root of the zygoma by the union of the superficial and middle temporal veins. It passes downward behind the ramus of the mandible through the substance of the parotid gland—here lying lateral to the superficial temporal and external carotid arteries. At the angle of the mandible it runs medially and somewhat forward, and, passing either deep or superficial to the stylo-hyoid and digastric muscles, joins the anterior facial to form the common facial vein.

The **tributaries** received by the posterior facial vein are:—(a) the superficial

Fig. 511.—The Veins of the Head, Neck, and Axilla. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



temporal veins; (b) the middle temporal vein; (c) the transverse facial vein; (d) the articular veins; (e) the posterior parotid veins; (f) the anterior auricular veins; (g) the stylo-mastoid vein; and (h) the internal maxillary vein through which occurs the principal drainage of the pterygoid plexus.

(a) The **superficial temporal** vein [v. temporalis superficialis] returns the blood from the parietal region of the scalp. It is formed by the union of an anterior and a posterior branch: the former communicates with the supraorbital and frontal veins; the latter with the posterior auricular and occipital veins and the temporal vein of the opposite side. These branches lie superficial to the corresponding branches of the superficial temporal artery, which they roughly though not accurately follow. Like the artery, they lie between the skin and the cranial aponeurosis, and descend over the temporal fascia to unite a little above the zygoma, and just in front of the auricle of the ear, to form the superficial temporal trunk. The vein thus formed continues its course downward with the trunk of the temporal artery, and opposite the zygoma is joined by the middle temporal vein to form the common temporal vein.

(b) The **middle temporal** vein [v. temporalis media] corresponds with the orbital branch of the temporal artery, and communicates in front with the ophthalmic vein, the external palpebral veins, and the infraorbital veins, and then runs backward between the layers of the temporal fascia to join the superficial temporal vein. The middle temporal vein communicates with the deep temporal veins, and through them with the pterygoid venous plexus.

(c) The **transverse facial** vein [v. transversa faciei] corresponds to the transverse facial artery. (d) **Articular** veins [vv. articulares mandibulæ] form the plexus around the temporo-mandibular joint; this plexus receives the **tympanic** veins [vv. tympanicæ), which, together with its corresponding artery, passes through the petrotympanic fissure. (e) **Posterior parotid** veins [vv. parotideæ posteriores] emerge from the substance of the parotid gland. (f) **Anterior auricular** veins [vv. auriculares anteriores], from the auricle of the ear. (g) **Stylo-mastoid** vein [v. stylomastoidea] from the facial canal. (h) The **internal maxallary** vein accompanies the first part of the internal maxillary artery. It begins at the posterior confluence of the veins forming the pterygoid plexus, and passes backward between the stylo-mandibular ligament and the neck of the mandible. It ends by joining the posterior facial vein.

The **pterygoid plexus** [plexus pterygoideus] is formed by the veins which correspond to the branches of the internal maxillary artery. It is situated, partly on the medial surface of the internal pterygoid muscle, and partly around the external pterygoid muscle. The veins entering into this plexus are:—the two **middle meningeal veins** [vv. meningeæ mediæ], which accompany the artery of that name; the **posterior superior alveolar** (dental); the **inferior alveolar** (dental); the **masseteric**; the **buccal**; the **pterygoid** veins from the pterygoid muscles; the **deep temporal** veins [vv. temporales profundæ], by which the plexus communicates with the temporal plexus; the **spheno-palatine** vein; the **infraorbital**; the **superior palatine**; a branch of communication with the lower branch of the **ophthalmic** vein, which courses through the inferior orbital (spheno-maxillary) fissure; and the **rete foraminis ovalis** and **Vesalian** vein, through which the plexus communicates with the cavernous sinus. The plexus ends posteriorly in the internal maxillary vein, which joins the posterior facial vein, and anteriorly in a communicating vessel (the deep facial vein), which passes forward and downward between the buccinator and masseter muscles to join the anterior facial vein.

The above-mentioned veins, forming by their confluence the pterygoid plexus, correspond in their course so nearly with that of their companion arteries that a detailed description is not necessary. Although for convenience described with the superficial veins, they are all deeply placed.

Near the angle of the mandible there is almost always a communicating branch between the posterior facial and the external jugular veins. When large, this branch may drain the greater part of the blood from the posterior facial.

C. The Common Facial Vein

The **common facial** vein [v. facialis communis] is a short thick stem contained within the carotid triangle. It is formed, just below the angle of the mandible, by the union of the anterior and posterior facial veins. It ends opposite the hyoid bone, by opening into the internal jugular vein. In addition to the vessels which form it, sometimes it receives the superior thyreoid, the pharyngeal, and the lingual or the sublingual veins.

D. The External Jugular Vein

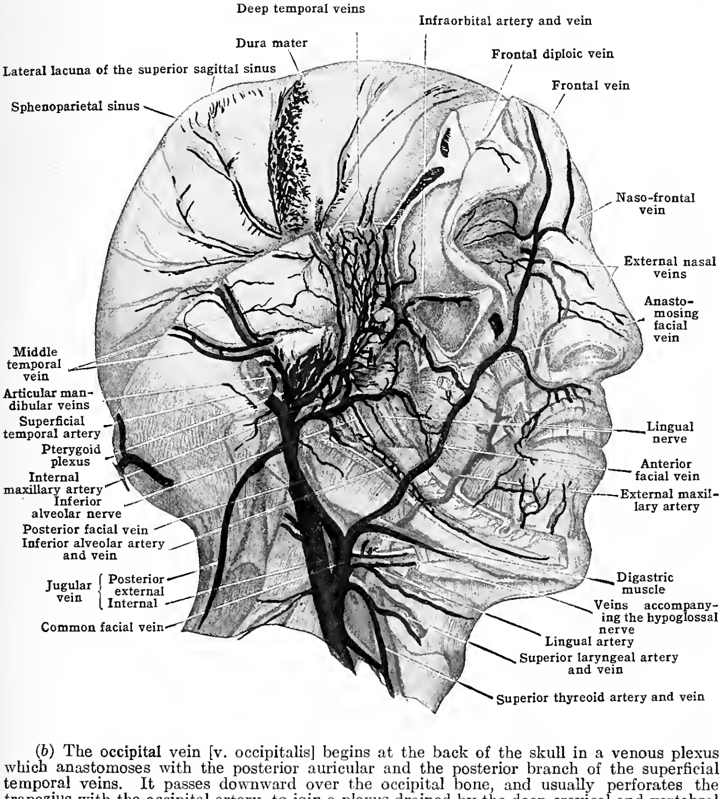
The **external jugular** vein [v. jugularis externa] (fig. 510) is formed by the confluence of the posterior auricular and a short communicating trunk from the posterior facial near the angle of the mandible. It runs obliquely downward and backward across the sterno-mastoid muscle to a point opposite the middle of the clavicle, where it terminates as a rule in the subclavian vein. A line drawn from a point midway between the mastoid process and angle of the jaw to the middle of the clavicle will indicate its course. It is covered by the skin, superficial fascia, and platysma, and is crossed by a few branches of the cervical plexus, the great auricular nerve running parallel to it at the upper part of the neck. It is separated from the sterno-mastoid by the anterior layer of the deep cervical fascia.

Just above the clavicle it perforates the cervical fascia, by which it is prevented from readily collapsing, the fascia being attached to its walls. It then opens into the subclavian vein, occasionally into the internal jugular, or into the confluence of the subclavian and internal jugular veins. It contains a pair of valves about 2.5 to 5 cm. (1 to 2 in.) above the clavicle, and a second pair where it enters the subclavian vein. Neither of these valves is sufficient to prevent the blood from regurgitating, or injections from passing from the larger vein into the external jugular.

Tributaries and communications.—These include;—(a) The posterior auricular vein; (b) the occipital vein; (c) a branch of communication with the posterior facial vein; (d) the posterior external jugular vein; (e) the transverse scapular vein; and (f) the anterior jugular vein.

(*a*) The **posterior auricular** vein [v. auricularis posterior] begins in a venous plexus on the posterior part of the parietal bone. This plexus communicates with the vein of the opposite side across the sagittal suture, and with the posterior branch of the superficial temporal vein in front, and with the occipital vein behind. It descends over the back part of the parietal bone and the mastoid process of the temporal bone, lying with its artery behind the ear, and joins a branch from the posterior facial vein to form the external jugular.

FIG. 512.—THE VEINS OF THE FACE. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



(*b*) The **occipital** vein [v. occipitalis] begins at the back of the skull in a venous plexus which anastomoses with the posterior auricular and the posterior branch of the superficial temporal veins. It passes downward over the occipital bone, and usually perforates the trapezius with the occipital artery, to join a plexus drained by the deep crevical and vertebral veins. It also communicates with the posterior auricular, and in many cases this forms the chief path of drainage. One of its branches, usually the most lateral, receives a **mastoid emissary** vein [emissarium mastoideum] which issues through the mastoid foramen of the temporal bone, and in this way forms a communication with the transverse sinus.

(*c*) The branch of **communication with the posterior facial** vein occurs a short distance below the point at which the posterior facial receives the internal maxillary vein. It is very constant and is placed immediately behind the angle of the mandible. Through it the external jugular usually receives a considerable proportion of the blood returning from the temporal and pterygoid regions.

(*d*) The **posterior external jugular** vein (fig. 512) descends from the upper and back part of the neck, receiving small tributaries from the superficial structures and muscles. At times it communicates with the occipital, or may appear as a continuation of that vein. It opens into the external jugular as the latter vein is leaving the sterno-mastoid muscle.

(*e*) The **transverse scapular** vein [v. transversa scapulæ] corresponds to the transverse scapular (suprascapular) artery. If double, these venæ comitantes usually form one trunk before they open into the external jugular vein. They contain well-marked valves.

(*f*) The **anterior jugular vein** [v. jugularis anterior] begins below the chin by communicating with the mental, submental, inferior labial, and inferior hyoid veins. It descends a little lateral to the middle line, receiving branches from the superficial structures at the front and side of the neck, and occasionally a branch from the larynx and thyreoid body. Just above the clavicle it turns laterally, and, piercing the fascia, passes beneath the sterno-mastoid muscle and opens into the external jugular vein just before the latter joins the subclavian; at times it opens into the subclavian vein itself. In its course down the neck it communicates with the external jugular; and, as it turns laterally beneath the sterno-mastoid, sends a branch across the trachea, between the layers of cervical fascia, to join the anterior jugular of the opposite side. This communicating vein, the **jugular venous arch** [arcus venosus juguli], may open directly into the external jugular or into the internal jugular vein; occasionally one or both ends may open into the subclavian or innominate vein. It may be divided in the operation of tracheotomy, and is then often found greatly engorged with blood. Another branch, often of considerable size, courses along the anterior margin of the sterno-mastoid and joins the anterior facial vein. When the anterior jugular vein is large, the external jugular is small, and *vice versa*. It is usually also of large size when the corresponding vein on the opposite side is absent, as is frequently the case. It contains no valves.

THE DEEP VEINS OF THE HEAD AND NECK

The **deep veins of the head and neck** may be divided into:—(1) the veins of the diploë; (2) the venous sinuses of the dura mater encephali; (3) the veins of the brain; (4) the veins of the nasal cavities; (5) the veins of the ear; (6) the veins of the orbit; (7) the veins of the pharynx and larynx; and (8) the deep veins of the neck. The veins of the diploë terminate partly in the superficial veins already described, partly in the venous sinuses of the cranium, and partly in the deep veins of the neck. The venous sinuses open into the deep veins of the neck. The veins of the brain terminate in the venous sinuses. The veins of the nasal cavities terminate partly in the deep, and to some extent in the superficial veins. The veins of the ear join both the superficial and deep veins and the venous sinuses. The veins of the orbit terminate partly in the superficial veins, but chiefly in the venous sinuses. The veins of the pharynx and larynx enter the deep veins of the neck.

1. THE VEINS OF THE DIPLOE

The **veins of the diploë** [venæ diploicæ] (fig. 513) are contained in bony channels in the cancellous tissue between the external and internal laminae of the skull. They are of comparatively large size, with very thin and imperfect walls, and form numerous irregular communicating channels. They have no valves. They terminate in four or five main and descending channels, which open, some outward through the external cranial lamina into some of the superficial and deep veins of the head and face, and some inward through the internal lamina into the venous sinuses. They are divided into the frontal, anterior temporal, posterior temporal, and occipital.

The **frontal diploic veins** are contained in the anterior part of the frontal bone. They converge anteriorly to a single vein [v. diploica frontalis] which passes downward, perforates the external table through a small aperture in the roof of the supraorbital notch, and terminates in the supraorbital vein. They also communicate with the superior sagittal sinus.

The **anterior temporal** [v. diploica temporalis ant.] are contained in the posterior part of the frontal and in the anterior part of the parietal bone. They pass downward, and end, partly in the deep temporal veins by perforating the greater wing of the sphenoid bone, and partly in the spheno-parietal sinus.

The **posterior temporal** [v. diploica temporalis post.] ramifies in the parietal bone, and, coursing downward to the posterior inferior angle of that bone, passes either through a foramen in its inner table, or through the mastoid foramen into the transverse sinus.

The **occipital** [v. diploica occipitalis] ramifies chiefly in the occipital bone, and opens into the occipital vein or into the transverse sinus.

The diploic veins freely anastomose with one another in the adult; but in the fœtus, before the bones have united, each system of veins is distinct.

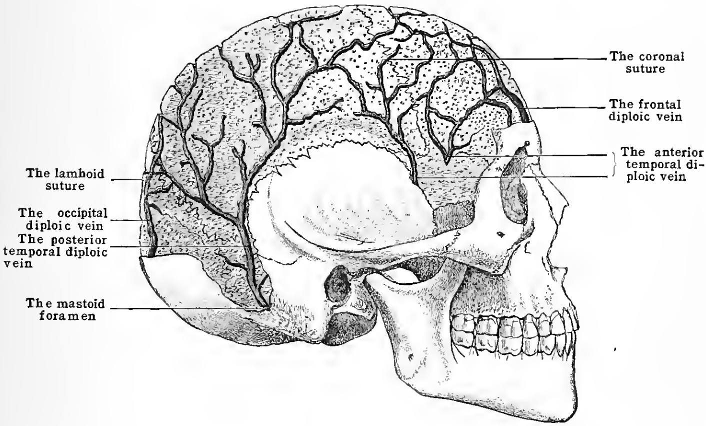
2. THE VENOUS SINUSES OF THE DURA MATER

The **venous sinuses of the dura mater** [sinus duræ matris] are endothelially lined blood-spaces, situated between the periosteal and meningeal layers of the dura mater. They are the channels by which the blood is conveyed from the cerebral veins, and from some of the veins of the meninges and diploë, into the veins of the neck. The sinuses at the base of the skull also carry the chief part of the blood from the orbit and eyeball to the jugular veins. At certain spots the sinuses communicate with the superficial veins by small vessels known as the emissary veins, which run through foramina in the cranial bones.

The venous sinuses are sixteen in number, six being median and unpaired, the remaining ten consisting of five lateral pairs. The median sinuses are:—(1) the superior sagittal; (2) the inferior sagittal; (3) the straight; (4) the occipital; (5) the circular; and (6) the basilar plexus. The lateral and paired sinuses are:—(7) the two transverse; (8) the two superior petrosal; (9) the two inferior petrosal; (10) the two cavernous; and (11) the two spheno-parietal. Occasionally there are two additional sinuses, the two petro-squamous.

(1) The **superior sagittal** (or longitudinal) **sinus** [sinus sagittalis superior] (fig. 515) lies in the median groove on the inner surface of the cranium along the attached margin of the falx cerebri. It extends from the foramen cæcum to the

Fig. 513.—The Veins of the Diploë.
(From a specimen in St. Bartholomew's Hospital Museum.)

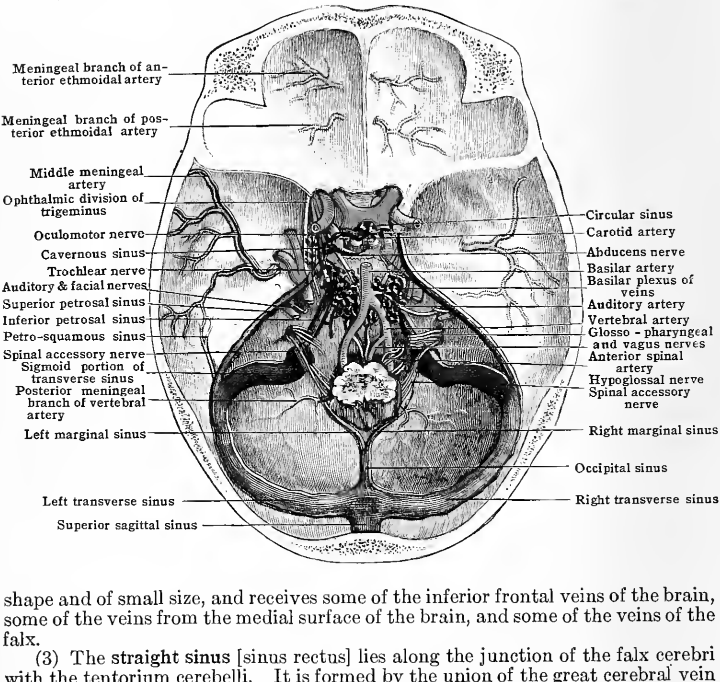


internal occipital protuberance. It grooves from before backward the frontal bone, the contiguous sagittal margins of the parietal bones, and the squamous portion of the occipital bone In the fœtus, and occasionally in the adult, it communicates (through the foramen cæcum) with the nasal veins. It communicates throughout life with each superficial temporal vein by means of a **parietal emissary** vein [emissarium parietale] which passes through the parietal foraman. It is triangular on section, the base of the triangle corresponding to the bone. Crossing it are a number of fibrous bands known as the *chords of Willis*, and projecting into it in places are the arachnoidal (Pacchionian) granulations. The parts of the sinus into which the arachnoidal granulations project are irregular lateral diverticula from the main channel known as the *lacunæ laterales* (fig. 517). In front the sinus is quite small, but it increases greatly in calibre as it runs backward. It receives at intervals the superior cortical cerebral veins and the veins from the falx. The former, for the most part, open into it in the direction opposite to that in which the blood is flowing in the sinus. They pass for some distance in the walls of the sinus before opening into it. Posteriorly, at the internal occipital protuberance, the superior sagittal sinus usually turns sharply to the right, and ends in the right transverse (lateral) sinus; the straight sinus then usually terminates in the left transverse (lateral) sinus.

Occasionally, however, the superior sagittal sinus ends in the left transverse sinus, the straight then passing into the right. At the angle of union between the superior sagittal sinus and the transverse sinus into which it empties there is a dilation, the **confluens sinuum** or torcular Herophili. At this point there is a communication between the right and left transverse sinuses. In some cases the communication is so free that the blood from the sagittal sinus flows almost equally into each transverse sinus. The confluens may communicate with the occipital vein through the **occipital emissary** vein [emissarium occipitale], which, when present passes through a minute foramen in the occipital protuberance.

(2) The **inferior sagittal** (or longitudinal) **sinus** [sinus sagittalis inferior] (fig. 515) is situated at the free margin of the falx cerebri. Beginning about the junction of the anterior with the middle third of the falx, it is continued backward along the concave or lower margin of that process to the junction of the falx with the tentorium, where it ends in the straight sinus. The sinus is cylindrical in

Fig. 514.—The Venous Sinuses.
(From a dissection by W. J. Walsham in St. Bartholomew's Hospital Museum.)



shape and of small size, and receives some of the inferior frontal veins of the brain, some of the veins from the medial surface of the brain, and some of the veins of the falx.

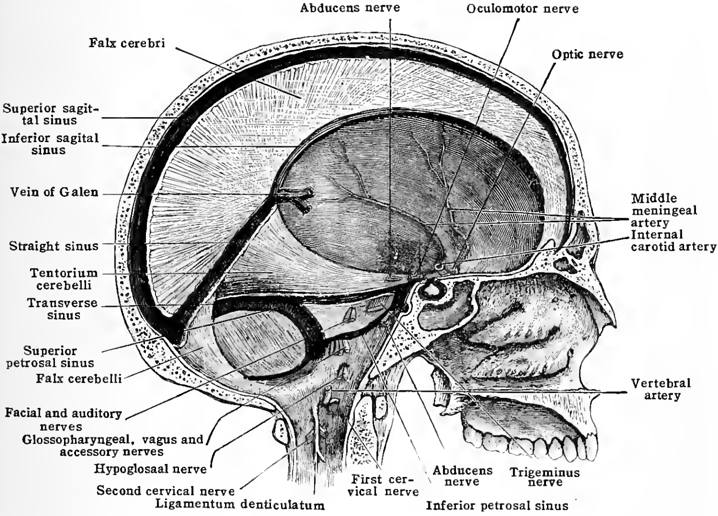
(3) The **straight sinus** [sinus rectus] lies along the junction of the falx cerebri with the tentorium cerebelli. It is formed by the union of the great cerebral vein (of Galen) and the inferior sagittal sinus. It receives in its course branches from the tentorium cerebelli and from the upper surface of the cerebellum. It runs downward and backward to the internal occipital protuberance, where it ends in the transverse sinus opposite to that joined by the superior sagittal sinus. On section it is triangular in shape, with its apex upward.

(4) The **occipital sinus** [sinus occipitalis] (fig. 514) ascends at the attached margin of the falx cerebelli, along the lower half of the squamous portion of the occipital bone from near the posterior margin of the foramen magnum to the internal occipital protuberance. It usually begins in a right and a left branch, known as the **marginal sinuses.** These proceed from the termination of each

transverse sinus, run around the foramen magnum, where they communicate with the venous vertebral retia, and unite at a variable distance from the internal occipital protuberance to form the single occipital sinus. Sometimes they remain separate as far as the occipital protuberance, then forming two occipital sinuses. One of the two marginal sinuses may be much smaller than the other, or be entirely absent. At the point where the marginal sinuses unite to form the single occipital sinus, there is a communication with the venous vertebral retia. The occipital sinus ends in the confluens sinuum. It receives in its course veins from the tentorium cerebelli, and from the inferior surface of the cerebellum. It communicates through the plexus of veins which surrounds the hypoglossal nerve [**rete canalis hypoglossi**] in the hypoglossal (anterior condyloid) canal with the vertebral vein and the longitudinal vertebral venous sinuses.

(5) The **circular sinus** [sinus circularis] (fig. 516) encircles the hypophysis cerebri. It consists of the two cavernous sinuses and their communications across

FIG. 515.—THE VENOUS SINUSES. (Longitudinal section.)



the median line by means of the **anterior and posterior intercavernous sinuses.** The intercavernous sinuses are small and cross the median line in front of and behind the hypophysis, respectively.

(6) The **basilar plexus** [plexus basilaris] is a venous plexus in the substance of the dura mater over the basilar part of the occipital bone. It extends from the cavernous sinus to the margin of the foramen magnum below. It communicates laterally with the inferior petrosal sinus, and inferiorly with the internal vertebral venous plexuses. One of the larger of the irregular venous channels forming the plexus passes transversely from one inferior petrosal sinus to the other. This venous plexus is serially homologous with the longitudinal vertebral venous sinuses on the posterior surfaces of the bodies of the vertebræ.

(7) The **transverse** (or lateral) **sinus** [sinus transversus] (figs. 514, 516) extends from the internal occipital protuberance to the jugular foramen. In this course it lies in the groove (which has been named after it) along the squamous portion of the occipital bone, the posterior inferior angle of the parietal bone, the mastoid portion of the temporal bone, and the jugular process of the occipital bone. It at first runs laterally and forward horizontally between the two layers of the tentorium cerebelli, following the curve of the groove on the occipital and on the mastoid angle of the parietal bone. On reaching the groove in the mas-

toid portion of the temporal bone it leaves the tentorium and curves medially and downward and then forward over the jugular process of the occipital bone, and ends in the posterior compartment of the jugular fossa in the superior bulb of the internal jugular vein. The S-shaped part of the sinus which lies on the mastoid portion of the temporal and jugular portion of the occipital bone is sometimes known as the **sigmoid sinus.** The transverse sinus receives the **internal auditory** veins [vv. auditivæ internæ] from the labyrinth, which emerge from the internal auditory meatus. It also receives veins from the temporal lobe of the cerebrum, some of the superior and inferior cerebellar veins, some of the veins of the medulla and pons, the occipital, and the posterior temporal and occipital veins of the diploë. At the point where it leaves the tentorium it drains the superior petrosal sinus and, when present, the petro-squamous sinus. It communicates with the occipital and vertebral veins through the mastoid and posterior condyloid foramina by means of the **mastoid** and **condyloid** emissary veins. As the transverse sinus lies between the layers of the tentorium it is on section prismatic in shape. The sigmoid portion is semicylindrical.

The right transverse sinus is usually the larger and the direct continuation of the superior sagittal sinus, and hence conveys the chief part of the blood from the cortical surface of the brain and vault of the skull. The left transverse sinus is usually the smaller and the direct continuation of the straight sinus, and hence returns the chief part of the blood from the central ganglia of the brain. The right and left sinuses communicate opposite the internal occipital protuberance.

The relation of the lateral sinus to the outside of the skull, especially to the mastoid process of the temporal bone, is of importance with reference to the operations of trephining the mastoid cells, opening the tympanum, and exposing the sinus itself, in septic thrombosis, etc. The course of the sinus corresponds to a line drawn from the external occipital protuberance to the base of the mastoid process, or to the asterion, and thence over the back of the mastoid process in a curved line toward its apex.

(8) The **superior petrosal sinus** [sinus petrosus superior] (figs. 514, 515) runs at the attached margin of the tentorium cerebelli, along the upper border of the petrous portion of the temporal bone. It connects the cavernous with the transverse sinus. Leaving the lateral and back part of the cavernous sinus just below the fourth nerve, it crosses the fifth nerve, and, after grooving the petrous bone, ends in the transverse sinus as the latter turns downward on the mastoid portion of the temporal bone. It receives veins from the temporal lobe of the cerebrum, veins from the cerebellum, veins from the tympanum through the squamo-petrosal fissure, and sometimes the anterior temporal veins of the diploë.

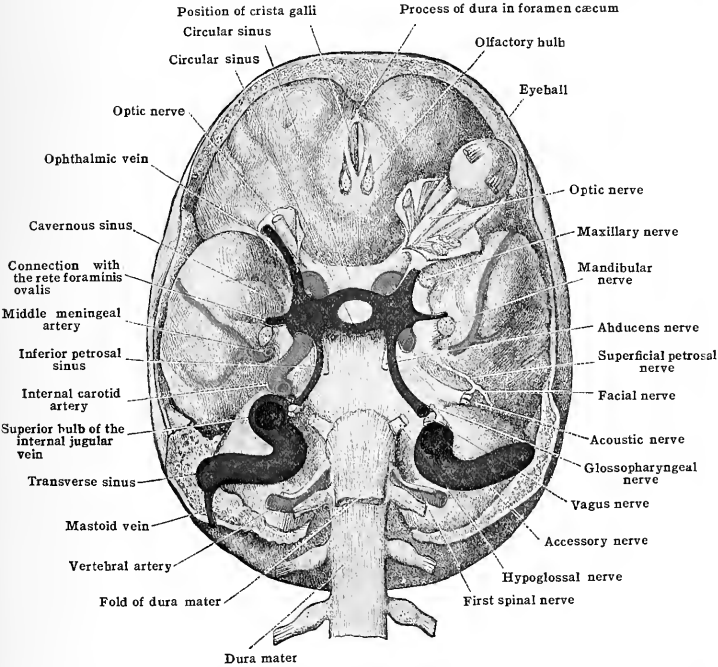
(9) The **inferior petrosal sinus** [sinus petrosus inferior] (figs. 514, 516) runs along the line of the petro-occipital suture, and connects the cavernous sinus with the commencement of the internal jugular vein. It is shorter than the superior petrosal, but considerably wider. As it crosses the anterior compartment of the jugular foramen, it separates the glosso-pharyngeal from the vagus and accessory nerves. It receives veins from the inferior surface of the cerebellum, from the medulla and pons, and from the internal ear. The last, the **vein of the cochlear canaliculus** [v. canaliculi cochleæ], issues through the canaliculus cochleæ.

(10) The **cavernous sinus** [sinus cavernosus] (fig. 516) is an irregularly shaped venous space situated between the meningeal and periosteal layers of the dura mater on the side of the body of the sphenoid bone. It extends from the medial end of the superior orbital (sphenoidal) fissure in front to the apex of the petrous bone behind. Its lateral wall is the more distinct, and contains the third and fourth nerves, and the ophthalmic division of the fifth nerve. The nerves take the above-mentioned order from above downward, and in the medio-lateral direction. The internal carotid artery and the sixth nerve also pass through the sinus, being separated from the blood by the endothelial lining. The right and left cavernous sinuses communicate across the middle line with the opposite sinus in front and behind the hypophysis cerebri as before mentioned.

The cavernous sinus is traversed by numerous trabeculæ or fibrous bands, so that there is no central space, but rather a number of endothelial-lined irregular lacunar cavities communicating one another. Hence its name cavernous, from its resemblance to cavernous tissue. **In front** it receives the ophthalmic vein, with which it is practically continuous, and just above the third nerve the spheno-parietal sinus. **Medially** it communicates with the opposite sinus, and **posteriorly** it ends in the superior and inferior petrosal sinuses. It also receives veins from the inferior surface of the frontal lobe of the brain, and some of the middle cerebral veins. Through the Vesalian vein, which runs in a minute foramen in the spinous process of the sphenoid bone, the sinus communicates with the pterygoid plexus of veins; through the **venous plexus around the petrosal portion of the internal carotid** [plexus venosus caroticus internus], with the internal jugular vein; and through a venous rete which leaves the cranium by the foramen ovale [rete foraminis ovalis] and by small veins passing through the foramen lacerum medium, with the pterygoid and pharyngeal plexuses.

(11) The **spheno-parietal sinus** [sinus sphenoparietalis] runs in a slight groove on the under surface of the lesser wing of the sphenoid bone. It originates in one of the meningeal veins near the apex of the lesser wing, and, running medially, passes through the sphenoidal fold of dura mater above the third nerve into the front part of the cavernous sinus. It generally receives the anterior temporal veins from the diploë.

FIG. 516.—THE VENOUS SINUSES AT THE BASE OF THE BRAIN. The dura mater has not been removed. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



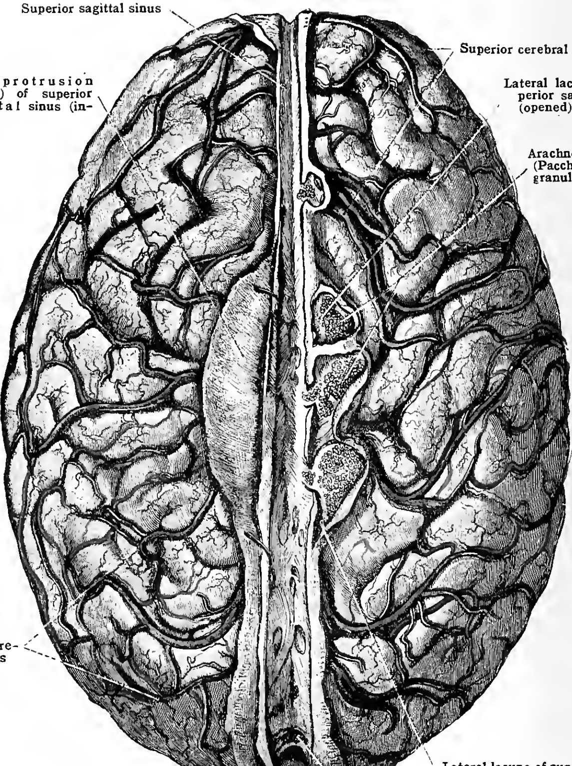
The **petro-squamous sinus** is occasionally present. It lies in a groove along the junction of the petrous and squamous portions of the temporal bone. It opens posteriorly into the transverse sinus at the spot where the latter enters on its sigmoid course. In front it sometimes, though very rarely, passes through a foramen in the squamous portion of the temporal bone between the mandibular fossa and the external auditory meatus into the temporal vein.

3. THE VEINS OF THE BRAIN

The **veins of the brain** present the following peculiarities:—(*a*) They do not accompany the cerebral arteries. (*b*) Ascending veins do not, as in other situations, run with descending arteries, but with ascending arteries, and *vice versa*. (*c*) The deep veins do not freely communicate. (*d*) The veins have very thin walls, no muscular coat, and no valves. (*e*) The veins opening into the sagittal, and some of those opening into the transverse (lateral) sinus pour in their blood in a direction opposite to the current in the sinuses, so impeding the flow in both vein and sinus. (*f*) The flow of blood in the sinuses is further retarded by the trabeculæ stretching across their lumen, and in the sagittal sinus by the blood having to ascend, when the body is erect, through the anterior half of its course.

The veins of the brain may be divided into the **cerebral** and the **cerebellar.**

FIG. 517.—THE VEINS OF THE BRAIN, SUPERIOR SURFACE. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



THE CEREBRAL VEINS

The **cerebral** veins, like the cerebral arteries, may be divided into the **cortical** and the **central.**

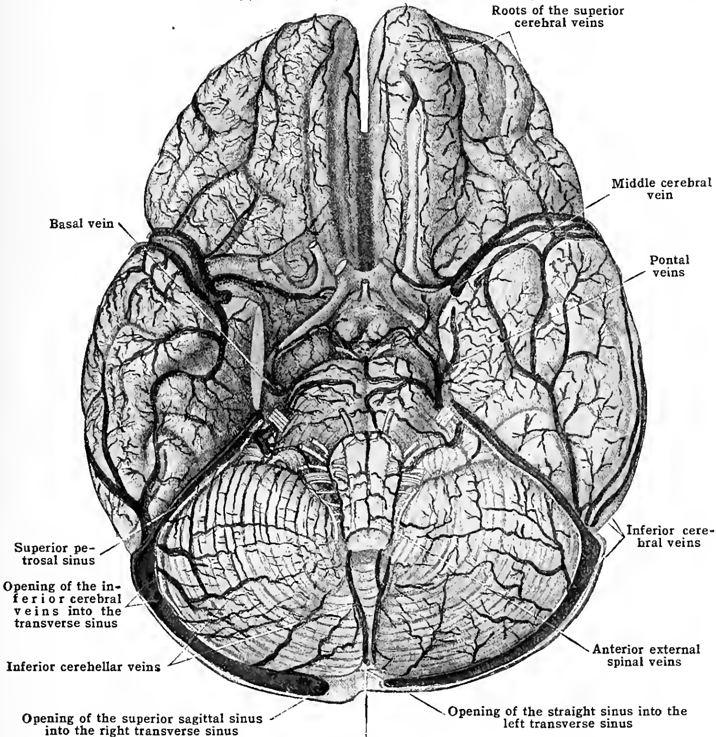
The **cortical** or **superficial** veins ramify on the surface of the brain and return the blood from the cortical substance into the venous sinuses. They lie for the most part in the sulci between the gyri, but some pass over the gyri from one sulcus to another. They consist of two sets: a superior and an inferior.

(1) The **superior cerebral veins** [venæ cerebri superiores] (fig. 517), some eight to twelve in number on each side, are formed by the union of branches from the convex and medial surfaces of the cerebrum. Those from the convex surface pass medially and forward toward the longitudinal fissure, where they are joined by the branches coming from the medial surface. After receiving a sheath from the arachnoid, they enter obliquely into the superior sagittal

sinus, running for some distance in its walls. These veins freely communicate with each other, thus differing from the cortical arteries. They also communicate with the inferior cortical veins. They may be roughly divided into (*a*) frontal; (*b*) paracentral; (*c*) central; (*d*) occipital.

(2) The **inferior cerebral** veins [venæ cerebri inferiores] (fig. 518), ramify on the base of the hemisphere and the lower part of its lateral surface. Those on the inferior surface of the frontal lobe pass, in part into the inferior sagittal sinus, and in part into the cavernous sinus. Those on the temporal lobe enter in part into the superior petrosal sinus, and in part into the transverse sinus, passing into the latter from before backward. A large vein from the occipital lobe winds over the cerebral peduncle and joins the great cerebral vein (of Galen) just before the latter enters the straight sinus. One of the inferior cortical veins is called the **middle cerebral** vein [v. cerebri media]; it runs in the lateral fissure (of Sylvius) and ends in the cavernous sinus. This vein is sometimes called the superficial Sylvian vein. Another, the great anasto-

FIG. 518.—THE VEINS OF THE BRAIN, INFERIOR SURFACE. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



mosing vein of Trolard, a branch of the middle cerebral, establishes a communication between the superior sagittal and cavernous sinuses by anastomosing with one of the superior cortical veins. A second anastomotic vein, that of Labbé, is also a tributary of the middle cerebral, and connects the veins over the temporal lobe with the transverse sinus.

A small inferior cerebral vein, the **ophthalmomeningeal vein,** establishes a communication between the cerebral veins and those of the orbit. It communicates with the veins of the base and is usually drained by the superior ophthalmic vein. It occasionally opens into the superior petrosal sinus.

The **central** or **deep** (ganglionic) veins return blood from the internal parts of the cerebrum, and converge to the great cerebral vein.

Fig. 519.—The Veins of the Brain, Lateral Surface. (After Toldt, "Atlas of Human Anatomy," London and New York.)

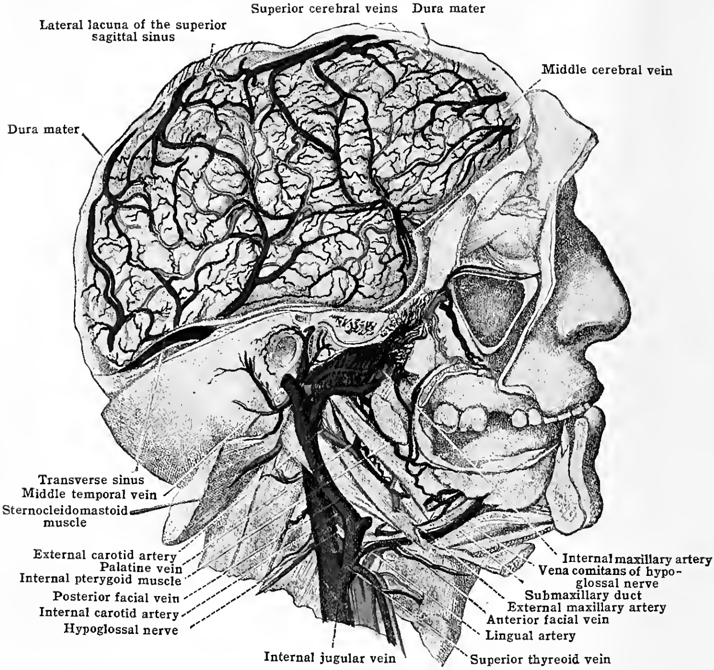


Fig. 520.—The Ophthalmic Veins. (After Quain.)

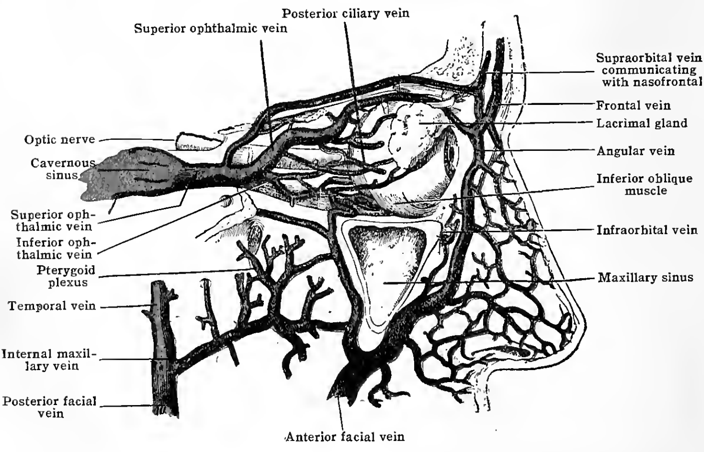


(3) The **internal cerebral** veins [vv. cerebri internæ] are two large venous trunks (the venæ Galeni) which leave the brain at the transverse fissure, that is, between the splenium of the corpus callosum and the corpora quadrigemina. In this region they unite to form the **great cerebral vein** [v. cerebri magna, Galeni], which opens into the anterior end of the straight sinus. The internal cerebral veins are formed by the union of the chorioid vein with the vena terminalis near the interventricular foramen. From this spot they run backward parallel to each other, between the layers of the tela chorioidea, and terminate in the way above mentioned.

Tributaries of the internal cerebral veins.—In addition to the vena terminalis and the chorioidal, the internal cerebral veins also receive the basal vein, the veins of the thalmus, the vein of the chorioid plexus of the third ventricle, and veins from the corpus callosum, the pineal body, the corpora quadrigemina, and posterior horn of the lateral ventricle. The united trunk, or great cerebral vein, receives veins from the upper surface of the cerebellum, and one of the posterior inferior cerebral veins.

The **chorioid** vein [v. chorioidea] runs with the chorioid plexus. It begins in the inferior cornu of the lateral ventricle, and ascends on the lateral side of the chorioid plexus along the margin of the tela chorioidea to the interventricular foramen, where it unites with the vena terminalis to form the internal cerebral vein. It receives tributaries from the hippocampus, corpus callosum, and fornix.

The **terminal** vein (or vein of the corpus striatum) [v. terminalis], formed by veins from the corpus striatum and thalamus, runs forward in the groove between those structures, passing in its course beneath the stria terminalis, and joins the chorioid (choroid) vein at the interventricular foramen. **Tributaries.**—It receives, in addition to the veins from the corpus striatum, thalamus and fornix, the **vena septi pellucidi** which receives blood from the septum pellucidum, and anterior cornu of the lateral ventricle.

The **basal** vein [v. basalis], runs backward over the cerebral peduncle, and enters the internal cerebral vein near the union of that vessel with the vein of the opposite side.

Tributaries.—A vein, the deep Sylvian, from the insula and surrounding convlutions; the inferior striate veins from the corpus striatum, which they leave through the anterior perforated substance; and the anterior cerebral veins from the front of the corpus callosum. It is also joined by interpenduncular veins from the structures in the interpeduncular space; ventricular veins from the inferior cornu of the lateral ventricle; and by mesencephalic veins from the mid-brain.

The Cerebellar Veins

The **cerebellar** veins are divided into the **superior** and **inferior.**

The **superior** [vv. cerebelli superiores] ramify on the upper surface of the cerebellum; some of them run medially over the superior vermis to join the straight sinus and great cerebral vein; others run laterally to the transverse and superior petrosal sinuses.

The **inferior** [vv. cerebelli inferiores], larger than the superior, run, some forward and laterally to the inferior petrosal and transverse sinuses, and others directly backward to the occipital sinus.

The Veins of the Medulla and Pons

The veins from the **medulla oblongata** and the **pons** terminate in the inferior petrosal and transverse sinuses.

4. THE VEINS OF THE NASAL CAVITIES

The venous plexuses on the inferior nasal concha (turbinate bone) and back of the septum are described with the Nose. The veins leaving the nasal cavities follow roughly the course of their corresponding arteries. Thus the spheno-palatine veins pass through the spheno-palatine foramen into the pterygoid plexus; the anterior and posterior ethmoidal veins join the ophthalmic. Small veins accompany branches of the external maxillary artery through the nasal bones and frontal processes of the maxillary bones, and end in the angular and anterior facial veins; and other small veins pass from the nose anteriorly into the superior labial, and thence to the anterior facial.

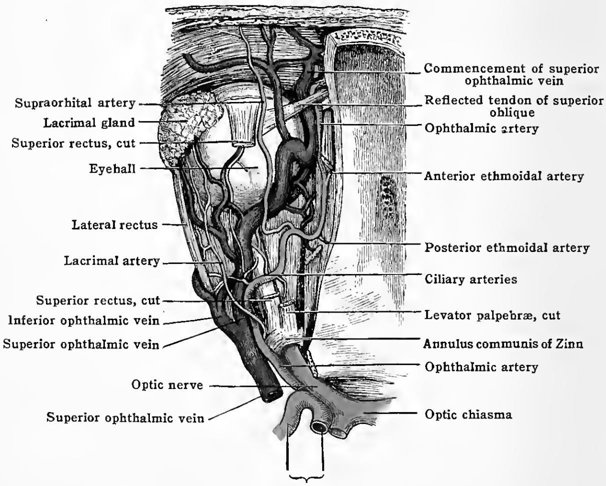
5. THE VEINS OF THE EAR

The veins from the external ear and external auditory meatus join the posterior facial and posterior auricular veins. The veins from the tympanum open into the superior petrosal sinus and posterior facial vein. The blood from the labyrinth flows chiefly through the **internal auditory** veins [vv. auditivæ internæ], which lie with the internal auditory artery in the internal auditory meatus, and enters the transverse or inferior petrosal sinus. Some of the blood from the labyrinth, however, passes through the vestibular vein which lies in the aquæductus vestibuli, into the inferior petrosal sinus. Some also passes through the **vena canaliculi cochleæ** which traverses the canal of the same name and empties into the commencement of the internal jugular vein.

6. THE VEINS OF THE ORBIT

The blood from the eyeball and orbit is returned by the superior ophthalmic vein into the cavernous sinus. This vein and its tributaries have no valves, and communicate with the frontal, supraorbital, inferior cerebral, and other veins. Hence under certain conditions, as from pressure on the cavernous sinus, the blood

FIG. 521.—THE VEINS OF THE ORBIT.



may flow in the contrary direction to the normal—i. e., from behind forward into the frontal and supraorbital, and thence through the angular vein into the anterior facial; or upward into the cerebral venous system. In this way pressure on the retinal veins is quickly relieved, and little or no distension occurs in cases of obstruction in the cavernous sinus.

The **superior ophthalmic** vein [v. ophthalmica superior] begins at the medial angle of the eyelid by a free communication with the frontal, supraorbital, and angular veins, and thence runs backward and laterally with the ophthalmic artery across the optic nerve to the medial end of the superior orbital (sphenoidal) fissure, where it is usually joined by the inferior ophthalmic vein. It then passes backward between the two heads of the lateral rectus muscle below the sixth nerve, leaves the orbit through the medial end of the superior orbital (sphenoidal) fissure and enters the front part of the cavernous sinus. In this course it lies anterior and superficial to the ophthalmic artery.

Tributaries.—(1) The naso-frontal vein; (2) the superior muscular veins; (3) the veins of the lids and conjunctiva; (4) the ciliary veins; (5) the anterior and posterior ethmoidal veins; (6) the lacrimal vein; (7) the central vein of the retina; and (8) the inferior ophthalmic vein.

(1) The **naso-frontal** vein [v. naso-frontalis] begins by a free communication with the supraorbital vein and enters the orbit through the frontal notch or foramen. It frequently joins the superior ophthalmic vein quite far back in the orbit (see fig. 520).

(2) The **muscular** veins [vv. musculares] are derived from the levator palpebræ, superior rectus, superior oblique, and medial rectus.

(3) The **palpebral** and **conjunctival** veins [vv. palpebrales; vv. conjunctivales ant. et post.], both anterior and posterior, open into the superior ophthalmic.

(4) The **ciliary** veins, the veins of the eyeball, are divided into two sets. An **anterior** [vv. ciliares ant.] emerge from the eyeball with the anterior ciliary arteries, and open

into the muscular veins returning the blood from the four recti. They form a circumcorneal ring of **episcleral** veins [vv. episclerales]. The **posterior set**, which drain the **venæ vorticosæ**, leave the globe midway between the cornea and the entrance of the optic nerve. The latter veins are four or five in number, the upper ending in the superior, the lower in the inferior ophthalmic vein (fig. 520).

(5) The **anterior and posterior ethmoidal** veins [vv. ethmoidales ant. et post.), correspond in their course with the arteries of the same name. They enter the orbit through the anterior and posterior ethmoidal foramina, and join either the ophthalmic direct, or one or other of the superior muscular branches.

(6) The **lacrimal** vein [v. lacrimalis] returns the blood from the lacrimal gland, and corresponds in its course to the lacrimal artery.

(7) The **central vein of the retina** [v. centralis retinæ] runs with the central artery in the optic nerve. It joins the superior ophthalmic at the back of the orbit.

(8) The **inferior ophthalmic** vein [v. ophthalmica inferior], smaller than the superior, is formed near the front of the orbit by the confluence of the inferior muscular with the lower posterior ciliary veins. It runs backward below the optic nerve, along the floor of the orbit, and either joins the superior ophthalmic vein, or opens separately into the cavernous sinus. A large communicating branch passes downward through the inferior orbital (spheno-maxillary) fissure to join the pterygoid plexus of veins. It receives muscular twigs from the inferior and lateral rectus and from the inferior oblique, and some posteior ciliary veins.

7. THE VEINS OF THE PHARYNX AND LARYNX

The **pharyngeal** veins [vv. pharyngeæ] are arranged in the form of a plexus, between the constrictor muscles and the pharyngeal or prevertebral fascia. The **pharyngeal plexus** receives branches from the mucous membrane, the pterygoid canal [vv. canalis pterygoidei] from the soft palate, the Eustachian tube and the anterior recti and longus colli muscles. Above, it communicates with the pterygoid plexus of veins; below it drains into the internal jugular vein.

The **veins of the larynx** end partly in the **superior laryngeal** vein [v. laryngea superior], which opens into the internal jugular vein, and partly in the **inferior laryngeal** vein [v. laryngea inferior], which terminates in the plexus thyroideus impar. The laryngeal plexus of veins communicates with the pharyngeal plexus.

8. THE DEEP VEINS OF THE NECK

The **deep veins of the neck** include the internal jugular, vertebral, deep cervical, erior thyreoid, thyreoidea ima, thymic, tracheal, and œsophageal veins.

The Internal Jugular Vein

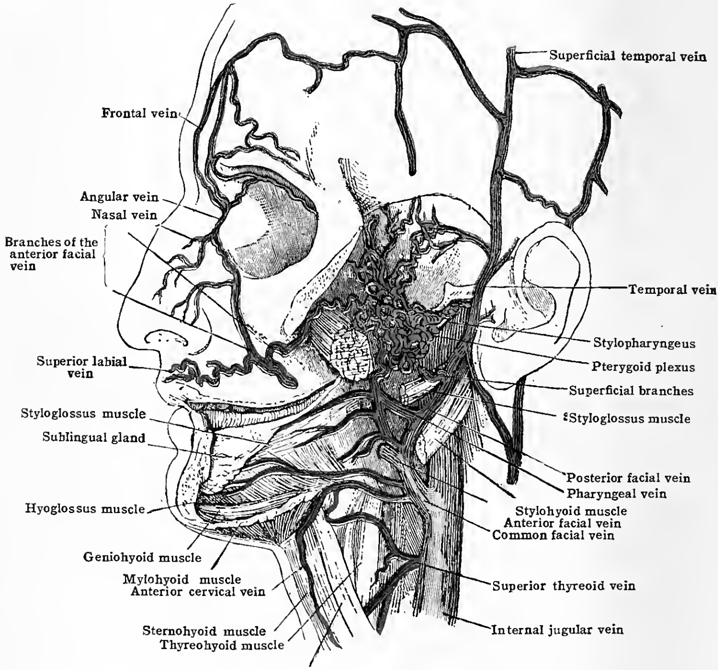
The **internal jugular** vein [v. jugularis interna] begins at the jugular fossa, and is the continuation of the transverse sinus. It passes down the neck, in company first with the internal carotid artery and then with the common carotid artery, to a point a little lateral to the sterno-clavicular articulation, where it joins the subclavian to form the innominate vein. At its commencement in the larger, posterior and lateral part of the jugular foramen, it is somewhat dilated, forming the **superior bulb** of the jugular vein [bulbus v. jugularis superior] (fig. 522). This dilated part of the internal jugular vein lies in the jugular fossa of the temporal bone and is therefore in immediate relation to the floor of the tympanum. At first the internal jugular lies in front of the rectus capitis lateralis, and behind the internal carotid artery, from which it is separated by the hypoglossal, glossopharyngeal, and vagus nerves, and by the carotid plexus of the sympathetic. As it descends it passes gradually to the lateral side of the internal carotid, and retains this relation as far as the upper border of the thyreoid cartilage. Thence it runs to its termination along the lateral side of the common carotid artery, being contained in the same sheath with it and the vagus nerve, but separated from these structures by a distinct septum. The vein generally overlaps the artery in front. About 2.5 cm. (1 in.) above its termination it contains a pair of imperfect valves below which a second dilation usually occurs in the vein. This, **the inferior bulb** [bulbus v. jugularis inferior], extends as low as the junction of the internal jugular with the subclavian. It not infrequently receives the termination of the external jugular vein.

Tributaries.—At the superior bulb the internal jugular vein receives the inferior petrosal sinus; the vein of the cochlear canaliculus, and a meningeal vein; opposite the angle of the jaw, veins from the pharyngeal plexus, and often a communicating branch from the external jugular vein; opposite the bifurcation of the carotid it is joined by the common facial, and a little lower down by the lingual, sternomastoid, and the superior thyreoid veins. At the level of the cricoid cartilage by the middle thyreoid when this vein is present.

The inferior petrosal sinus is described with the other sinuses of the brain (p. 652); the pharyngeal plexus with the veins of the pharynx (see p. 659); and the common facial vein with the superficial veins of the scalp and face (p. 646).

The **lingual vein** [v. lingualis], begins near the tip of the tongue, where it accompanies the arteria profunda linguæ. It lies at first beneath the mucous membrane covering the under surface of the tongue. It then passes backward medial to the hyo-glossus, and in company with the lingual artery. After receiving the **sublingual vein** [v. sublingualis] and the **dorsal**

Fig. 522.—The Internal Jugular Vein. (After Henle).



lingual veins [vv. dorsales linguæ], which roughly correspond to their respective arteries, it is joined by the small **v. comitans nervi hypoglossi** which follows the upper border of the hypoglossal nerve. The trunk finally crosses the common carotid artery and opens into the internal jugular vein. The lingual vein communicates with the pharyngeal veins and with tributaries of the anterior facial. It occasionally terminates in the posterior or in the common facial vein. The sternomastoid vein [v. sternocleidomastoidea] accompanies the artery of the same name and empties into the internal jugular.

The **superior thyreoid** vein [v. thyreoidea superior] emerges from the upper part of the thyreoid gland, in which it freely anastomoses with the other thyreoid veins. This anastomosis, the **plexus thyreoideus impar**, occurs both in the substance of the organ and on its surface beneath the capsule. The vein then passes upward and laterally into the internal jugular vein, crossing the common carotid artery in its course. At times it forms a common trunk with the common facial vein. Its **tributaries** are the sterno-hyoid, sterno-thyreoid, and thyreo-hyoid veins from the muscles bearing those names; and the crico-thyreoid and superior laryngeal veins which correspond with the crico-thyreoid and superior laryngeal arteries respectively. These require no special description.

A separate vein frequently passes out from the capsule of the thyreoid gland near the lower part of the lateral lobe, crosses the common carotid, and opens into the main superior thyreoid vein or into the internal jugular vein a little below the cricoid cartilage. In the former case it is regarded as part of the superior thyreoid vein system; in the latter it is generally known as the **middle thyreoid** vein.

The Vertebral Vein

The **vertebral** vein [v. vertebralis] does not accompany the vertebral artery in its fourth stage, that is, within the skull, but begins in the posterior vertebral venous plexus of the suboccipital triangle. It then enters the foramen in the transverse process of the altas, and passes with the vertebral artery through the foramina in the transverse processes of the cervical vertebræ, forming a plexus around the artery. On leaving the transverse process of the sixth cervical vertebra it crosses in front of the subclavian artery and opens into the innominate vein. It has one or two semilunar valves at its entrance into the innominate vein. In the suboccipital triangle it communicates with the internal vertebral venous plexuses, with the deep cervical, and occipital veins, and is joined by veins from the recti and oblique muscles and the pericranium.

Tributaries.—As it passes down the neck it receives (1) intervertebral veins, which issue along with the cervical nerves, from the spinal canal; (2) tributaries from the anterior and posterior vertebral venous plexus from the bodies of the cervical vertebræ and their transverse processes; and (3) tributaries from the deep cervical muscles. Just before it terminates in the innominate it is joined by (4) the anterior vertebral vein, a small vein which accompanies the ascending cervical artery, and, sometimes, by the deep cervical vein.

The Deep Cervical Vein

The **deep cervical** vein [v. cervicalis profunda], larger than the vertebral, passes down the neck posterior to the cervical transverse processes. It corresponds to the deep cervical artery from which it is separated by the semispinalis cervicis muscle.

It begins in the posterior vertebral venous plexus and receives tributaries from the deep muscles of the neck. It communicates with, or entirely drains, the occipital vein by a branch which perforates the trapezius muscle. The deep cervical vein then passes forward beneath the transverse process of the seventh cervical vertebra to open into the innominate vein near the vertebral, or into the latter near its termination. Its orifice is guarded by a pair of valves.

The Inferior Thyreoid and Thyreoidea Ima Veins

The **inferior thyreoid** veins [vv. thyreoidea inferiores] descend from the lower part of the thyreoid gland obliquely lateralward to the innominate veins. The **right vein** crosses the innominate artery just before its bifurcation, and ends in the right innominate vein a little above the superior vena cava. It receives inferior laryngeal veins and veins from the trachea, and has valves at its termination in the innominate. The **left vein** passes obliquely over the trachea behind the sterno-thyreoid muscle, and opens into the left innominate vein. It also receives laryngeal and tracheal veins, and sometimes the thyreoidea ima; it is guarded by valves where it opens into the innominate trunk.

The **thyreoidea ima** vein [v. thyreoidea ima] is single and placed approximately in the median line. It begins in the thyreoid isthmus from the plexus thyreoideus impar, runs downward upon the anterior surface of the trachea, and opens into the left innominate vein or into the left inferior thyreoid.

The Thymic, Tracheal and Œsophageal Veins

These small veins usually open into the left innominate vein. The **thymic** veins [vv. thymicæ], small in the adult, open into the left innominate or into the inferior thyreoid or thyreoidea ima vein. The **tracheal** veins [vv. tracheales] anastomose with the laryngeal and bronchial veins. The **œsophageal** veins [vv. œsophageæ] from the upper part of the œsophagus, anastomose with the lower œsophageal veins and with the pharyngeal plexus.

THE VEINS OF THE THORAX

THE SUPERFICIAL VEINS OF THE THORAX

The **superficial veins** of the front of the thorax can be seen in fig. 537. They form a plexus over the entire chest which the portion over the mammary gland is called the mammary plexus. The laterally placed lateral thoracic and costo-axillary veins drain the mammary plexus and communicate with the thoraco-epigastric vein. These three veins terminate in the axillary vein (p. 671). The veins nearer the median line are drained by the internal mammary vein and its anterior intercostal and superior epigastric tributaries. The veins over the entire thorax are in free communication with the superficial veins of the abdominal wall (p. 683).

THE DEEP VEINS OF THE THORAX

The **deep veins of the thorax** are:—the pulmonary veins, and the vena cava superior and its innominate and other tributaries. Of these veins, the pulmonary, the vena cava superior, and the innominate veins have already been described, as have the tributaries of the latter arising in the neck.

The following veins are described below:—(1) The azygos and ascending lumbar veins, which discharge their blood into the vena cava superior; (2) the veins of the vertebral column, which are tributary to the azygos veins through the intercostals; (3) the internal mammary veins, and (4) the superior phrenic, anterior mediastinal and pericardiac veins, all of which open into the innominate veins.

I. THE AZYGOS AND ASCENDING LUMBAR VEINS

The azygos veins are longitudinal veins, the remnants of the posterior cardinals, which are the main collecting trunks for the posterior part of the body in the embryo. They lie along the sides of the thoracic vertebræ, and collect the blood from the intercostal veins; they are the upward continuation of longitudinal anastomotic trunks, the **ascending lumbar veins** which take origin in the abdomen. The azygos veins are three in number, the **azygos** (azygos major) on the right side, and the hemiazygos (azygos minor) and accessory hemiazygos (azygos tertia) on the left.

The **azygos** vein [v. azygos] begins in the abdomen as a continuation upward of the ascending lumbar vein. Through this means it connects with the iliac veins and it has also an anastomosis with the vena cava inferior which may become very important in cases of obstruction of the vena cava. It runs up through the posterior mediastinum on the right side of the front of the bodies of the thoracic vertebræ as high as the fourth thoracic vertebra, in this part of its course lying to the right of the aorta and thoracic duct; it then curves forward over the root of the right lung, and opens into the vena cava superior immediately before the latter pierces the pericardium.

It usually contains an imperfect pair of valves at the point where it turns forward from the fourth thoracic vertebra to arch over the root of the lung; and still more imperfect valves are found at varying intervals lower down the vein.

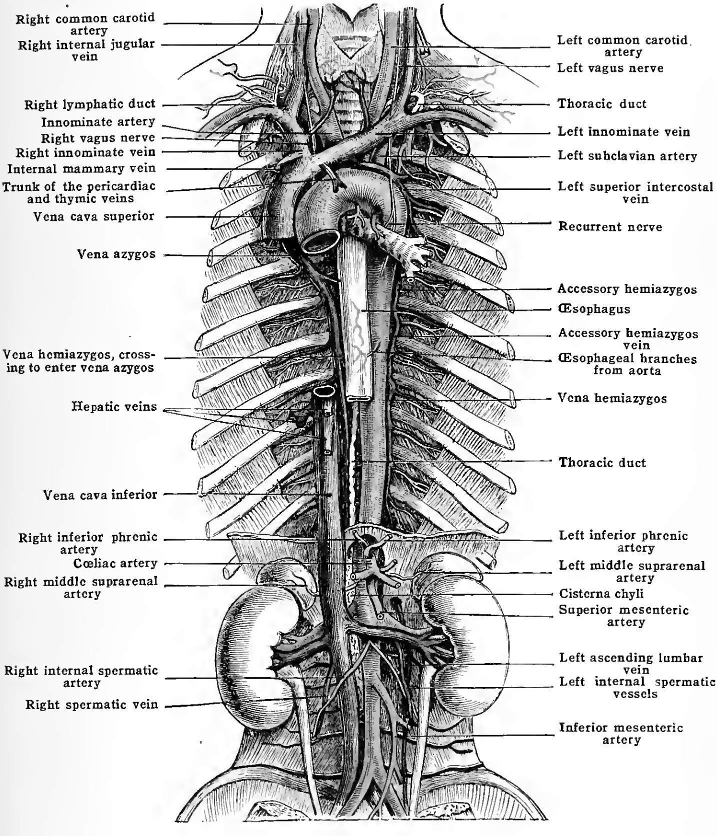
It receives the intercostal veins of the right side, except the first two or three. These veins (usually excepting the first) are collected into a common trunk before joining the azygos vein. It also receives the hemiazygos and accessory hemiazygos, the right posterior bronchial vein, and small œsophageal and posterior mediastinal veins.

The **hemiazygos** vein [v. hemiazygos] begins in the abdomen by communicating, like the azygos vein, with the ascending lumbar vein of its own side. It courses up the posterior mediastinum to the left of the bodies of the lower thoracic vertebræ as high as the eighth or ninth, where it turns obliquely to the right, and, crossing in front of the vertebral column behind the aorta and the œsophagus, opens into the vena azygos. In its course it crosses over three or four of the lower left intercostal arteries, and is covered by the pleura.

Tributaries.—(1) The lower four or five left intercostal veins; (2) the lower end of the accessory hemiazygos vein (sometimes); (3) small left mediastinal veins; and (4) the lower left œsophageal veins.

The **accessory hemiazygos** [v. azygos accessoria] varies considerably in size, position, and arrangement, and is often continuous with, or drained by, the left superior intercostal vein. It lies in the posterior mediastinum by the left side of the bodies of the fifth, sixth, and seventh or eighth thoracic vertebræ, and is more

Fig. 523.—The Superior and Inferior Venæ Cavæ, the Innominate Veins, and the Azygos Veins.



or less vertical in direction. It communicates above with the left superior intercostal vein, and below either joins the hemiazygos or passes obliquely across the seventh or eighth thoracic vertebra to join the azygos vein. It crosses the corresponding left intercostal arteries, and is covered by the pleura.

Tributaries.—(1) The fourth, fifth, sixth, seventh, and sometimes the eighth intercostal veins; and (2) the left posterior bronchial vein.

The **ascending lumbar** vein [v. lumbalis ascendens] begins, on either side, in the neighbourhood of the sacral promontory. It is here in free communication, by means of the anterior sacral plexus, with the middle and lateral sacral veins, and with the common iliac, hypogastric and ilio-lumbar veins. It ascends in front of the lumbar transverse processes communicating with the lumbar veins, the vena cava inferior and, usually, with the renal vein. The right vein enters the thorax between the aorta and the right medial crus of the diaphragm, and is continued upward as the vena azygos. The left vein pierces the left medial crus and becomes the hemiazygos.

The intercostal veins [vv. intercostales].—The intercostal veins are twelve in number on each side, the last one being subcostal. They correspond to the intercostal arteries. There is one vein to each artery, the vein lying above the artery whilst in the intercostal space. Each vein receives a dorsal tributary which accompanies the posterior ramus of an intercostal artery between the transverse process of the vertebræ and the neck of the rib. These dorsal branches not only return the blood from the muscles of the back, but receive a spinal branch from the vertebral venous plexuses. The intercostal veins also receive small tributaries from the bodies of the vertebræ. The termination of the intercostal veins is different on the two sides and also varies greatly in different individuals. The intercostal vein from the first space on either side may join the superior intercostal vein, but commonly opens directly into the innominate or one of its tributaries, most frequently the vertebral.

On the right side.—The second intercostal vein joins with the third or with the third and fourth to form the **right superior intercostal** vein [v. intercostalis suprema dextra]. This vein opens into the azygos vein as the latter is arching over the root of the right lung. The rest join the azygos directly. The upper of these have well-marked valves where they join the azygos vein; in the lower veins these valves are imperfect. All the intercostal veins are provided with valves in their course between the muscles.

On the **left side** the second intercostal vein joins the third and fourth to form a single trunk, the **left superior intercostal** vein [v. intercostalis suprema sinistra]. This vein passes upward across the arch of the aorta and opens into the left innominate vein. The left superior intercostal frequently communicates at its lower end with the accessory hemiazygos vein, which is occasionally tributary to it. In most cases a small tributary runs up over the front of the aortic arch to join the superior intercostal vein; it is a vestige of the left common cardinal and from it a small fibrous cord can often be traced through the vestigial fold of the pericardium to the oblique vein of the left atrium (p. 523).

The left fifth, sixth and seventh intercostal veins commonly open into the accessory hemiazygos, and the eighth or ninth and succeeding veins into the hemiazygos. The method of termination of the intercostal veins of the left side is subject to such variation that a normal arrangement can scarcely be said to exist at all. The eighth may open directly into the azygos, as may the seventh and ninth or even more of the veins; the hemiazygos and accessory hemiazygos being correspondingly reduced in size.

The **posterior bronchial** veins [vv. bronchiales posteriores] correspond to the bronchial arteries, but do not return the whole of the blood carried to the lungs by those vessels—that part which is distributed to the smaller bronchial tubes and the alveolæ being brought back by the pulmonary veins. The posterior bronchial veins issue from the lung substance behind the structures forming the root of the lung. The right vein generally joins the vena azygos just before the latter vein enters the superior vena cava. The left vein opens into accessory hemiazygos vein. The bronchial veins at the root of the lung receive small tributaries from the bronchial glands, from the trachea, and from the posterior mediastinum.

The **œsophageal** veins [vv. œsophageæ] from the thoracic portion of the œsophagus end in part in the vena azygos, and in part in the vena hemiazygos. They anastomose with the upper œsophageal veins, and with the coronary vein.

The **posterior mediastinal** veins, small and numerous, open into the azygos and hemiazygos veins.

2. THE VEINS OF THE VERTEBRAL COLUMN

The venous plexuses around and within the vertebral column extending from the cranium to the coccyx may be divided into two categories:—(1) the **external** and (2) the **internal vertebral venous plexuses.** The external plexuses consist of two parts, the *anterior vertebral venous plexuses* situated on the anterior aspect of the vertebral bodies and the *posterior vertebral venous plexuses* ramifying over the posterior aspect of the vertebral arches, spines, and transverse processes. The internal plexuses consist of *two longitudinal venous sinuses* situated between the vertebræ and the posterior longitudinal ligament, and of two *vertebral venous retia* placed immediately external to the dura mater. The sinuses of the internal plexuses communicate freely with one another and with the internal retia and external plexuses. They receive the external spinal veins and the *basivertebral veins* from the bodies of the vertebræ. The venous circulation of the vertebral column is drained by the vertebral, intercostal, lumbar and sacral veins either directly or by means of (3) the **intervertebral** veins.

1. The **external vertebral venous plexuses** [plexus venosi vertebrales externi] include the following:

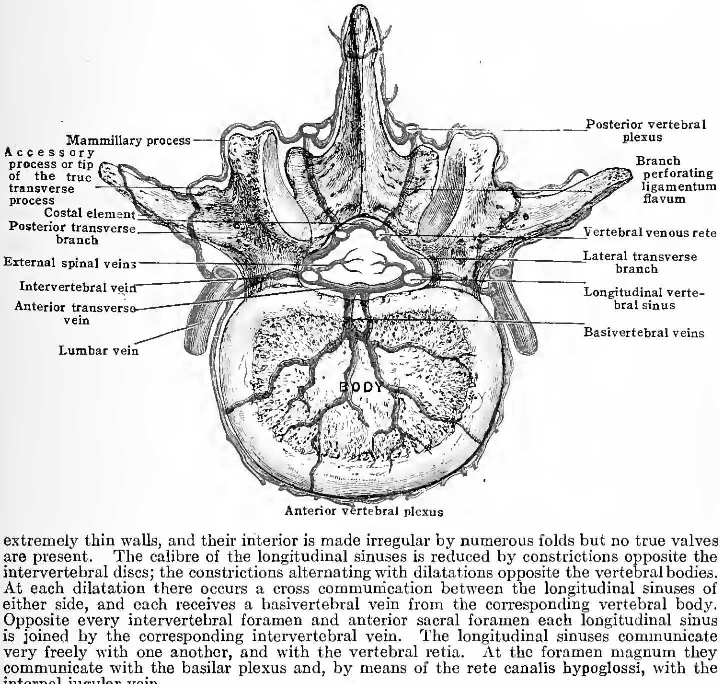
(*a*) The **anterior vertebral venous plexuses** [plexus venosi vertebrales anteriores] (fig. 524) consist of small veins ramifying in front of the bodies of the vertebræ. These veins communicate with the basivertebral veins and are larger in the cervical region than elsewhere.

(*b*) The **posterior vertebral venous plexuses** [plexus venosi vertebrales posteriores] (fig. 524) are situated around the transverse, articular, spinous processes and laminæ of the vertebræ. Communications take place between the plexuses of each segment and with the veins of the neighbouring muscles and integuments. Branches are also sent, through the ligamenta flava, to the internal vertebral venous plexuses, and, between the transverse processes, to the intervertebral veins.

2. The **internal vertebral venous plexuses** [plexus venosi vertebrales interni] (fig. 524):—

(*a*) The two **longitudinal vertebral sinuses** [sinus vertebrales longitudinales] run throughout the entire length of the vertebral canal. They are situated behind the bodies of the vertebræ on either side, between the bone and the posterior longitudinal ligament. The sinuses have

Fig. 524.—The Veins of the Vertebral Column.



extremely thin walls, and their interior is made irregular by numerous folds but no true valves are present. The calibre of the longitudinal sinuses is reduced by constrictions opposite the intervertebral discs; the constrictions alternating with dilatations opposite the vertebral bodies. At each dilatation there occurs a cross communication between the longitudinal sinuses of either side, and each receives a basivertebral vein from the corresponding vertebral body. Opposite every intervertebral foramen and anterior sacral foramen each longitudinal sinus is joined by the corresponding intervertebral vein. The longitudinal sinuses communicate very freely with one another, and with the vertebral retia. At the foramen magnum they communicate with the basilar plexus and, by means of the **rete canalis hypoglossi**, with the internal jugular vein.

(*b*) The **venous rete of the vertebræ** [retia venosa vertebrarum] (fig. 524) extend from the foramen magnum to the coccyx. They consist of two main retia situated posteriorly and laterally to the dura between the latter and the vertebral arch. They communicate very freely with one another across the median line; with the posterior external plexus by means of twigs perforating the ligamenta flava; and with the longitudinal vertebral sinuses by means of lateral branches. At the foramen magnum they communicate with the occipital sinus.

(*c*) The **external spinal** veins consist of two sets—anterior and posterior—which are drained by means of veins following the nerve roots, into the internal vertebral venous plexus.

The **anterior external spinal** veins [vv. spinales externæ anteriores] form a tortuous anastomosing vessel in the region of the anterior median fissure.

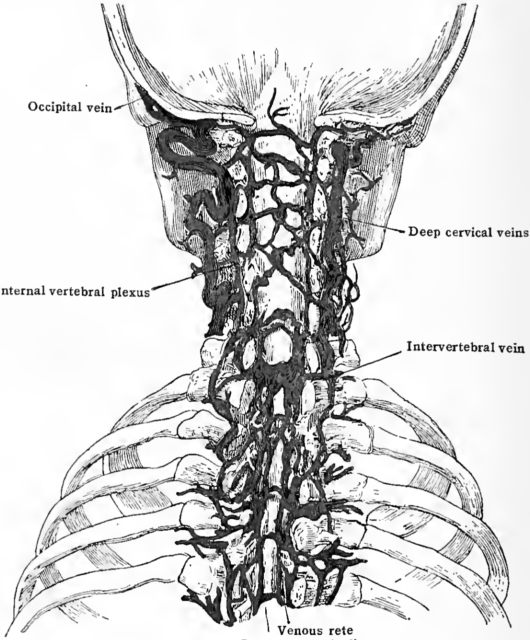
The **posterior external spinal** veins [vv. spinales externæ posteriores], smaller than the anterior run longitudinally on the posterior surface of the cord.

The external spinal veins form a wide-meshed plexus in the pia mater which drains the **internal spinal** veins [vv. spinales internæ] (see Spinal Cord).

(*d*) The **basivertebral** veins [vv. basivertebrales] (fig. 524) collect the blood from the cancellous tissue of the bodies of the vertebræ, and consist of a tunica intima only. They take a radial direction converging to the transverse vessels connecting the longitudinal vertebral sinuses. They communicate with the anterior external plexus and with the intercostal veins.

3 The **intevertebral** veins [vv. intervetebrales] (fig. 524), emerge from each longitudinal

Fig. 525.—The Vertebral Venous Plexuses. (After Henle.)



sinus and pass out through the intervertebral or anterior sacral foramina. They open into the vertebral, intercostal, lumbar or sacral veins according to region and receive numerous tributaries from the anterior and posterior external vertebral venous plexuses. They are instrumental in draining the venous system of the vertebral column and spinal cord.

3. THE INTERNAL MAMMARY VEIN

The internal mammary vein [v. mammaria interna] is formed by the union of the venæ comitantes corresponding to the superior epigastric and musculo-phrenic arteries. The right and left internal mammary veins pass upward, in company with the corresponding arteries, to open into the right and left innominate respectively.

Tributaries.—In addition to the superficial veins of the thorax, the internal mammary veins receive the anterior intercostal, anterior bronchial and pericardiac veins.

The **superior epigastric** vein [v. epigastrica superior] assists in the drainage of the subcutaneous abdominal veins [vv. subcutaneæ abdominis].

The **anterior bronchial** veins [vv. bronchiales anteriores] arise in the bronchial walls and communicate with the tracheal and posterior bronchial veins.

4. THE SUPERIOR PHRENIC, ANTERIOR MEDIASTINAL, AND PERICARDIAC VEINS

The **superior phrenic** [vv. phrenicæ superiores], the **anterior mediastinal** [vv mediastinales anteriores], and pericardiac [vv. pericardiacæ] veins are small vessels, corresponding to the arteries of those names. They pass over the arch of the aorta and open into the lower and anterior part of the left innominate.

THE VEINS OF THE UPPER EXTREMITY

The **veins of the upper limb** consist of two sets—a **superficial** and a **deep.** The superficial veins ramify in the subcutaneous tissue above the deep fascia, and they do not accompany arteries. The deep veins accompany the arteries, and have practically the same relations as those vessels. The superficial and deep veins communicate at frequent intervals through the intermuscular veins which run between the muscles and perforate the deep fascia. Both sets of veins are provided with valves, but the valves are more numerous in the deep than in the superficial. There are usually valves where the deep veins join the superficial. The superficial veins are larger than the deep, and take the greater share in returning the blood.

I. THE SUPERFICIAL VEINS OF THE UPPER EXTREMITY

The **superficial veins** begin in two irregular plexuses, one in the palm and the other on the back of the hand. The plexus in the palm is much finer, and communicates with the superficial volar veins of the fingers. The latter discharge their blood into the dorsal venous rete by means of the veins of the folds between the fingers, or the **intercapitular** veins [vv. intercapitulares] (fig. 426).

The veins of the back of the hand begin in a longitudinal plexus over the fingers, and at the bases of the fingers the veins of the adjacent digits are connected by **digital venous arches** [arcus venosi digitales], from which arise the **dorsal metacarpal** veins [vv. metacarpeæ dorsales]; these form upon the back of the hand a **dorsal venous rete** [rete venosum dorsale manus] (fig. 427).

Of the veins of the arm, two stand out prominently, the basilic and the cephalic. Both of these arise from the veins of the back of the hand, curve around to the volar surface of the forearm, and pass to the upper arm (fig. 426).

The **basilic** vein [v. basilica],* arises on the back of the hand from the ulnar end of the dorsal venous rete, which usually forms an arch. It curves around the ulnar side of the forearm to the volar surface and passes to the elbow and the upper arm, where it lies in the median bicipital sulcus. It extends up to about the middle third of the sulcus, and, piercing the brachial fascia, joins the brachial vein.

The **cephalic** vein [v. cephalica],* begins at the radial end of the dorsal venous rete or arch and curves around the radial border of the forearm to the volar surface not far above the thumb. It passes to the elbow and the upper arm, but, unlike the basilic, it maintains its superficial course up to the shoulder, lying first in the lateral bicipital sulcus and then in the groove between the pectoralis major and the deltoid. Just below the clavicle it turns into the depth, and empties into the axillary vein.

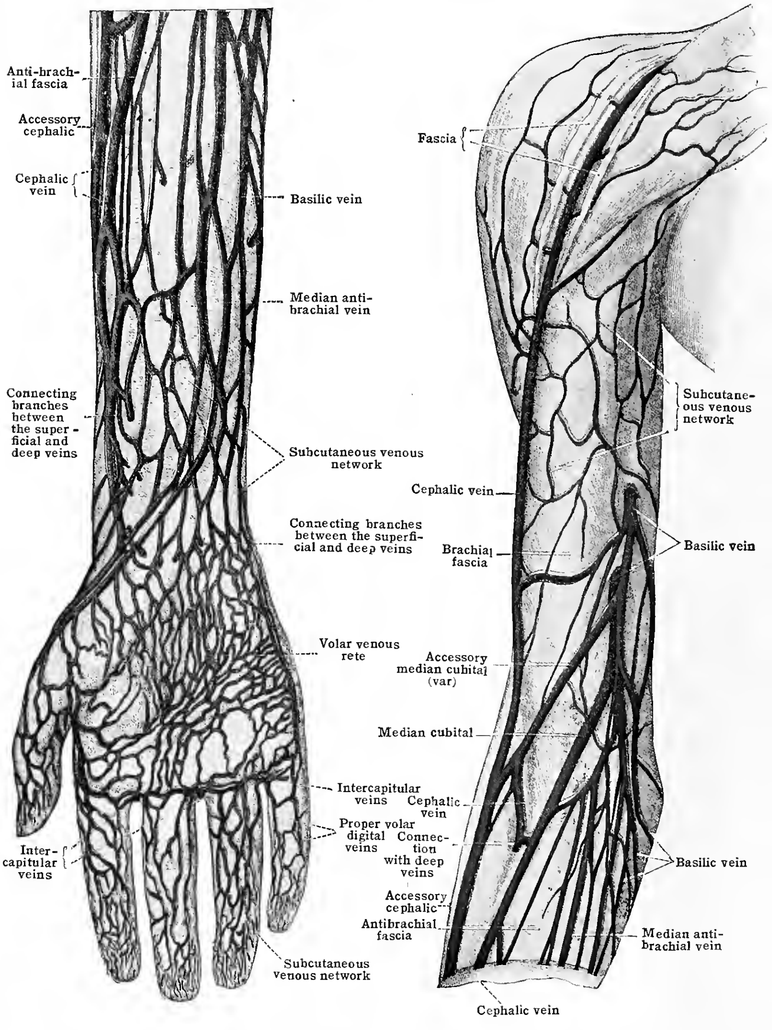
In the forearm plexus one or more longitudinal veins besides these are usually distinct. One lateral to the cephalic is known as the **accessory cephalic** [v. cephalica accessoria] (formerly the radial) vein; one near the centre is known as the **median antibrachial** [v. mediana antibrachii], (formerly the anterior ulnar) vein.

At the elbow there is usually an oblique connecting branch, the **median cubital** vein [v. mediana cubiti] (formerly termed median basilic) which extends

* The basilic vein here described corresponds to the posterior ulnar and basilic; the cephalic corresponds to the median, median cephalic and cephalic of the older terminology employed in English text-books. The BNA terminology has the great advantage that it can be readily used to described any form of venous pattern. The English terminology applies only to cases in which the M-shaped arrangement occurs upon the volar surface of the elbow. Berry and Newton find the latter arrangement in only 13 per cent. out of 300 cases examined.

from the cephalic up to the basilic. In some cases this anastomosis is made by a division of the **median antibrachial** into two branches, a **median cephalic** and

FIG. 526.—THE SUPERFICIAL VEINS OF THE ARM AND FOREARM. (After Toldt, "Atlas of Human Anatomy," Rebman, uondon and New York.)

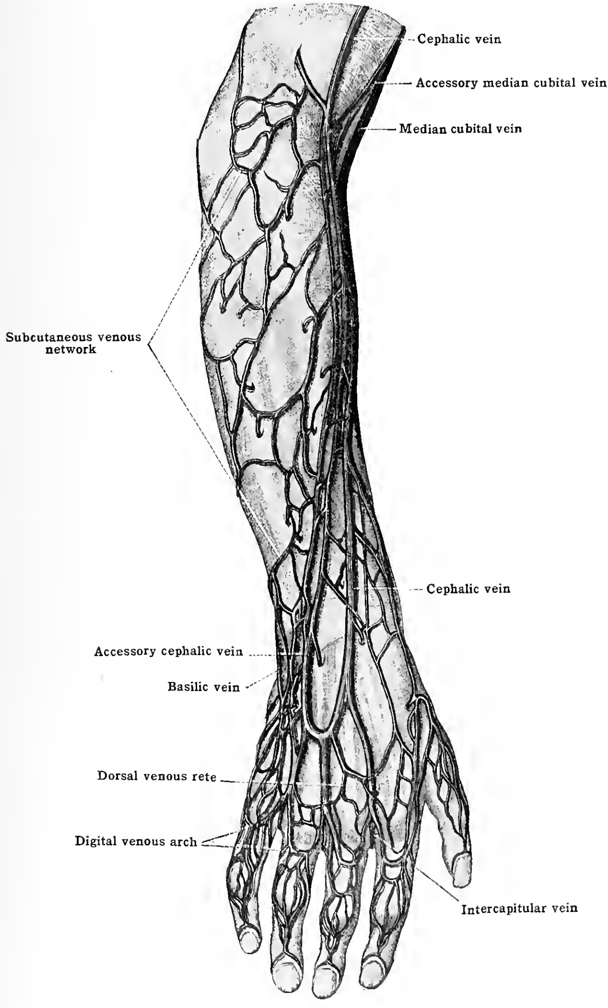


NOTE.—In the limb here represented the direct venous channel on the radial side of the forearm, the accessory cephalic (formerly radial) vein, is continued directly into the cephalic above the elbow. The cephalic in the forearm (formerly median) is mainly drained by the basilic through the median antecubital. The vein opposite the bend of the elbow, which usually forms the segment of the cephalic formerly known as the median cephalic vein, is here a small channel draining into an accessory median cubital. The basilic vein of the forearm (formerly posterior ulnar) is represented by a plexus of small venous channels.

median basilic. Occasionally the cephalic in the upper arm is reduced to a small tributary, which takes the course of the cephalic in the forearm, but bends ulnarward at the elbow to form the basilic. Numerous connections occur between the deep and the superficial veins at the elbow.

The superficial plexus of veins in the upper arm consists of small vessels that pass to the cephalic vein.

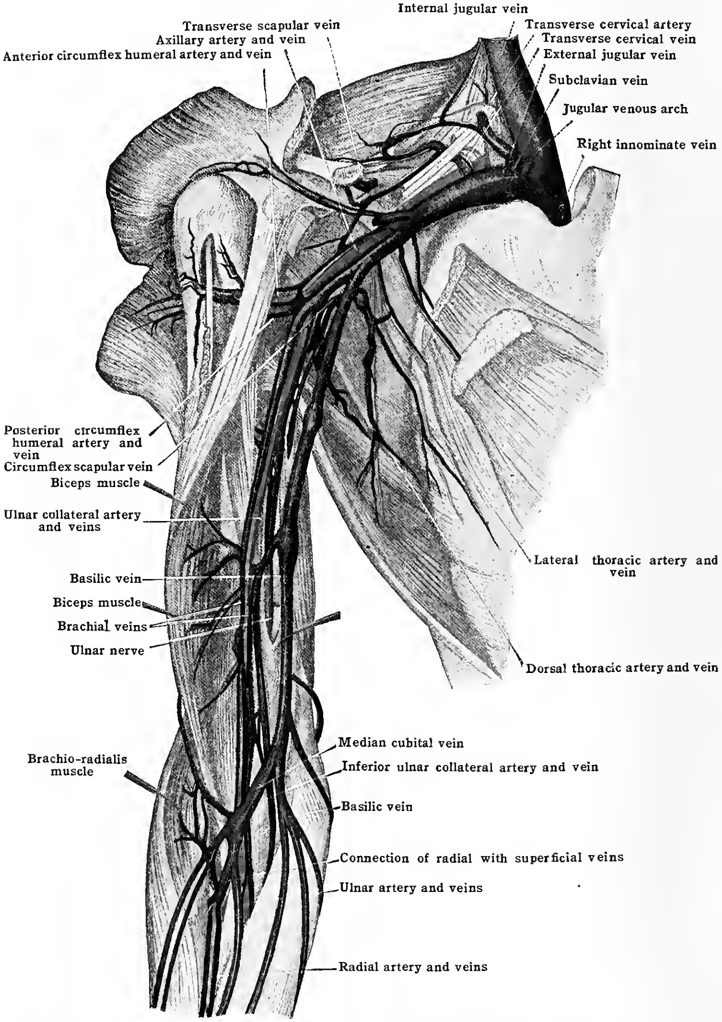
Fig. 527.—Veins of the Back of the Forearm. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



II. THE DEEP VEINS OF THE UPPER EXTREMITY

The **deep veins of the upper extremity** accompany their corresponding arteries. There are two veins to each artery below the level of the axilla, known as the venæ comitantes. The deep veins all contain numerous valves, and

Fig. 528.—Deep Veins of the Arm and Axilla. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



communicate at frequent intervals through intermuscular veins with the superficial vessels.

Beginning at the fingers, two minute **proper volar digital** veins [venæ digitales volares propriæ], accompany each digital artery along the sides of the fingers, and uniting at the cleft, form **common volar digital** veins [vv. digitales volares communes], which join the venæ comitantes of the arteries, forming the superficial palmar arch. In like manner the veins accompanying the arteries forming the deep arch receive tributaries, **the volar metacarpal** veins [vv. metacarpeæ volares], corresponding to the branches of that arch. A **superficial** and a **deep volar venous arch** [arcus volaris venosi superficialis et profundus] are thus formed accompanying the arterial arches. The venæ comitantes from the ulnar side of the superficial and deep arches unite at the spot where the ulnar artery divides into the superficial and deep branch to form two **ulnar venæ comitantes** [vv. ulnares]; whilst those on the radial side of the superficial and deep arch accompany the superficial volar artery and the termination of the radial artery respectively, and unite at the spot where the superficial volar is given off from the radial artery, to form the **radial venæ comitantes** [vv. radiales]. The ulnar and radial venæ comitantes thus formed course up the forearm with their respective arteries, receiving numerous tributaries from the muscles amongst which they run, and giving frequent communications to the superficial veins. They finally unite at the bend of the elbow to form the **brachial venæ comitantes** [vv. brachiales]. The ulnar venæ comitantes receive, before joining the radial, the companion veins of the interosseous arteries. At the bend of the elbow the deep veins are connected with the basilic or with the median antibrachial vein by a short, thick trunk (fig. 528).

The **brachial venæ comitantes** accompany the brachial artery. At the lower border of either the teres major or subscapularis muscle, the more medial vein receives the more lateral and the basilic vein, to form a single axillary vein.

The venæ comitantes of the arteries of the arm anastomose with one another by frequent cross branches.

The **axillary** vein [v. axillaris], is formed by the junction of the medial brachial vena comitans with the basilic vein at the lower border of either the teres major or subscapularis muscle. It is a vessel of large size, conveying as it does nearly the whole of the returned blood from the upper extremity. It accompanies the axillary artery through the axillary fossa, lying to its medial side and, at the upper part of the space, on a slightly posterior plane. At the lateral border of the first rib it changes its name to the subclavian. It has one or two axillary lymphatic nodes in close connection with it, and is liable, if care is not taken, to be wounded in removing these glands. The vein contains a pair of valves, usually placed near the lower border of the subscapularis muscle.

Tributaries:—(1) The **subscapular** veins which accompany the subscapular artery; (2) the **circumflex** veins accompanying the circumflex arteries; (3) the **lateral thoracic** vein [v. thoracalis lateralis] a large vein which accompanies the lateral thoracic artery and receives numerous **thoraco-epigastric** veins [vv. thoracoepigastricæ] from the epigastric and lower thoracic regions; (4) the **costo-axillary** veins [vv. costoaxillares] the radicles of which arise in the pectoral region from the **mammary plexus** [plexus venosus mamillæ]; and (5) the **cephalic** vein.

The **subclavian** vein [v. subclavii] (fig. 528), is the continuation of the axillary. It begins at the lateral border of the first rib, and terminates by joining the internal jugular to form the innominate vein opposite the lateral end of the sterno-clavicular articulation. It lies anterior to the subclavian artery and on a lower plane, and is separated from the artery in the second part of its course by the scalenus anterior muscle. The subclavian vein, just before it is joined by the external jugular, contains a pair of valves.

Tributaries.—The subclavian vein receives the thoracoacromial vein near its distal end, and the external jugular vein near the lateral border of the sterno-mastoid muscle. The transverse cervical veins terminate in the subclavian near the external jugular, or in the latter vein, or in a plexiform arrangement formed between the transverse scapular, transverse cervical and external jugular veins. The external jugular vein is described with the superficial veins of the head and neck (p. 646).

The **thoracoacromial** vein [v. thoracoacromialis], receiving tributaries corresponding to the branches of the artery of the same name, terminates near the lateral border of the first rib.

The **transverse cervical** veins [vv. transversæ colli] receive tributaries corresponding in distribution to the branches of the transverse cervical artery. They emerge from beneath the trapezius muscle, cross the posterior triangle, and usually terminate in the subclavian vein. They usually terminate as a single vein the orifice of which is guarded by a pair of valves. Occasionally the cephalic vein, or a branch from the cephalic (the jugulo-cephalic), passes over the clavicle to the subclavian.

III. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

All the veins of the abdomen, pelvis, and lower extremities, with the exception of the superior epigastric (p. 666), and ascending lumbar vein (p. 521), which join with the superior caval system, enter directly or indirectly into the vena cava inferior. The veins corresponding to the parietal branches of the abdominal aorta, except the middle sacral vein, open directly into the vena cava inferior; the middle sacral vein only indirectly through the left common iliac vein. Of the visceral veins corresponding to the visceral branches of the abdominal aorta, those which return the blood from the stomach, intestines, pancreas, and the spleen end in a common trunk called the portal vein.

The portal vein [vena portæ] enters the liver and there breaks up into a network of smaller vessels somewhat after the manner of an artery. This network contains venous blood, and is moulded upon the tissue-elements of the organ itself. The smaller vessels consist, like capillaries (from which they differ in developmental history) of intima only; they are called **sinusoids.** The venous blood is returned from the sinusoidal plexus by the hepatic veins which open into the vena cava inferior as that vessel lies in the fossa venæ cavæ of the liver.

Of the other visceral veins, both renals, the right suprarenal, and the right spermatic or ovarian open directly into the vena cava inferior; whilst the left suprarenal and left spermatic or ovarian are drained through the left renal.

Two of the superficial veins of the lower part of the anterior abdominal wall, the superficial epigastric and superficial circumflex iliac, enter the great saphenous vein; and two of the deep veins from the like situation, the inferior epigastric and deep circumflex iliac, enter the external iliac vein. The blood in these vessels, however, can flow upward as well as in the normally downward direction. In obstruction of the vena cava inferior they become greatly enlarged, and form, with the superior epigastric vein and with other superficial veins of the thorax with which they anastomose, one of the chief channels for the return of the blood from the lower limbs.

The veins of the pelvis, which receive the veins from the perinæum and gluteal region, join the hypogastric vein.

THE VENA CAVA INFERIOR

The **vena cava inferior** (fig. 529) is the large vessel which returns the blood from the lower extremities and the abdomen and pelvis. It is formed by the confluence of the right and left common iliac veins opposite the body of the fifth lumbar vertebra, ascends in front of the lumbar vertebræ to the right of the abdominal aorta, passes through the caval opening in the diaphragm, and ends in the lower and back part of the right atrium of the heart on a level with the lower border of the ninth thoracic vertebra. At its origin it lies behind the right common iliac artery on a plane posterior to the aorta, but as it ascends it passes slightly forward and to the right, reaching a plane anterior to the aorta, and becoming separated from that artery by the right medial crus of the diaphragm and the caudate lobe of the liver. While in contact with the liver it lies in a deep groove [fossa venæ cavæ] on the posterior surface of that organ, the groove being often converted into a distinct canal by a thin portion of the hepatic substance bridging across it. As it passes through the diaphragm its walls are attached to the tendinous margins of the caval opening, and are thus held apart when the muscle contracts. On the thoracic side of the diaphragm it lies for about 1.2 cm. ($\frac{1}{2}$ in.) within the pericardium, the serous layer of that membrane being reflected over it.

Relations.—In front it is covered by the peritoneum, and crossed by the right spermatic artery, branches of the aortic plexus of the sympathetic, the transverse colon, the root of the mesentery, the duodenum, the head of the pancreas, the portal vein, and the liver. The median group of the lumbar lymphatic nodes are also in front of it below, and at its commencement the right common iliac artery rests upon it.

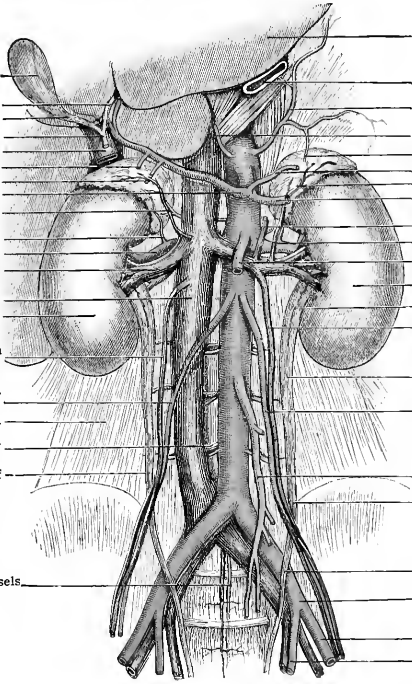
Behind, it lies on the lumbar vertebræ, the right lumbar arteries, the right renal artery, the right cœliac (semilunar) ganglion, and the right medial crus of the diaphragm.

To the **right** are the peritoneum, liver, and psoas muscle.

To the **left** is the aorta, and higher up the right medial crus of the diaphragm.

Tributaries.—The vena cava inferior receives the following veins:—(1) the renal veins; (2) the right suprarenal vein; (3) the right spermatic or the right

FIG. 529.—THE ABDOMINAL AORTA AND VENA CAVA INFERIOR.



ovarian vein; (4) the lumbar veins; (5) the inferior phrenic veins; (6) the hepatic veins; and (7) the right and left common iliac veins.

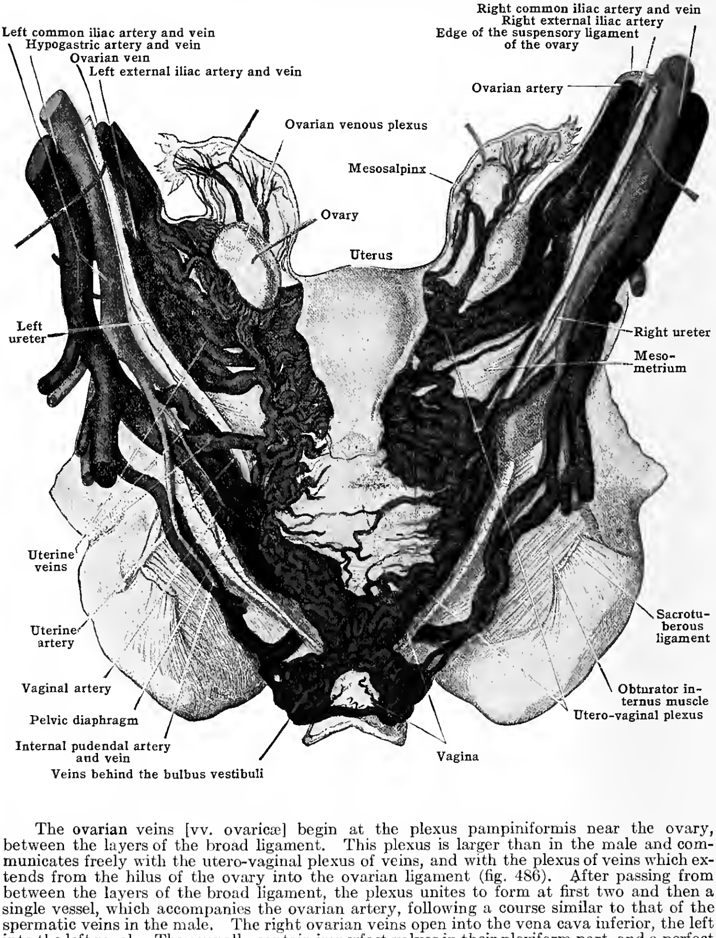
(1) The **renal** veins [vv. renales] (fig. 529) return the blood from the kidneys. They are short but thick trunks, and open into the vena cava nearly at right angles to that vessel. The vein on the left side, like the kidney, is a little higher than on the right, and is also longer, in consequence of its having to cross the aorta.

Each renal vein lies in front of its corresponding artery. The left vein crosses in front of the aorta, just below the origin of the superior mesenteric artery. It is covered by the inferior portion of the duodenum, and receives the left spermatic, or the left ovarian in the female, and usually the left suprarenal, and sometimes the left phrenic. There are rudiments of valves in each vein where it joins the vena cava. Those on the right side, however, are less well marked.

(2) The **suprarenal** veins [vv. suprarenales] (fig. 529).—There is usually only one suprarenal vein on each side to return the blood brought to the suprarenal body by the three suprarenal arteries. On the **right side** the vein opens directly into the vena cava, above the opening of the right renal vein. On the **left side,** it opens into the left renal.

(3) The spermatic veins [vv. spermaticæ] (fig. 529) return the blood from the testis. They begin by the confluence of small branches from the body of the testis and epididymis. As they proceed up the spermatic cord, in front of the internal spermatic artery and ductus deferens, they become dilated and plexiform, constituting the **pampiniform plexus** [plexus pampiniformis] (fig. 541). After passing through the subcutaneous inguinal ring, the inguinal canal, and the abdominal inguinal ring, the plexus communicates with the inferior epigastric vein and is continued as two veins. Along with the artery the veins pass up beneath the peritoneum, and on the left side also beneath the sigmoid colon, across the psoas muscle and ureter. They receive small tributaries from the ureter and peritoneum, and proceed as a single trunk, on the right side to the vena cava inferior, and on the left side to the left renal vein. There are commonly a number of imperfect valves in the spermatic plexus and a perfect pair at the termination of each spermatic vein. On the left side, however, the terminal valve may be wanting.

FIG. 530.—THE VEINS OF THE FEMALE PELVIS. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **ovarian veins** [vv. ovaricæ] begin at the plexus pampiniformis near the ovary, between the layers of the broad ligament. This plexus is larger than in the male and communicates freely with the utero-vaginal plexus of veins, and with the plexus of veins which extends from the hilus of the ovary into the ovarian ligament (fig. 486). After passing from between the layers of the broad ligament, the plexus unites to form at first two and then a single vessel, which accompanies the ovarian artery, following a course similar to that of the spermatic veins in the male. The right ovarian veins open into the vena cava inferior, the left into the left renal. They usually contain imperfect valves in their plexiform part, and a perfect valve where they join the vena cava and renal vein respectively.

(4) The **lumbar** veins [vv. lumbales], four to five on either side accompany the lumbar arteries and collect venous blood from the muscles of the back and abdomen. They terminate by passing beneath the tendinous arches of the psoas major, along the sides of the lumbar vertebræ, and opening into the vena cava inferior. The veins of the left side are longer than those of the right and pass behind the aorta. Each vein receives a dorsal tributary corresponding in distribution to the dorsal branch of the lumbar artery. Between the dorsal tributaries and the posterior vertebral venous plexus there occurs a free communication. There is also an anastomosis between the main lumbar veins and the anterior vertebral venous plexus around the bodies and transverse processes of the lumbar vertebræ. By means of these communications the intervertebral veins, the internal and external vertebral and spinal plexuses are partly drained. In addition to these anastomoses the lumbar veins are connected with one another and with common iliac, hypogastric, ilio-lumbar, renal, azygos and hemiazygos veins by means of the *ascending lumbar vein* (p. 663).

(5) The **inferior phrenic** veins [v. phrenica inferior] follow the course of the inferior phrenic arteries; the right opens into the vena cava direct; the left into the suprarenal, the left renal, or the vena cava.

(6) The **hepatic** veins [vv. hepaticæ], the largest tributaries of the vena cava, return the blood from the liver. Commencing in the substance of the liver (see Liver), they converge as they approach its posterior surface, and unite to form two or there large trunks, which open into the vena cava as it lies in the fossa venæ cavæ. Some smaller vessels from the caudate lobe, and other parts of the liver in the nighbourhood of the caval fossa, open directly into the vena cava. The hepatic veins contain no valves, but, in consequence of opening obliquely into the vena cava, a semilunar fold occurs at the lower magin of each orifice.

THE PORTAL VEIN

The veins corresponding to the inferior mesenteric, the superior mesenteric, and to some of the branches of the cœliac artery, do not join the vena cava inferior direct, but unite to form a common trunk—the **portal vein.**

This vein enters the liver, and breaks up in its substance into **sinusoids** from which the blood is again ultimately collected by the hepatic veins, and carried by them into the vena cava inferior. The terminal branches of the hepatic artery also empty into the hepatic sinusoids, and their blood likewise finds its way finally into the hepatic veins, and thence into the vena cava inferior. The portal vein and its tributaries have no valves.

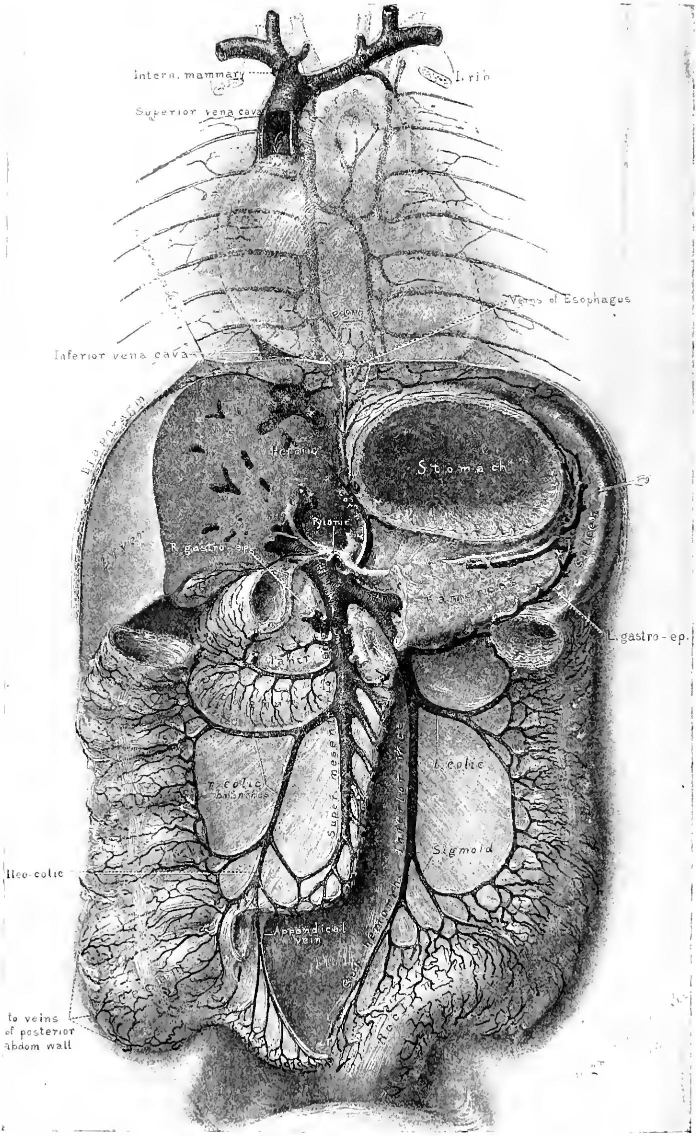
The **portal** vein [v. portæ] (fig. 531), is a thick trunk 7 or 8 cm. (3 in.) in length. It is formed behind the head of the pancreas, opposite the right side of the body of the second lumbar vertebra, by the union of the superior mesenteric with the splenic veins. It passes upward and to the right behind the superior part of the duodenum, and then between the layers of the lesser omentum. In the latter situation it passes in front of the foramen epiploicum and is accompanied by the hepatic artery and the hepatic duct. Finally it enters the porta of the liver, and there divides into a right and a left branch. In this course the hepatic artery and the common bile duct are in front, the former to the left, the latter to the right. It is surrounded by branches of the hepatic plexus of the sympathetic nerve, and by numerous lymphatic vessels and some glands. The connective tissue sheath enclosing these structures is called the **fibrous capsule of Glisson** [capsula fibrosa, Glissoni]. Just before it divides it is somewhat dilated, the dilated portion being called the **sinus of the portal vein.** The division into right and left branches takes place toward the right end of the porta of the liver. The **right branch** is shorter and thicker than the left, and supplies the right lobe of the liver and a branch to the quadrate lobe. The **left branch** is longer and smaller than the right, and supplies the left lobe, and gives a branch to the caudate (Spigelian) and quadrate lobes. It is joined, as it crosses the left sagittal fossa, by a fibrous cord, known as the **ligamentum teres hepatis** (obliterated **vena umbilicalis**), and posteriorly by a second fibrous cord, the **ligamentum venosum** (oblietrated **ductus venosus**). The position of the original course of the umbilical vein across the left portal is marked, in adult life, by a dilation of the latter vein, called the **umbilical recess.**

Tributaries.—The pyloric, the coronary (gastric), the cystic, the superior mesenteric, and the splenic.

The **pyloric** vein begins near the pylorus in the lesser curve of the stomach, and, running from left to right with the right gastric artery, opens directly into the lower part of the portal vein. It receives branches from the pancreas and duodenum.

The **coronary** vein [v. coronaria ventriculi] (fig. 533) runs with the left gastric artery at first from right to left, among the lesser curvature of the stomach, toward the cardiac end, and then, turning to the right, passes across the spine from left to right to end in the portal trunk a

Fig. 531.—The Portal Vein. (From Kelly, by Brödel.)



little higher than the pyloric vein. At the cardiac end of the stomach it receives small branches from the œsophagus.

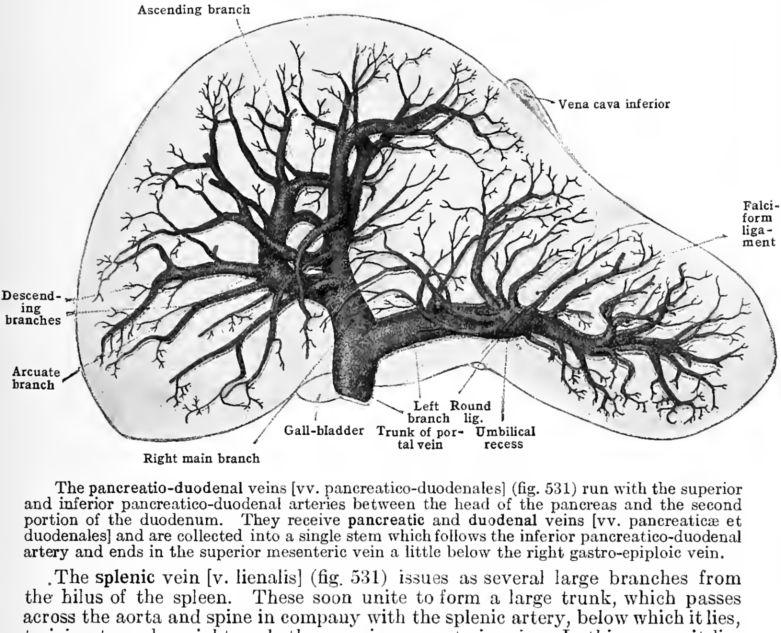
The **cystic** vein [v. cystica] (fig. 533) returns the blood from the gall-bladder. It usually opens into the right branch of the portal vein.

The **superior mesenteric** vein [v. mesenterica superior] (fig. 534) begins in tributaries which correspond with the branches of the superior mesenteric artery. It courses upward a little in front and to the right of the artery, passing with that vessel from between the layers of the mesentery. It passes in front of the inferior portion of the duodenum, and behind the pancreas, where it joins the splenic vein to form the portal trunk (fig. 531).

Tributaries.—In addition to the tributaries corresponding to the branches of the superior mesenteric artery—viz. the *ileo-colica, colica dextra, colica media*, and *venæ intestinales* (fig. 534)—it receives the **right gastro-epiploic** and the **pancreatico-duodenal veins** just before its termination in the portal vein.

The **right gastro-epiploic** vein [v. gastroepiploica dextra] (fig. 533) accompanies the artery of that name. It runs from left to right along the greater curvature of the stomach, receiving branches from the anterior and posterior surfaces of that viscus, and from the great omentum, and, passing behind the superior portion of the duodenum, ends in the superior mesenteric vein just before that vessel joins the portal trunk.

Fig. 532.—The Portal Vein within the Liver. (After Rex.)



The **pancreatio-duodenal veins** [vv. pancreatico-duodenales] (fig. 531) run with the superior and inferior pancreatico-duodenal arteries between the head of the pancreas and the second portion of the duodenum. They receive **pancreatic** and **duodenal** veins [vv. pancreaticæ et duodenales] and are collected into a single stem which follows the inferior pancreatico-duodenal artery and ends in the superior mesenteric vein a little below the right gastro-epiploic vein.

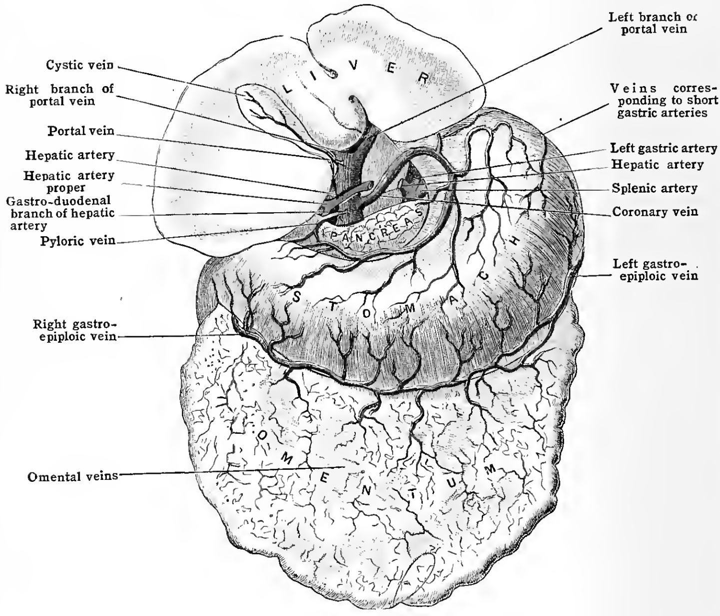
The **splenic** vein [v. lienalis] (fig. 531) issues as several large branches from the hilus of the spleen. These soon unite to form a large trunk, which passes across the aorta and spine in company with the splenic artery, below which it lies, to join at nearly a right angle the superior mesenteric vein. In this course it lies behind the pancreas; and at its union with the superior mesenteric to form the vena portæ in front of the vena cava inferior.

Tributaries.—It receives the **short gastric** veins [vv. gastricæ breves], from the fundus of the stomach, the **left gastro-epiploic** vein, and the **inferior mesenteric** vein. As it lies in contact with the pancreas it receives some small **pancreatic** veins [vv. pancreaticæ].

The **left gastro-epiploic** vein [v. gastroepiploica sinistra] (fig. 533) accompanies the left gastro-epiploic artery. It runs from right to left along the greater curvature of the stomach, receives branches from the stomach and omentum, and opens into the commencement of the splenic vein.

The **inferior mesenteric** vein [v. mesenterica inferior] (fig. 531) begins at the rectum as the superior hæmorrhoidal vein. This emerges from the hæmorrhoidal plexus in which it communicates freely with the middle and inferior hæmorrhoidal veins. It passes out of the pelvis with the inferior mesenteric artery; but, after receiving the **sigmoid** and **left colic** veins [vv. sigmoideæ et v. colica sinistra] which accompany the arteries of the same names, it leaves the artery and runs upward on the psoas to the left of the aorta and behind the peritoneum. On approaching the pancreas it turns medially, and passes obliquely behind that gland to join the splenic vein just before the latter unites with the superior mesenteric to form the vena portæ.

Fig. 533.—The Veins of the Stomach and the Portal Vein. (From a dissection by W. J. Walsham.)



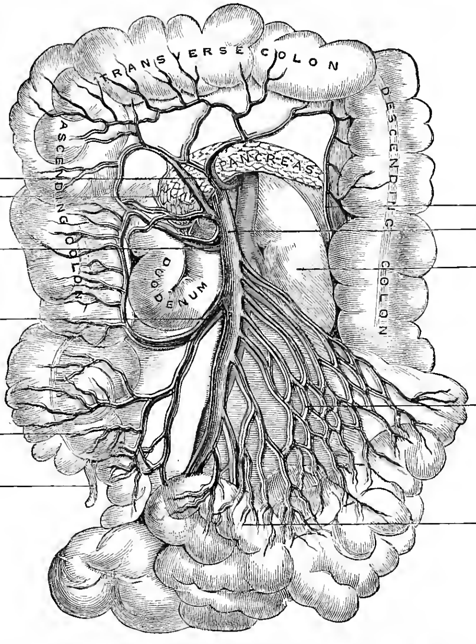
The adult portal vein and its tributaries contain no valves, a circumstance which adversely affects the circulation of blood within this system. The liability to excessive pressure in the most dependent part of the portal system is evidenced by the great frequency of the condition known as piles, due to dilatation of the veins of the internal hæmorrhoidal plexus. In early life valves are present in the veins of the stomach and of the intestinal wall but these undergo retrogression.

The accessory portal veins.—Since the blood returning from the abdominal portion of the digestive tract and spleen must pass through the hepatic capillaries before returning to the heart, extensive obliteration of these capillaries, such as occurs in certain diseases of the liver, would prevent the return of the portal blood to the heart were it not for anastomoses between tributaries of the portal vein and those of the caval systems, constituting what have been termed accessory portal veins. Some of the more important of these are—(1) between the branches of the coronary vein of the stomach and the œsophageal veins which open into the vena azygos; (2) between the **parumbilical** veins [vv. parumbilicales], which communicate with the portal vein above and descend upon the ligamentum teres to the anterior abdominal wall to anastomose with the superior and inferior epigastric and superior vesical veins; (3) between the superior and middle hæmorrhoidal veins, the latter opening into the hypogastric, and (4) between a wide-meshed retro-peritoneal plexus of veins which communicates with the portal vessels over the posterior surface of the liver and the veins of the pancreas, duodenum and ascending and descending colon on the portal side, and with the phrenic and azygos veins on the systemic.

THE COMMON ILIAC VEINS

The **common iliac** veins [vv. iliacæ communes], (fig. 536) are formed opposite the sacro-iliac articulation by the confluence of the external iliac and hypogastric (internal iliac) veins. They converge as they ascend, and unite opposite the upper border of the fifth lumbar vertebra and a little to the right of the median line to form the vena cava inferior.

Fig. 534.—The Superior Mesenteric Vein.
(The colon is turned up, and the small intestines are drawn over to the left side.)



The **right** vein, shorter and more vertical in direction than the left, passes obliquely behind the right common iliac artery to its lateral side, where it is joined by the left common iliac vein.

The **left** vein lies to the medial side of the left common iliac artery, and, after crossing in front of the promontory of the sacrum and the fifth lumbar vertebra below the bifurcation of the aorta, passes beneath the right common iliac artery to join the right vein and form the vena cava inferior. The left vein may contain an imperfect valve.

Tributary.—The ilio-lumbar veins may enter the lower part of the common iliac, or open into the hypogastric vein. The left vein receives the middle sacral vein.

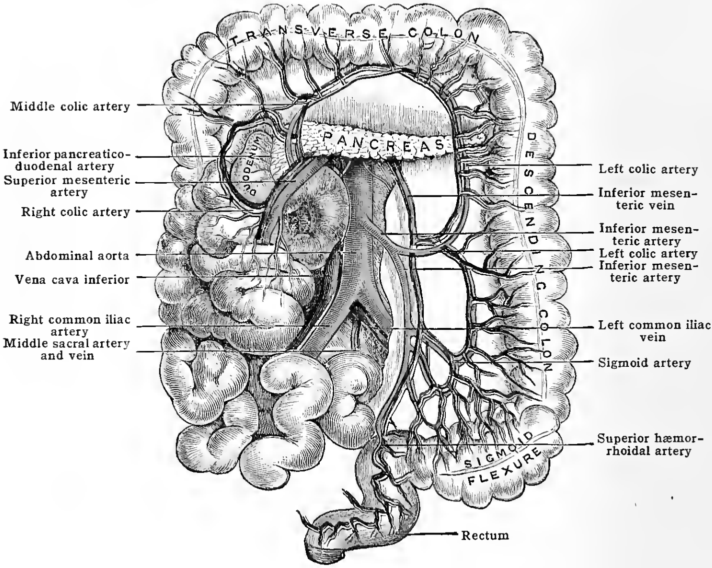
The **middle sacral** vein [v. sacralis media] opens usually as a single trunk into the left common liiac vein. The venæ comitantes which form it ascend on either side of the middle sacral artery in front of the sacrum. They communicate with the lateral sacral veins, forming the **anterior sacral plexus** [plexus sacralis anterior] which receives the sacral intervertebral veins, and anastomoses freely with the neighbouring lumbar and pelvic veins. Below, the middle sacral veins communicate with the hæmorrhoidal veins.

THE HYPOGASTRIC VEIN

The **hypogastric (internal iliac)** vein [v. hypogastrica] (fig. 536) is formed by the confluence of the veins (except the umbilical) corresponding to the branches of the hypogastric artery. It varies considerably in length, but is usually quite a short trunk, extending from the upper part of the great sciatic foramen to the sacro-liac articulation, where it joins the external iliac to form the common iliac vein. It lies behind and a little medial to the hypogastric artery. It contains no valve.

Tributaries.—The hypogastric vein receives directly or indirectly the following vessels; the superior gluteal, ilio-lumbar, lateral sacral, obturator, inferior

FIG. 535.—THE INFERIOR MESENTERIC VEIN.
(The colon is turned up, and the small intestines are drawn to the right side.)



gluteal (sciatic), internal pudendal, and (in the female) the uterine veins; also branches from the pudendal, vesical, and hæmorrhoidal plexuses. The **single umbilical vein**—the vein corresponding to the right and left hypogastric arteries and their continuation, the umbilical arteries—does not enter the pelvis, but, leaving the umbilical arteries at the navel, passes along the falciform ligament to the liver. After birth it is converted into the ligamentum teres hepatis. (See PORTAL VEIN, p. 675.)

The **superior gluteal** veins [vv. gluteæ superiores] accompany the superior gluteal artery and, passing through the upper part of the great sciatic foramen, open into the hypogastric vein near its termination, either separately or as a single trunk.

The **ilio-lumbar** veins [vv. ilio lumbales] open into the hypogastric a little higher than the superior gluteal. At times they join the common iliac vein.

The **lateral sacral** veins [vv. sacrales laterales] (fig. 536) join the superior gluteal or the hypogastric at or about the same situation as the gluteal. They form with the middle sacral veins a plexus in front of the sacrum, which receives tributaries from the sacral canal.

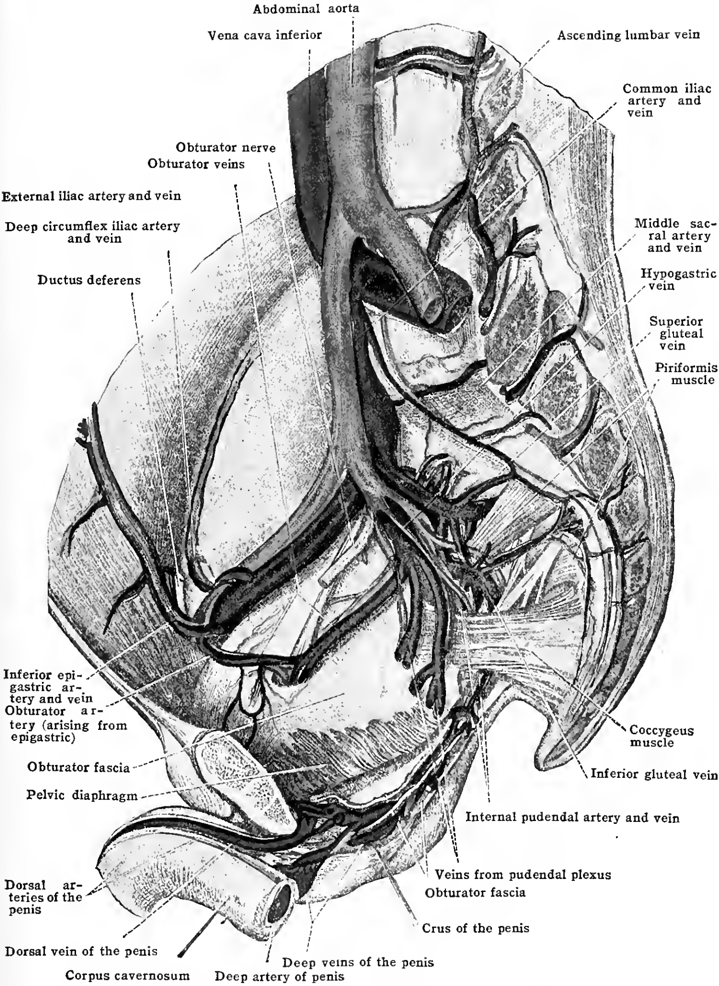
The **obturator** vein [v. obturatoria] (fig. 536), which lies below the obturator artery as it crosses the side of the pelvis, opens into the front of the hypogastric vein a little below the superior gluteal. Its branches correspond to those of the artery.

The **inferior gluteal** veins [vv. gluteæ inferiores] accompany the inferior gluteal (sciatic) artery, and, as a rule, unite to form a single trunk before joining the hypogastric a little below the obturator vein.

All the above veins so closely follow the ramifications of their respective arteries that no further special description of them is required. They all contain valves.

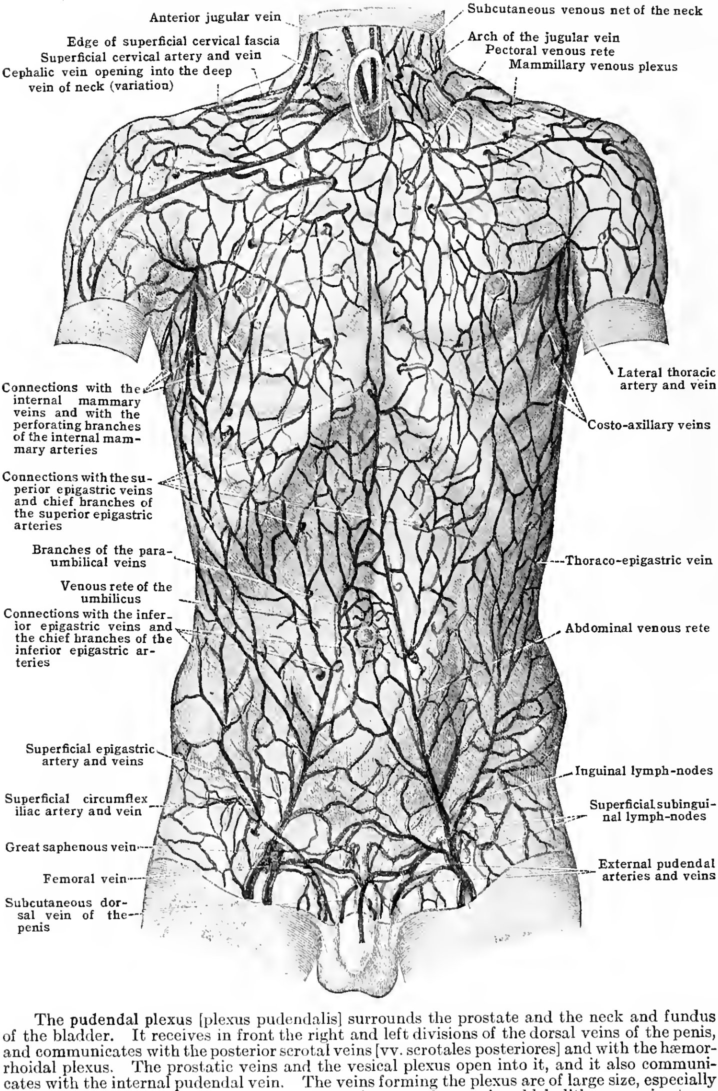
The **internal pudendal vein** [v. pudenda interna] (fig. 536) begins at the termination of the deep veins of the penis [vv. profundæ penis] which issue from the corpus coavernosum penis with the artery of that body. These veins communicate with the dorsal vein at the root of the penis In its course the internal pudendal vein runs with the internal pudendal artery, receiving tributaries corresponding to the branches of that vessel. It terminates in the lower part of the hypogastric vein.

Fig. 536.—The Veins of the Pelvis, Male. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **dorsal vein of the penis** [v. dorsalis penis] (fig. 536) begins in a plexus around the corona glandis, then runs along the centre of the dorsum of the penis between the two dorsal arteries. In this course it receives large tributaries from the interior of the organ, which, emerging for the most part between the corpus cavernosum urethræ and corpus cavernosum penis, wind obliquely over the lateral surface of the latter structure to the dorsum of the penis to end in the dorsal vein. At the root of the penis the dorsal vein communicates with the subcutaneous veins of the dorsum of the penis and, leaving the arteries, passes straight backward between the two layers of the fundiform (suspensory) ligament. It then goes between the subpubic linament and the upper part of the fascia of the urogenital diaphragm (fig. 542). Here it bifurcates, each branch passing backward and downward to the pudendal plexus of veins. At times the dorsal vein begins as two branches, which run between the dorsal arteries and only unite to form a single trunk about 3.7 cm. ($1\frac{1}{2}$ in.) from the symphysis. After dividing into a right and a left branch within the pelvis, each vessel generally communicates with the obturator vein by a branch passing over the back of the pubis to the obturator foramen.

Fig. 537.—The Subcutaneous Arteries and Veins of the Anterior Body Wall. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **pudendal plexus** [plexus pudendalis] surrounds the prostate and the neck and fundus of the bladder. It receives in front the right and left divisions of the dorsal veins of the penis, and communicates with the posterior scrotal veins [vv. scrotales posteriores] and with the hæmorrhoidal plexus. The prostatic veins and the vesical plexus open into it, and it also communicates with the internal pudendal vein. The veins forming the plexus are of large size, especially in old men, in whom they often become varicose, and contain phleboliths, or vein-stones

The plexus is surrounded by a kind of capsule formed by the superior fascia of the pelvic diaphragm. It terminates in a single stem on each side which opens into the hypogastric vein.

In the female the smaller pudendal plexus surrounds the urethra and receives the **dorsal and deep veins of the clitoris** [vv. dorsales et profundæ clitoridis], veins from the vestibule, and the **posterior labial** veins [vv. labiales posteriores]. It communicates freely with the utero-vaginal plexus and is drained by the hypogastric veins.

The **vesical plexus** [plexus vesicalis] surrounds the apex, the sides, and the anterior and posterior surfaces of the bladder. It is situated between the muscular coat and the peritoneum, and where the bladder is uncovered by peritoneum external to the muscular coat in the pelvic cellular tissue. It opens into the pudendal plexus.

The **utero-vaginal plexus** [plexus uterovaginalis] connects with the hæmorrhoidal, vesical, and uterine plexuses. Its lower part drains through the internal pudendal veins and the pudendal plexus, and its upper protion largely through the ovarian veins, and partly through the **uterine veins** [vv. uterinæ] to the hypogastric (fig. 530).

The **hæmorrhoidal plexus** [plexus hæmorrhoidalis] surrounds the rectum, and is situated at the lower part of that tube. It consists of two portions, one of which, the internal hæmorrhoidal plexus, is situated between the muscular and mucous coats, while the other, the external hæmorrhoidal plexus, rests upon the outer surface of the muscular coat. The veins of this latter plexus terminate in the inferior, middle, and superior hæmorrhoidal veins. The **inferior** [vv. hæmorrhoidales inferiores] join the internal pudendal; the **middle** [v. hæmorrhoidalis media] accompanies the middle hæmorrhoidal artery and opens into the hypogastric and superior hæmorrhoidal veins; the **superior** (p. 678) forms the commencement of the inferior mesenteric vein, and through this the blood gains the portal vein. None of these veins have any valves, hence the enlargement of the inferior hæmorrhoidal veins, when the portal vein is obstructed, as in cirrhosis of the liver. Through the hæmorrhoidal veins a free communication is established between the systemic and portal system of veins.

THE EXTERNAL ILIAC VEIN

The **external iliac** vein [v. iliaca externa] (fig. 536), is the upward continuation of the femoral. Beginning at the lower border of the inguinal ligament, it accompanies the external iliac artery medially upward along the brim of the minor pelvis, lying at first on the superior ramus of the pubis, and then on the psoas major muscle. It terminates by joining the hypogastric vein behind the hypogastric artery, opposite the lower border of the sacro-iliac articulation, to form the common iliac vein. It lies at first medial to the external iliac artery, and on the left side remains medial to the artery throughout its course. On the right side, however, as it ascends, it gradually gets behind the artery. It contains one or two valves.

In addition to the femoral, the external iliac receives the **inferior epigastric** vein [v. epigastrica inferior] (fig. 536) and the deep circumflex iliac vein [v. circumflexa ilium profunda] (fig. 541), which accompany the arteries of the same name.

THE SUPERFICIAL VEINS OF THE ABDOMINAL WALL

The plexus of superficial veins of the anterior abdominal wall is continuous with that of the thorax (fig. 537). Its main channels are the superficial circumflex iliac, the superficial epigastric, and the external pudendal, all of which open into the great saphenous vein. These communicate, by means of subcutaneous abdominal veins, with the superior epigastric vein, and, by means of the thoraco-epigastric veins, with the lateral thoracic and costo-axillary. The superficial veins communicate very freely with the deeper veins of the abdominal wall, and, by means of parumbilical veins, they communicate to a slighter extent with the portal system.

The superficial veins of the lumbar region form an abundant plexus which drains through the dorsal and lateral perforating branches of the intercostal, lumbar, and sacral veins.

THE VEINS OF THE LOWER EXTREMITY

The **veins of the lower extremity** are divided into the superficial and the deep. The **superficial** veins lie in the subcutaneous tissue superficial to the deep fascia, through which they receive numerous communicating branches from the deep veins. They are collected chiefly into two main trunks, which, beginning on the foot, extend upward, one, the great saphenous, lying antero-medially, and the other, the small saphenous, postero-laterally. The former finally joins the femoral vein by passing through the deep fascia at the groin; the latter, the popliteal by perforating the fascia at the ham. The **deep** veins, on the other hand, accompany their corresponding arteries. All the veins of the lower limb have valves which are more numerous than in the veins of the upper extremity and in the deep than in the superficial veins.

I. THE SUPERFICIAL VEINS OF THE LOWER EXTREMITY

The **superficial veins of the lower limb** begin in the plexuses of the foot. The **dorsal digital** veins [vv. digitales pedis dorsales] collect blood from the dorsal surfaces of the toes and unite in pairs, around each cleft, to form the **dorsal metatarsal** veins [vv. metatarseæ dorsales pedis]. The dorsal metatarsal veins, of which the first and fifth are larger than the others, join the **dorsal venous arch** [arcus venosus dorsalis pedis]. This arch is convex toward the toes and crosses near the bases of the metatarsal bones. From the medial and lateral ends of the arch the great and small saphenous veins, respectively, take origin. The area of the dorsum of the foot contained between the arch and the two saphenous veins is covered by the **dorsal venous rete** [rete venosum dorsale pedis] which extends as high as the ankle-joint (fig. 539).

On the plantar surface the **plantar digital** veins [vv. digitales plantares] return the venous blood to the clefts of the toes and unite to form the **common digital** veins [vv. digitales communes pedis]. The common digital veins join freely with one another on the sole to form the **plantar venous rete** [rete venosum plantare]. There are numerous communications between the superficial veins of the dorsum and sole. These occur both in the clefts of the toes, by means of the **intercapitular** veins [vv. intercapitulares], and around the margins of the foot. Communications between the superficial and deep veins of the foot are very free (fig. 540).

The **great** (or internal) **saphenous** vein [v. saphena magna] (fig. 538) commences as the medial end of the dorsal venous arch, and, after receiving branches from the sole which join it by turning over the medial border of the foot, passes upward in front of the medial malleolus, and then obliquely upward and backward about a finger's breadth from the posterior border of the tibia in company with the saphenous nerve, which becomes superficial just below the knee. Continuing its course upward, it passes behind the medial epicondyle, and then runs upward on the medial side of the front of the thigh to about 3.7 cm. ($1\frac{1}{4}$ in.) below the inguinal ligament, where it dips through the fossa ovalis (saphenous opening) in the fascia lata, and ends in the femoral vein.

Tributaries.—In its course up the leg and thigh it receives numerous unnamed cutaneous tributaries. As it passes up the thigh it often receives a large vein, the femoro-popliteal which communicates with the small saphenous, and several of the cutaneous veins on the lateral part of the thigh, and a second vein, the **accessory saphenous** [v. saphena accessoria], formed by the union of the cutaneous veins from the medial and back part of the thigh (fig. 538). The great saphenous vein contains from ten to twenty valves.

Immediately before entering the fossa ovalis the great saphenous vein receives the superficial epigastric, superficial circumflex iliac, and external pudendal veins, though any of these veins—or all of them—may pierce the fascia separately and enter the femoral vein.

The **superficial epigastric** vein [v. epigastrica superficialis] anastomoses with the superficial abdominal, and parumbilical veins.

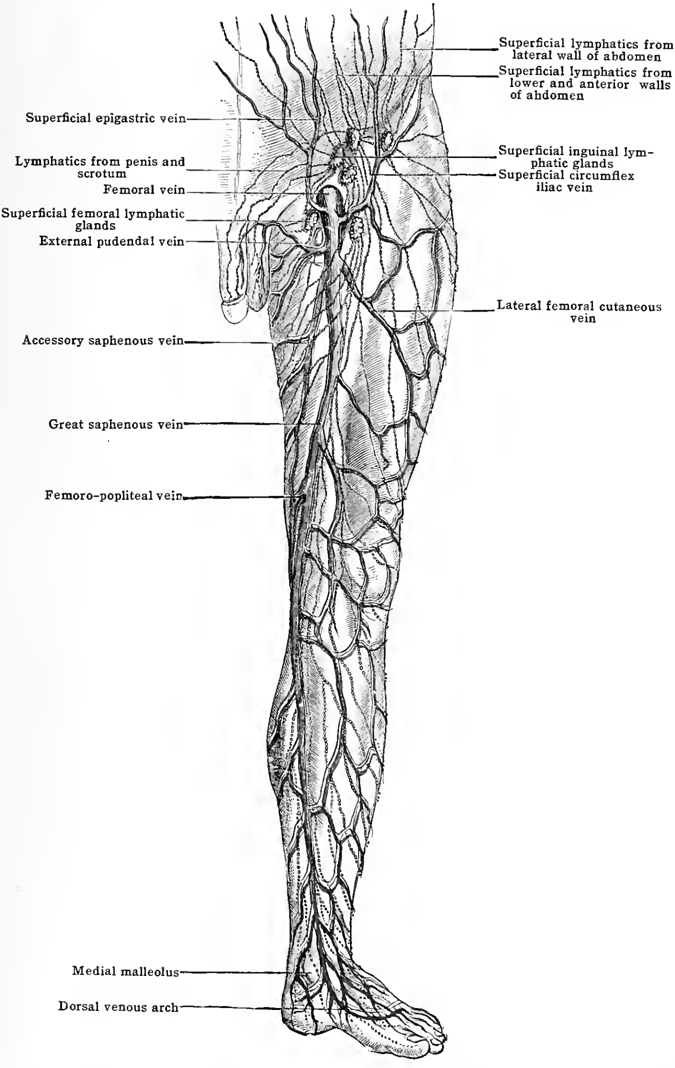
The **superficial circumflex iliac** vein [v. circumflex ilium superficialis] anastomoses with the thoraco-epigastric and the superficial circumflex iliac veins.

The **external pudendal** veins [vv. pudendæ externæ] collect venous blood from the **anterior scrotal or labial** veins, which anastomose with the posterior scrotal or labial veins, and from the **subcutaneous veins of the dorsum of the penis** [vv. dorsales penis subcutaneæ].

The small **saphenous** vein [v. saphena parva] (fig. 539) begins at the lateral end of the venous arch on the dorsum of the foot. After receiving branches from the sole, which turn over the lateral border of the foot, it passes behind the lateral malleolus, and then upward and, lying at first along the lateral side of the tendo Achillis, afterward along the back of the calf, in company with the sural (short saphenous) nerve, to about the lower part of the centre of the popliteal space, where it perforates the deep fascia, and, sinking between the two heads of the gastrocnemius, opens into the popliteal vein.

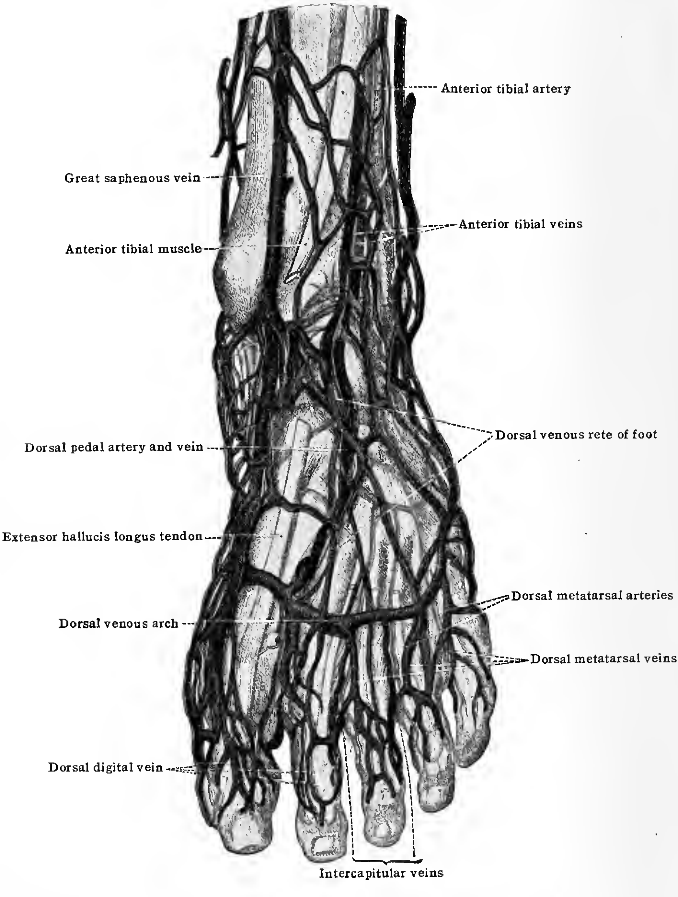
Tributaries.—As it passes up the calf between the superficial and deep fascia, it receives numerous cutaneous veins from the heel, and the lateral side and back part of the leg, and

FIG. 538.—THE SUPERFICIAL VEINS AND LYMPHATICS OF THE LEFT LOWER LIMB. (Walsham.)



communicates at intervals, through transverse or intermuscular branches, with the deep veins accompanying the peroneal artery. Just before perforating the deep fascia, it receives a large descending branch, the **vena femoropoplitea,** from the lower and back part of the thigh. This communicates with a plexus of veins upon the posterior and lateral regions of the thigh and with the great saphenous. In many cases the small saphenous vein is entirely drained, by means of the femoro-popliteal, into the great saphenous. Under these circumstances the usual place of termination of the small saphenous is marked by a small vein opening into the popliteal. A small offshoot from the inferior sural branch of the popliteal artery accompanies this vein for a

Fig. 539.—The Veins of the Dorsum of the Foot. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

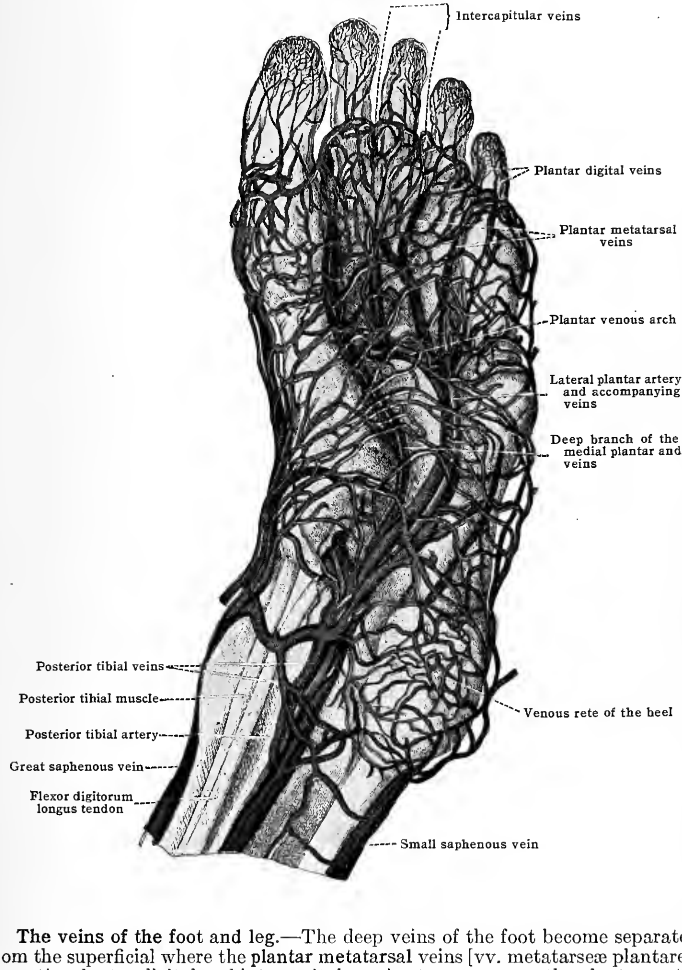


short distance down the back of the calf. The small saphenous vein contains from nine to twelve valves.

II. THE DEEP VEINS OF THE LOWER EXTREMITY

The **deep veins of the lower extremity** accompany the arteries, and have received corresponding names. From the foot to the knee there are two veins to each artery. These veins run on either side of the corresponding artery, and communicate at frequent intervals with each other across it. They are known as the venæ comitantes. From the knee upward there is a single main vein to each artery, except at the back of the thigh and in the gluteal region, where there are commonly two.

FIG. 540.—THE VEINS OF THE SOLE OF THE FOOT. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



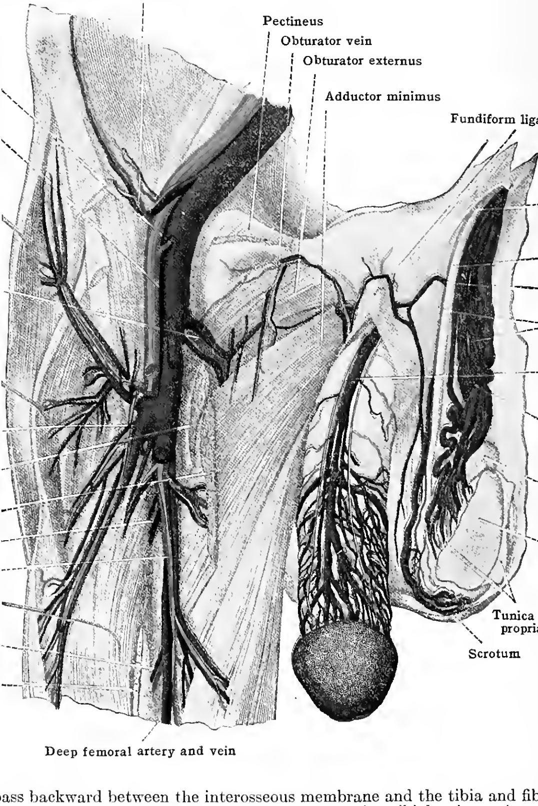
The veins of the foot and leg.—The deep veins of the foot become separated from the superficial where the **plantar metatarsal** veins [vv. metatarseæ plantares] leave the plantar digital and intercapitular veins to accompany the plantar metatarsal arteries. The plantar metatarsal veins empty into the **plantar venous arch** [arcus venosus plantaris] which accompanies the arterial plantar arch in the depth of the sole. (fig. 540)

The **posterior tibial** veins [vv. tibiales posteriores] drain the plantar venous arch and the superficial rete (fig 542).

They follow the posterior tibial artery up the leg, receiving tributaries corresponding to its branches, the largest of which are the peroneal veins [vv. peroneæ]. They unite with the anterior tibial venæ comitantes at the lower border of the popliteus muscle.

The **anterior tibial** veins [vv. tibiales anteriores] begin in the dorsal venous rete and accompany the anterior tibial artery up the leg receiving tributaries corresponding to branches of the artery.

Fig. 541.—The Femoral Vein. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



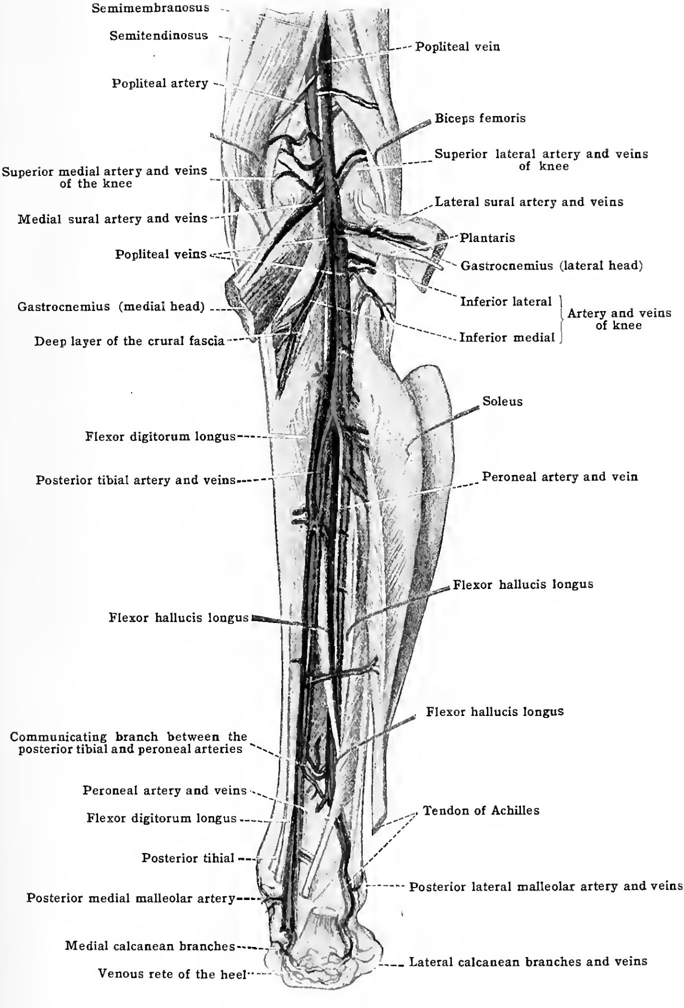
They pass backward between the interosseous membrane and the tibia and fibula to unite with the posterior tibial veins. The posterior and anterior tibial veins unite at the lower border of the popliteus muscle to form the popliteal vein.

All these veins contain numerous valves, and communicate, by means of intermuscular branches, with the superficial veins.

The **popliteal** vein [v. poplitea] (fig. 542), is formed by the confluence of the venæ comitantes of the anterior and posterior tibial arteries at the lower border of the popliteus, and extends upward to the opening in the adductor magnus at the junction of the middle and lower third of the thigh, where it changes its name to femoral.

It accompanies the popliteal artery, lying superficial to it in the whole of its course, and tightly bound down to it by its fascial sheath. At the lower part of the space it is a little medial to the artery, but, crossing the vessel obliquely as it ascends, lies a little lateral to it at the upper part of the space. The tibial (internal popliteal) nerve lies superficial to the vein, being lateral to it above, then posterior to it, and then a little to its medial side. The popliteal vein contains two or three valves.

FIG. 542.—THE DEEP VEINS OF THE LEG. (After Toldt, "Atlas of Human Anatomy," Rebman. London and New York.)



The popliteal receives the small saphenous vein. It is also joined on its lateral and medial sides by the *accessory popliteal* veins [vv. popliteæ accessoriæ] which form common trunks of termination of the sural and articular veins of the respective sides. The medial vein receives in addition, through a plexus extending as high as the opening in the adductor magnus, the veins accompanying the a. genu suprema.

The **femoral vein** [v. femoralis], the continuation of the popliteal upward, extends from the tendinous opening in the adductor magnus to the inguinal ligament. In this course its relations are similar to those of the femoral artery. As the vein passes through the adductor canal, it lies behind and a little lateral to the artery. At the apex of the femoral trigone (Scarpa's triangle) it is still posterior to the artery, but gradually passes to the medial side as it ascends through the trigone (fig. 541).

In the neighbourhood of the inguinal ligament the femoral vein lies on the same plane as the artery from which it is separated by a delicate prolongation of the fascia stretching between the front and back layers of the femoral sheath. On the medial side the vein is separated by a similar septum from the femoral canal. The femoral vein contains five pairs of valves.

Tributaries.—The femoral vein receives (in addition to the great saphenous vein, and, in some cases the superficial veins of the epigastrium and groin) the profunda veins and a variable number of small femoral venæ comitantes.

The **profunda femoris** veins [vv. profundæ femoris] arise from the venæ comitantes corresponding to branches of the profunda femoris artery. The **medial and lateral circumflex** veins [vv. circumflex femoris mediales et laterales] collect blood from the muscles of the adductor and lateral rotator regions. The **perforating** veins anastomose with femoro-popliteal and other veins of the posterior femoral region, and with the circumflex and accessory popliteal veins. They return blood from the femur and the adductor, hamstring and vasti muscles.

The **venæ comitantes**, much smaller than the main femoral vein, accompany the femoral artery on either side. They anastomose with one another, with the femoral, and often with the popliteal vein. They terminate in the femoral a short distance above the profunda veins.

MORPHOGENESIS AND VARIATIONS OF THE VEINS

The veins of the adult human body tend to accompany the arteries; this tendency is more pronounced in the trunk, neck, and extremities than in the cranium. Developmental history shows that the primitive distribution of the veins of the trunk resembles that of the arteries of the same region in its bilateral symmetry only. Also that the changes which modify the primitive bilateral symmetry of the chief veins are not only more extensive but of a different nature from those producing a similar effect upon the arteries. In both cases the main body-vessels begin as a pair of main longitudinal trunks and end as a main unpaired channel (or channels in the case of the venous system) situated near the median plane of the body. In the case of the venous system the change results from wholesale destruction of the vessels on the left of the body accompanied by enlargement of those upon the right. In the arterial system destruction occurs to a much more limited extent; the definitive channel results mainly from blending of the two primitive aortæ.

The main venous channels of the cranium and extremities are primitively superficial; in the cranium they remain so. In the extremities new veins are formed which follow the main arteries; to these the more primitive channels become tributary.

The heart, as soon as it assumes the simple tubular form is found to receive four veins. These, the two vitelline and two umbilical veins, enter the sinus venosus, a vitelline and an umbilical vein on either side. The umbilical veins are lateral to the vitellines, and are paired within the body only; they arise from the placenta, and traverse the belly-stalk as a single trunk. The vitelline veins return blood from the yolk sac, and, at first, are independent throughout.

At a later period two other pairs of veins arise for the venous drainage of the embryonic body. They are the pre- and post-cardinals which drain the cephalic and caudal regions respectively. The right pre-cardinal vein unites with the right post-cardinal to form the right common cardinal (duct of Cuvier). The latter runs in a medial direction to join the sinus venosus lateral to the right umbilical. On the left side the arrangement matches that on the right to produce a primitively symmetrical pattern.

During development changes are brought about in the primitive veins which end in the production of the adult venous system as follows: the common and pre-cardinals, together with the subclavian veins and the cephalic ends of the post-cardinals, are transformed into the vena cava superior and its larger tributaries. The remainder of the post-cardinal system is instrumental in the production of the vena cava inferior and its tributaries. Finally the intra-embryonic portions of the vitelline and umbilical veins participate in the formation of the portal and hepatic systems of veins together with the proximal end of the vena cava inferior.

The following brief account of morphogenesis and variations is divided into three headings (1) vena cava superior and its tributaries; (2) vena cava inferior and its tributaries, and (3) the portal system.

A. THE VENA CAVA SUPERIOR AND ITS TRIBUTARIES

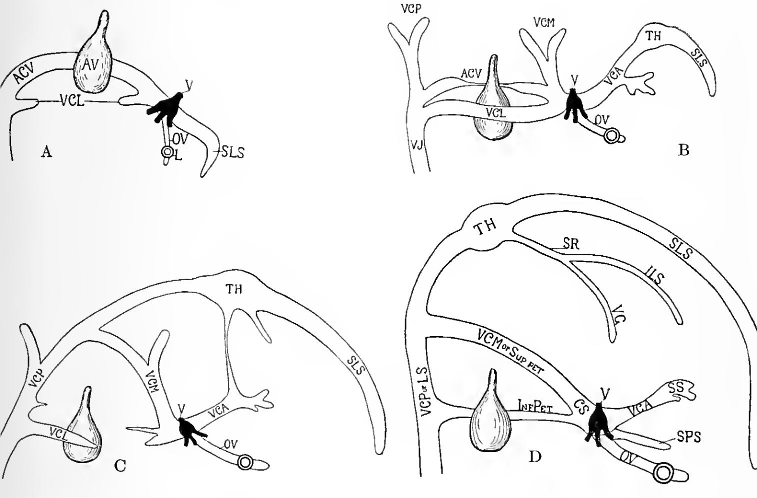
1. MORPHOGENESIS

The **pre-cardinal** veins at first return blood from the head only, but as the heart recedes into the thorax the cardinal veins migrate with it. In so doing the common cardinals lag somewhat behind and in consequence their direction, primitively transverse, approaches the longitudinal. The pre-cardinals, which have increased in relative length, now course symmetrically along the neck into the thorax. At a stage of 16 mm., the definitive subclavian vein has migrated from the common to the pre-cardinal, which henceforth receives the main venous flow from the upper extremity as well as from the head. The symmetrical arrangement of the cardinal veins is disturbed at a stage of about 18 mm., by the development of a transverse connection between the right and left pre-cardinals (fig. 544). This connection, the left innominate vein, arises, probably, by the development of cross-anastomoses uniting the lateral veins draining the developing thymus and thyreoid glands. On the right side of the embryo the veins of the adult are now recognisable as follows:—the vein (pre- and common cardinal) extending from the left innominate to the heart becomes the vena cava superior. The pre-cardinal, from the left innominate to the subclavian, becomes the right innominate. From the subclavian to the cranium it becomes the internal jugular.

The vessel of the left side corresponding to the vena cava superior now rapidly diminishes in size. It extends from the left innominate vein (the extreme left end of which corresponds in its method of formation to the entire right innominate) to the right atrium. In so doing it passes ventral to the aortic arch and the foot of the left lung, dorsal to the left artium, and through part of the coronary sulcus.

Fig. 543.—Semidiagrammatic Reconstructions of the Cranial Venous System. (Mall.) A, 4 Weeks; B, 5th Week; C, Beginning of 3rd Month; D, An Older Fœtus.

A.c.v; pre-cardinal vein; A.V., otic vesicle; Inf.Pet., inferior petrosal sinus; L., eye; O.V., superior ophthalmic vein; S.L.S., superior sagittal sinus; S.P.S. sphenoparietal sinus; S.R., sinus rectus; S.S., middle cerebral vein; T.H., confluens sinuum; V., semilunar ganglion; V.C.A., v. cerebralis anterior; V.J., internal jugular vein; V.C.L., v. capitis lateralis; V.C.M. or sup. pet., v. cerebralis media and superior petrosal sinus; V.C.P. or L.S., v. cerebralis posterior and transverse sinus.



The segmental veins draining the second, third and fourth intercostal spaces of the left side open, by a common stem formed by the left pre-cardinal, into the left innominate. The corresponding segmental veins of the right side open, by a common stem, into the vena azygos. The collecting stem, on either side, is the *vena intercostais suprema*. The method of origin of the azygos, hemiazygos and accessory hemiazygos veins is treated with the inferior caval system. Below the superior intercostal tributary, the left superior cava is lost to within a short distance of the sinus venosus. Here its lower end persists as the oblique vein of the left atrium and the left end of the coronary sinus. The former course of the left superior cava is often indicated in the adult by a small fibrous cord, uniting the extremities of the persisting veins and passing through the ligamentum v. cavæ sinistræ (p. 523).

Within the cranium the pre-cardinal veins are primitively in close contact with the brain and medial to the semilunar, acustico-facial, glossopharyngeal and vagus ganglia. The portion of each vein extending from the semilunar ganglion to the facial canal (its exit from the cranium) early becomes involved in a process of anastomosis-migration which eventually places it lateral to the ganglia and to the otocyst. The new vein formed in the latter situation is called the vena capitis lateralis (fig. 543). The portion of the pre-cardinal vein which remains medial to the semilunar ganglion persists as the adult *cavernous sinus* and receives a primitive vein (v. cerebralis anterior) which drains the orbit and the mid- and forebrain. The forebrain tributaries of the right and left v. cerebralis anterior unite to from a median vein, the definitive *superior sagittal sinus*, which at first drains into the cavernous sinus. There are two other primitive cerebral veins; the v. cerebralis media and v. cerebralis posterior. The first receives blood from the cerebellar region and drains into the cavernous sinus. The second, the v. cerebralis posterior, also receives blood from the hind-brain and, leaving the skull through the jugular foramen, joins the pre-cardinal (internal jugular) vein in the neck. Several changes occur from now on (fig. 543) which bring about the definitive relations of the dural sinuses and transfer the main venous exit from the stylomastoid to the jugular foramen. The right v. cerebralis posterior joins the superior sagittal sinus and this becomes the *right transverse sinus*. The left v. cerebralis posterior communicates with the junction of the superior sagittal and right transverse sinuses (now the *confluens sinuum*) and becomes *the left transverse sinus*. The confluens receives the sinus rectus, which forms its adult connections with the *inferior petrosal sinus* and *great cerebral vein*. The v. cerebralis media joins the transverse sinus to become the *superior petrosal sinus*. The latter forms a new (intracranial) means of drainage for the cavernous sinus and its tributaries. The original drainage channel of the cavernous sinus (v. capitis lateralis), having been supplanted. disappears. The *superior cerebral veins* drain into the superior sagittal sinus. The remaining portion of the interrupted v. cerebralis anterior drains the *middle cerebral vein* and *spheno-parietal sinus*. The *inferior petrosal sinus* arises *de novo*.

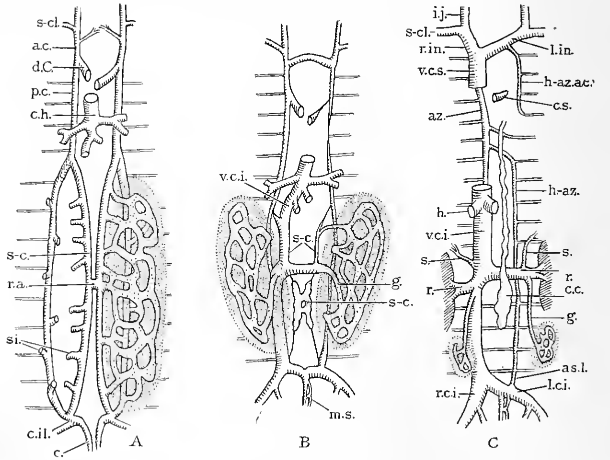
In the upper extremity the venous drainage is at first superficial and opens into the post-cardinal and umbilical veins. The ulnar limb of the loop-like early venous channel (marginal vein) becomes the *primitive ulnar vein*, but does not open into the pre-cardinal until a stage later than that of 10 millimetres. The primitive ulnar forms the *basilic*, *part of the brachial*, the *axillary*, and *subclavian* veins. It receives the large thoraco-epigastric trunk. The *cephalic vein*, which at first joins the external jugular, is of secondary formation. The venæ comitantes are formed later still.

2. VARIATIONS

The great veins of the thorax may present variations from the normal as a result of *absence of the left innominate vein*. In this case there are two superior cavæ, not necessarily of equal size, each of which receives an internal jugular and subclavian vein. Persistence of the left

Fig. 544.—The Transformation of the Postcardinal System of Veins, C representing the Adult. The Wolffian Body is Dotted. (Lewis.)

a.c., precardinal; as. l., ascending lumbar; az., azygos; c., caudal; c.h., common hepatic; c. il., common iliac; c.s., coronary sinus; d.C., common cardinal; g., spermatic or ovarian; h., hepatic; h.-az., hemiazygos; h.-az. ac., accessory hemiazygos (here draining into the intercostalis suprema); i. j., internal jugular; l.c.i., left common iliac; l. in., left innominate; m.s., middle sacral; p.c., posterior cardinal; r., renal; r.a., renal anastomosis; r.c.i., right common iliac; r. in., right innominate; s., suprarenal; s-c., subcardinal; s-cl., subclavian; s.l., sinusoids; v.c.i., vena cava inferior; v.c.s., vena cava superior.



vena cava superior without failure of the left innominate may occur in three classes of cases: (*a*) In which both cavæ are present, equal in size or asymmetrical. (*b*) In which the *left cava only* occurs, associated with situs inversus. (*c*) In which the *left cava only* is present, *without situs inversus*. The left vena cava superior, when present, crosses in front of the aortic arch and enters the right atrium by way of the coronary sinus, collecting the coronary veins. Cases are on record of a left superior cava terminating in the left atrium.

The azygos veins.—Variations of these veins and of the intercostal veins have been dealt with on pp. 663–664. For their morphogenesis, see under vena cava inferior.

The **veins of the neck, face, and scalp.**—These veins have so many variations in detail that it is difficult, in the case of some veins, to assign their normal distribution. The *external jugular*, for instance, is usually described in English text-books as a tributary of the subclavian vein; it is assigned by the BNA to the internal jugular. It is frequently found to open into the angle between the two, or, forming a plexus with its tributaries, drain into both. The origin of the external jugular vein is also exceedingly variable. The external jugular may be small, or absent, in which case the *anterior jugular* is large. The reverse may be the case since the external jugular frequently receives the *posterior*, and sometimes the *common facial*. Fortunately venous variations are not of prime surgical importance.

Veins of the cranium.—The *venous sinuses* of the dura mater are not subject to important variations. Variations in the relative size of the *transverse sinuses* have been referred to on p. 651. The *petro-squamous sinus*, occasionally present, is described on p. 653. The *occipital* and *inferior sagittal sinuses* are frequently absent.

The *cerebral veins* are liable to great variation in detail: the *great cerebral vein* may be absent, as a single trunk, in which case the *internal cerebral veins* open directly into the sinus rectus. The *middle cerebral vein* may open into the sphenoparietal, or superior petrosal sinus or into the basilar plexus.

Veins of the upper extremity.—The subclavian vein is occasionally posterior to the artery, or splits to enclose the latter and the anterior scalenus. Either case represents a partial retention of the early condition in which the vein passes behind the brachial plexus. Variations in the *superficial veins* have been referred to on p. 668. The question of the most common distribution of these vessels has lately been fully reviewed by Berry and Newton. The *cephalic vein* occasionally opens into the external jugular by persistence of the embryonic jugulo-cephalic vein.

B. THE VENA CAVA INFERIOR AND ITS TRIBUTARIES

1. MORPHOGENESIS

The right and left **post-cardinal** veins (fig. 544) are at first symetrical in size and position. Early in development each posterior cardinal vein becomes involved in the growth of the corresponding mesonephros, and the original venous channel is converted into a system of sinusoids. In the sinusoidal circulation of each mesonephros two main longitudinal venous channels soon make their appearance. One lies ventro-medial to the mesonephros and is called the *sub-cardinal* vein. The other, which lies dorsal to the mesonephros, receives the segmental veins and is frequently called the post-cardinal. Since the mesonephric segment of the post-cardinal vein has obviously passed out of existence, the vein in question (unlabelled in fig. 544) will be here distinguished as the *dorsal trunk*. The sub-cardinals communicate freely between themselves and with the dorsal trunks, lie ventral to the mesonephric arteries, and are at first symmetrical. The cephalic end of the right sub-cardinal now acquires a communication with the common hepatic vein, thus providing a new means of drainage for the sub- and post-cardinal systems (fig. 544). The rapidly enlarging main venous channel resulting from this alternative method of drainage follows the right dorsal trunk as far as the level of the permanent renal veins. It is then transferred, by means to an anastomosing channel, to the right sub-cardinal and, through this, to the common hepatic vein; it becomes the *vena cava inferior*. From now on the portions of the sub-cardinal veins not participating in the formation of the cava dwindle rapidly. A cross anastomosis between the right and left sub-cardinals persists as the portion of the adult left *renal vein* which crosses ventral to the aorta. By means of it the remainder of the left renal; the left *internal spermatic* and left *suprarenal* veins are connected with the vena cava. The left lumbar and left common iliac veins are also transferred to the vena cava, probably by direct anastomosis with the left post-cardinal vein. The vena cava inferior is at first lateral to the right ureter, its transference to the medial side occurs through anastomosis.

The portion of the right posterior cardinal vein above the mesonephric region, together with its continuation into the dorsal trunk, becomes the *azygos* vein (fig. 544). The corresponding vessel upon the left side is transformed into the *accessory hemiazygos* and *hemiazygos* veins. The hemiazygos vein is drained into the azygos by means of an anastomosing channel which may also drain the accessory hemiazygos. The variability of the means of drainage of the accessory hemiazygos vein, by means of anastomosing channels, is referred to on p. 663. The *ascending lumbar* veins are anastomosing channels of new formation.

In the **lower extremity,** as in the upper, the original superficial plexus is gradually drained by a loop-like marginal vein. The fibular limb of this loop, the primitive fibular vein, becomes *small saphenous;* it follows the sciatic nerve and opens into the post-cardinal. The next vein to be developed is the *great saphenous;* the small saphenous is transferred to this by an anastomosing vein which is usually present in the adult—the *femoropopliteal* vein. The deep veins are of later formation. The drainage of the small saphenous is usually taken over by the popliteal vein.

2. VARIATIONS

In determining the probable embryonic cause of variations of the vena cava inferior the possibility of abnormal persistence of the sub-cardinal veins must be remembered. The position of transverse anastomoses with regard to the aorta is often the key to diagnosis. Instructive cases of abnormalities of the vena cava inferior have recently been published by v. Alten and by Neuberger (see References). Both articles contain bibliographies. The chief variations are as follows:—

(1) The inferior vena cava, in cases of transposition of the viscera, may lie on the left side of the aorta. (2) Without transposition it may also lie to the left of the aorta, crossing to the right to gain the caval opening immediately below the diaphragm, or after receiving the left renal vein. (3) It may be double, the left cava than usually passing across the aorta into the right after receiving the left renal vein. A communication between the right and left veins in the position of the normal left common iliac vein may or may not then exist. (4) The inferior vena cava may be absent, the blood from the lower extremities passing by a large vein in the position of the ascending lumbar and azygos veins through the diaphragm to open into the superior vena cava. The hepatic veins then open directly into the right atrium through the normal caval opening in the diaphragm. (5) The inferior vena cava may receive the left spermatic vein. (6) It may receive a left accessory renal vein passing behind the aorta, and into this the usual tributaries of the left renal vein may open. (7) It may receive several accessory renal veins; as many as seven on each side have been met with. (8) The lumbar veins may enter it on one or both sides as a common trunk.

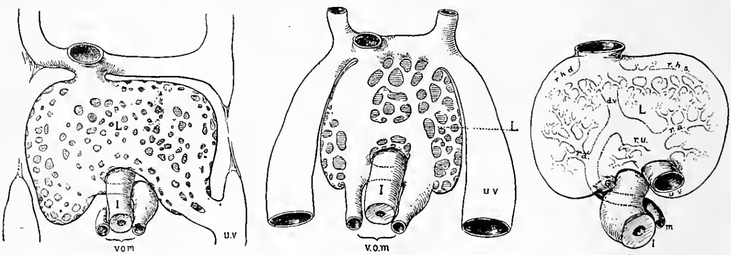
The variations in the veins of the lower extremity are for the most part unimportant. They have been mentioned in the description of the corresponding veins.

3. THE PORTAL SYSTEM OF VEINS

The portal system arises by transformations in the vitelline and umbilical veins. The proximal ends of the vitelline veins, where they lie between the umbilicals, are early enveloped in, and invaded by, the growing liver. The columns of liver cells, while not penetrating the endothelium, subject the vitelline veins to a process of fenestration by which the original channels are subdivided into innumerable smaller vessels or sinusoids. The *sinusoids* arising from the two vitelline veins intercommunicate to form one continuous network in which the vessels are larger in the afferent (portal) and efferent (hepatic) areas than in the intermediate zone.

Fig. 545.—Semidiagrammatic Reconstructions of the Veins of the Liver, Ventral Aspect (Mall). A, Embryo of 4.5 mm. Long; B, 4 mm. (more advanced than A); C, 7 mm.

d.v., ductus venosus; I., intestine; L., liver; m., superior mesenteric (continued as portal) vein; r.a., ramus angularis; r. a'., right branch of portal vein; r.h.d., right hepatic vein; r.h.s., left hepatic vein; r.u., recessus umbilicalis; u.v., left umbilical vein (the right umbilical vein is not labelled); v.o.m., vitelline veins.



The two umbilical veins now form communications with the portal area of the sinusoidal network and eventually lose their original connections with the sinus venosus (fig. 545). The fate of the umbilical veins differs on the two sides; the right degenerates, from the sinus venosus to the common umbilical vein, and leaves the left to receive all the blood flowing from the placenta. The left, having lost its connection with the sinus venosus, discharges its blood partly into the portal sinusoidal zone, and partly, by means of the newly formed direct channel, the *ductus venosus*, into the right vitelline (fig. 545).

The hepatic end of the right vitelline vein enlarges considerably, for the left vitelline loses its original connection with the sinus venosus. It transmits blood both from the sinusoids and from the ductus venosus to the sinus venosus, and is called the common hepatic.

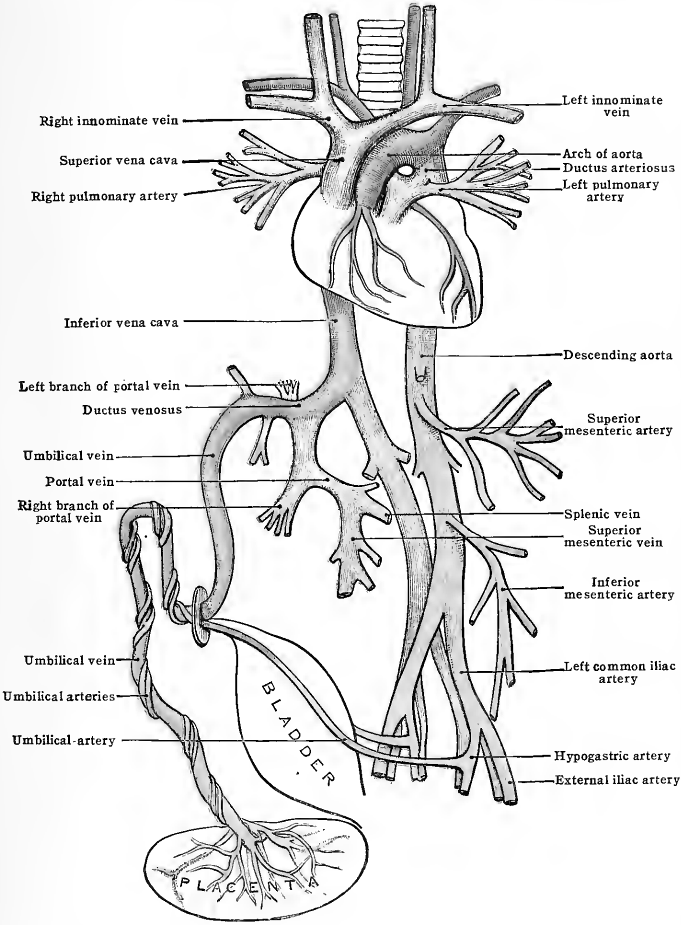
The vitelline veins are not only connected within the liver, but their distal ends become united upon the yolk-stalk to form a single trunk. A third communication between them is effected by a transverse vessel passing dorsal to the duodenum. The portion of the right vitelline below the transverse vessel disappears, as does the portion of the left between it and the liver. A tortuous vitelline vein is thus produced which enters the liver by passing dorsal to the intestine from left to right. This vessel is joined, to the left of the intestine, by the superior mesenteric vein and, dorsal to it, by the splenic. When the portion of the vitelline below the termination of the superior mesenteric finally disappears the vessel extending from the splenic vein to the liver becomes the portal vein of the adult.

Important variations of the portal system are rarely found in the adult. The mechanism of anomalies found in the embryo have been investigated by Begg (Amer. Jour. Anat., Vol. 13).

FŒTAL CIRCULATION

The changes which accompany the transformation of the fœtal type of circulation into that of the adult are initiated by the first inspiration. Prior to this act the functions of external respiration and digestion are performed by the

FIG. 546.—THE HEART, WITH THE ARCH OF THE AORTA, THE PULMONARY ARTERY, THE DUCTUS ARTERIOSUS, AND THE VESSELS CONCERNED IN THE FŒTAL CIRCULATION. (From a preparation of a fœtus in the Museum of St. Bartholomew's Hospital.)



mother; the fœtal venous blood passing to the placenta through the umbilical arteries and returning through the umbilical vein.

At the time of birth the right and left chambers of the heart communicate only by means of an oblique passage between the overlapping atrial septa (p. 511). The pulmonary artery and descending aorta communicate by means of the ductus arteriosus (p. 508).

Arterial blood, transmitted from the placenta through the umbilical vein, passes almost entirely by way of the ductus venosus to the vena cava inferior. From here it passes through the right atrium; then, obliquely between the atrial septa into the left atrium, from which it passes through the left ventricle and into the ascending aorta. Escaping largely through the branches of the aortic arch, it is distributed to the head and upper extremities, and returned to the vena cava superior. Having reached the right atrium it passes, to the right of the stream from the vena cava inferior (p. 513), through the atrio-ventricular ostium into the right ventricle. The blood issuing from the right ventricle into the pulmonary artery goes almost entirely (the lungs being functionless) into the ductus arteriosus and so into the descending aorta. Having performed two circuits, the blood returns to the placenta through the umbilical branches of the hypogastric arteries.

The two streams, arterial and semi-venous, cross one another in the right atrium. The degree of intermixture, if any, which occurs in this cavity has been the subject of much discussion; for literature and experimental evidence on this point see Pohlmann, A. (Johns Hopkins Hosp. Bul., Vol. 18, 1907.)

When the lungs assume their function at birth the pressure in the left atrium is suddenly raised by an inrush of blood. The overlapping atrial septa (primum and secundum) are brought into lateral apposition and thus the blood entering the right atrium finds but one exit—the atrio-ventricular ostium. Since the vessels of the expanded lungs now transmit a greatly increased volume of blood, the stream passing through the ductus venosus is diminished proportionately. The blood traversing the aortic arch, released from the check exerted by the lateral stream pouring from the ductus arteriosus, passes more readily into the descending aorta; thus the adult equilibrium is established.

SECTION VI

THE LYMPHATIC SYSTEM

REVISED FOR THE FIFTH EDITION

By ELIOT R. CLARK, A.B., M.D.

ASSOCIATE IN ANATOMY, JOHNS HOPKINS MEDICAL SCHOOL

I. GENERAL ANATOMY OF THE LYMPHATIC SYSTEM

THE blood-vascular system has, as a part of its function, the collection of substances from the various tissues of the body which are to be conducted to the other tissues. In carrying on this function it is assisted by a second system of collecting vessels, the lymphatics.

This second system resembles the blood-vascular system in many ways, but differs markedly in others. Like the blood-vascular system, it is made up of minute endothelial-lined capillaries, where the absorption of substances occurs, and of larger conducting vessels. It differs from the blood-vascular system in two important particulars. While the blood-vascular system is provided with a pumping mechanism by which its fluid content is driven through a complete circuit from the heart, through artery, capillary, vein and back to the heart, the lymphatics merely conduct fluid *from* the capillaries to the larger vessels, which eventually empty their contents into the large veins of the neck. The second important difference between the two systems is found in the presence, along the course of the lymphatic vessels, of glands or nodes (fig. 553) [lymphoglandulæ] in which the vessels branch out into lymph capillaries. These are lined, as are the absorbing capillaries, with a single layer of endothelial cells, thus permitting an interchange of substances between the contents of the lymph capillaries and the lymphoid tissue around them.

Our present knowledge does not permit an exact statement of the complete extent of the lymphatic system. While, in a general way, the lymphatics may be said to be present wherever blood-capillaries occur, there are certain tissues where lymphatics have not been definitely demonstrated.

The general constitution of the lymphatic system will be considered under three heads—(1) the capillaries, (2) the collecting vessels and (3) the lymphoid organs.

1. *THE LYMPHATIC CAPILLARIES*

The lymphatic capillary, like the blood-capillary, is the portion of the lymphatic system which is chiefly concerned in the specific function of this system. In the blood-capillaries, where the blood is separated from the outside tissues by a single layer of flat endothelial cells, there occurs the interchange of fluid substances and of cells, while the heart, arteries and veins serve to transport the blood, modified in the capillaries, to other parts of the body. Similarly in the lymphatic system, it is in the capillaries, both those most peripheral and those in the lymph nodes, where the absorption and interchange of fluid substances and of cells takes place. Consequently it becomes of prime importance to obtain a clear understanding of the structure of the lymphatic capillaries, their relation to the other tissues, and their mode of functioning. At the outset, however, it must be admitted that our knowledge on this subject is far from complete.

Historical.—Previous to the development of microscopic anatomy, in the middle third of the 19th century, there was no accurate knowledge of such small structures as the lymphatic capillary. In order to explain the absorption of substances by the lymphatics, as well as the passage of substances from the blood-vessels through the tissues, various theories were invented. Prominent among such theories was that of the "vasa serosa," of H. Boerhaave and other 18th century anatomists and physiologists, which was perhaps most elaborately developed by Bichat, 1801–03. According to this theory there are two sets of minute vessels, too small for the passage of cellular elements. The one set leads from the blood-capillaries onto the various surfaces of the body and into the loose spaces in the tissues—the "exhalants." The other set leads from the body surfaces (including the serous cavities) and the loose spaces in the tissues to the lymphatics—the "inhalants" or "absorbants," which take in fluids by a sucking action.

This theory was somewhat shaken by the discovery of Magendie, in the first decade of the 19th century, that absorption may take place by the veins, as well as the lymphatics, and by the criticism of early 19th century anatomists who developed the technic of injection of lymphatics to a high point.

Our present conception of the lymphatic capillaries may be said to have started with Kölliker who, in 1846, saw, with the aid of the microscope, the lymphatic capillaries in the transparent tails of living frog larvae. He found them to be definite structures made up of a thin wall, from which projected fine-pointed processes, and in which were nuclei. Like Schwann who, in 1837, had studied the blood-capillaries in the tail of the frog larva, he erroneously supposed that the fine processes of the lymphatic capillaries were continuous with similar processes of the surrounding connective-tissue cells. Since, according to the conception current at the time, cells were thought to be hollow structures, with a membranous wall and fluid content, it was concluded that the mode of transmission of fluid from blood to lymphatic capillary took place through canaliculi inside these cells. This conception was elaborated by Virchow, in his Cellular-Pathologie.

In 1862 von Recklinghausen by means of the silver nitrate staining method discovered that the lymphatic vessels are lined with an endothelium made up of flattened cells whose outlines show as fine dark lines after this treatment. Again, however, as a result of the eagerness to find open passages through the tissues from blood to lymphatic capillary, an erroneous interpretation was made. von Recklinghausen held that the unstained parts outside the lymph vessels represent a system of irregularly shaped lymph-canaliculi ("Saftkanälchen") which are in open communication on the one hand with the blood-capillaries, and on the other with the lymphatics This conclusion has since been disproved by numerous investigators.

In a second series of observations, von Recklinghausen brought evidence in favor of open communications between the lymphatics and the peritoneal cavity. He watched, under the microscope, the passage into lymphatics, through minute openings, of milk, placed on a portion of the central tendon of the diaphragm. These minute openings he termed "stomata." Cohnheim described similar though smaller openings in blood-capillaries, and His described them in other lymphatic capillaries. Arnold termed the openings in the vessels "stigmata," as distinguished from the openings into the peritoneal cavity, or "stomata."

With the advent into microscopical technic of the various dyes for staining cell-nuclei and protoplasm, and the more precise methods for making histological studies, the endothelial wall of the lymphatic capillary has been definitely established, although much remains to be learned concerning the differences between the lymphatics of the various tissues.

Moreover, recent investigators have failed to find open connections between the lumen of the lymphatic vessel and the tissue outside. Kolossow failed to find the "stomata" of von Recklinghausen and the "stigmata" of Cohnheim, His and Arnold. The "stomata" have been carefully studied by a number of other recent investigators. All agree in finding a complete endothelial lining for the lymphatic capillaries lying underneath the peritoneum and pleura, with no openings or "stomata." Careful studies of the lymphatic capillaries in the transparent tails of living frog larvae, which may be clearly seen with the higher magnifications of the microscope, show that the endothelial lining of these capillaries is complete, with no trace of an opening into the spaces in the tissue outside (E. R. Clark).

Form.—The shape of the lymphatic capillaries has been found to vary enormously in the different parts of the body, where they have been studied. In general they form richly anastomosing plexuses, from which may extend cul-de-sacs, which end blindly. Such cul-de-sacs are especially noticeable in the dermal papillæ, in the filiform papillæ of the tongue, and in the intestinal villi. The plexuses are often present in two layers—a superficial and a deep. The vessels of the superficial plexus are of smaller calibre than those of the deep. These two sets of plexuses are particularly well seen in the skin and the gastro-intestinal tract. In relation to the blood-capillaries, the lymphatic capillaries are generally the more deeply placed.

In calibre, unlike the comparatively uniform diameter of blood-capillaries, the lymphatics vary enormously. In the same capillary a very narrow part may be succeeded by a very wide one (figs. 547, 548). Teichmann found lymphatic capillaries varying in diameter from a few thousandths of a millimetre to one millimetre. In the capsule of the spleen of the cow some measured more than 1.5 mm.! The capillaries are without valves.

Activity.—That the lymphatic endothelium is not exclusively a passive membrane has been shown by Clark in studies on the lymphatics in the transparent tails of living frog larvæ. The lymphatics here are seen to send out protoplasmic processes which, somewhat like an amœba, actively take into the interior of the lymphatic red blood-cells accidentally forced from the blood-capillaries into the tissue-spaces.

The mode of passage of leucocytes into or out of the lymphatics offers no such difficulties as that of the fluids, for they are able, through their power of amœboid movement, to pass independently through the endothelium—a process first directly observed by Cohnheim.

1. The Extent and Character of Lymphatic Capillaries

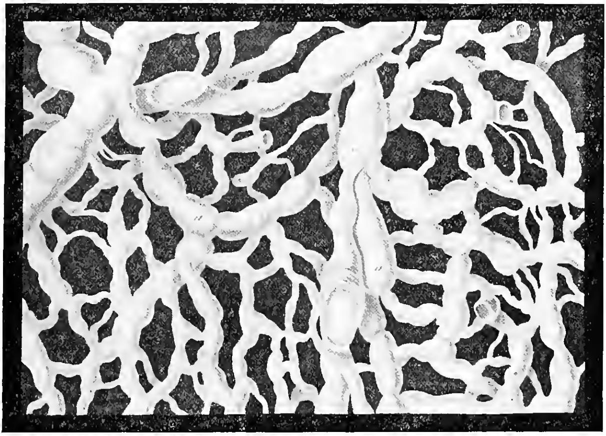
The *skin* over the entire surface of the body is richly provided with lymphatic capillaries. They form two sets of plexuses in the dermis, a superficial and a deep. The superficial set sends out blind cul-de-sacs into the dermal papillæ. The richest skin plexuses are found in the scrotum, the palms of the hand and palmar side of the fingers and in the soles of the feet and plantar side of the toes. In the loose *subcutaneous* fascia, according to Teichmann, there are present only the larger collecting vessels, with no lymphatic capillaries. Lymphatic capillaries of the *scrotum* are shown in Fig. 547.

The *conjuntiva*, both the sclerotic and corneal, is supplied with a rich plexus of capillaries, which are narrower in the corneal than in the sclerotic portion. At the corneal border the capillaries form a fairly regular ring which has been called by Teichmann a circulus lymphaticus.

At the various *orifices* of the body, the skin plexuses go over into the mucous plexuses, forming anastomoses with them. Throughout the entire *alimentary tract*, including the nasal cavities, the lymphatic capillaries form extensive plexuses which are in many places divided into a superficial plexus in the mucosa and a deeper plexus in the submucosa. In portions provided with a peritoneal covering, there is a third rich subserous plexus. In the tongue and the small intestine the plexus in the mucosa sends out blind cul-de-sacs; in the tongue into the filiform papillæ; in the small intestine into the villi. Where muscle is present along the alimentary tract, the lymphatics pass between the muscle bundles, but form no plexuses around them.

The lining of the *tracheal* and *bronchial passages* is supplied with a double plexus of lymphatic capillaries, a mucous and a submucous set, which vary in richness according to the looseness of the tissue. In the smaller bronchi but a single layer of capillaries is present, and, according to Miller, no capillaries are present around the air cells. Plexuses surround the pul-

Fig. 547.—The Lymphatics of the Scrotum. (After Teichmann.) Showing the transition of the capillaries to the vessels with valves (*a*, *a*, *a*).



monary arteries and veins. Under the *pleura* lie rich plexuses which connect with the deeper lymphatics around the veins only in places where the veins reach the surface of the lung.

Concerning the arrangement of the lymphatic capillaries in the *glands* derived from the alimentary tract much remains to be learned.

The *salivary glands* have been recently studied anew by Aagaard, who has found lymphatic capillaries accompanying the blood-vessels into the interior of the lobules, and forming here irregular plexuses.

The *thyreoid gland* contains lymphatic plexuses which lie in relation to the colloid-containing alveoli. Direct connection between the lymphatics and the alveoli has lately been described by Matzunaga, but this observation needs verification. The lymphatics are apparently concerned in the absorption of the colloidal secretion, for traces of it have been found in the lymphatics draining the gland.

Concerning the lymphatics of the *parathyreoids* nothing is known.

The course of the lymphatics draining the *thymus* has been recently described, but the nature of the capillaries in this gland is unknown.

The lymphatic capillaries of the *liver* are of great importance, for the lymph which flows from this organ forms a very considerable part of the total lymph which is collected into the thoracic duct. And yet very little is definitely known about the nature and distribution of the lymphatic capillaries in the interior of the organ. In the capsule there is a rich plexus, lying under the peritoneum, in which very large widenings have been described (called by Teichmann "Lymphbehälter"). In the interior rich plexuses surround the branches of the hepatic artery and portal vein (fig. 549), and plexuses have been described accompanying the branches of the portal vein into the lobules.

The linings of the large *bile-ducts* and the *gall-bladder* are provided with a submucous network of lymphatics (Sudler and Clermont). The gall-bladder has also a rich subserous plexus.

Concerning the lymphatic capillaries of the *pancreas* Bartels notes briefly that they form richly branched plexuses in the interlobular connective tissues, which surround larger or smaller parts of whole lobules, not the single gland elements.

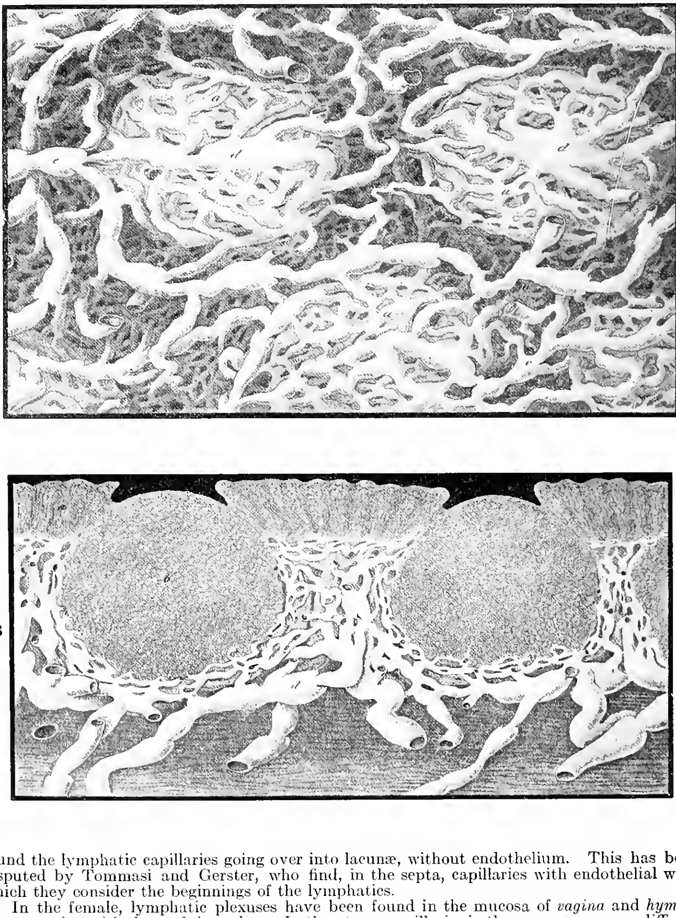
The mucous lining of the *genito-urinary tract*, wherever it has been carefully studied has been found provided with plexuses of lymphatics. In the *bladder* they form a rich plexus of irregular capillaries which lie immediately under the almost intraepithelial blood-capillaries. They connect, through the muscular layer, with a subserous plexus. The lymphatic plexus of the *urethra* anastomoses with the capillaries of the base of the bladder, and in the male with those of the glans penis. The lymphatic capillaries of the ductus deferens and of the seminal vesicles have not been studied. In the *prostate* (Camineti) the lymphatics form rich plexuses surrounding the glands, which connect with a very wide meshed subcapsular plexus, surrounding the entire gland.

In the *testis* there is a rich superficial plexus, lying directly beneath the tunica albuginea. Concerning the deep lymphatics of the testis there has been much dispute. Ludwig and Thomsa

Fig. 548.—Surface View and Section of Lymph-nodes of the Intestine. A. Solitary follicle. B. Peyer's patch. (After Teichmann.)

A

B



found the lymphatic capillaries going over into lacunæ, without endothelium. This has been disputed by Tommasi and Gerster, who find, in the septa, capillaries with endothelial wall, which they consider the beginnings of the lymphatics.

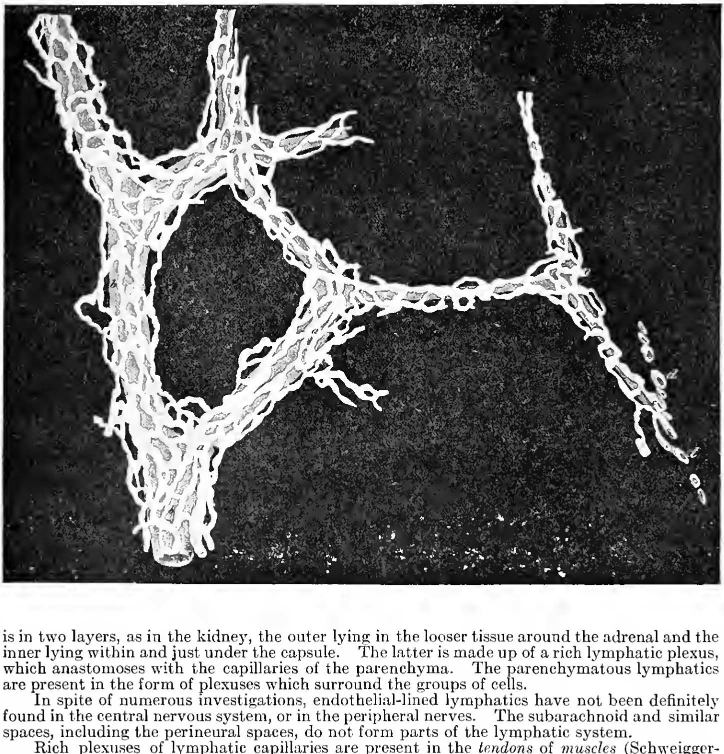
In the female, lymphatic plexuses have been found in the mucosa of *vagina* and *hymen*, anastomosing with those of the vulva. In the *uterus*, capillaries in the mucosa are very difficult to demonstrate. Definite lymphatics, however, have been found passing through the muscularis, and under the peritoneum a rich subserous plexus of capillaries is present. In the pregnant uterus these subserous capillaries are much distended (Schick). The *Fallopian tubes* are provided with lymphatics, but they have not been carefully described.

The *ovary* has a rich superficial lymphatic plexus. In the interior of the gland, according to His, the capillaries form networks in the connective-tissue framework. In the tunica externa of the follicles there is a rich plexus.

The *kidney* has two sets of lymphatics, a superficial, capsular set, and a deep set. The capsular set is divided into two layers, one lying directly beneath the peritoneum made up of a wide meshed plexus, and the other in the fibrous capsule of the kidney, with finer capillaries and narrower meshes, which anastomose with the deeper capillaries. The lymphatic capillaries of the kidney parenchyma have recently been described by Kumita. He found rich plexuses in both cortex and medulla, surrounding the straight and convoluted tubules, the loops of Henle and the collecting tubules. He also found a plexus surrounding and accompanying the blood-vessels into the interior of the glomeruli.

The lymphatic capillaries of the *adrenal* have also been described recently by Kumita. His results agree with those of Stilling, who studied the lymphatics of the adrenal of horse, cow and calf. Like the kidney, the adrenal possesses a superficial and a deep set. The superficial set

FIG. 549.—LYMPHATIC PLEXUS AROUND THE PORTAL VEIN IN AN ADULT MAN. (After Teichmann.) Showing the supporting relation of the vein.



is in two layers, as in the kidney, the outer lying in the looser tissue around the adrenal and the inner lying within and just under the capsule. The latter is made up of a rich lymphatic plexus, which anastomoses with the capillaries of the parenchyma. The parenchymatous lymphatics are present in the form of plexuses which surround the groups of cells.

In spite of numerous investigations, endothelial-lined lymphatics have not been definitely found in the central nervous system, or in the peripheral nerves. The subarachnoid and similar spaces, including the perineural spaces, do not form parts of the lymphatic system.

Rich plexuses of lymphatic capillaries are present in the *tendons* of *muscles* (Schweigger-Seidel and Ludwig). In muscles, themselves, the question of the presence of lymphatics has long been disputed, sometimes answered in the affirmative, more often in the negative. A recent study by Aagaard, however, would seem to place beyond doubt the presence of lymphatic capillaries in *striated muscles*. By long continued injection, he was able to find lymphatics in the intramuscular portions of the tendons, which extended out among the muscle fibres themselves. He also found capillaries in the tongue musculature.

The *heart* is provided with a subpericardial plexus of lymphatic capillaries. A subendocardial plexus has also been described (Sappey, Rainer). Bock has recently found that there is an extremely rich lymphatic network throughout the substance of the heart. According to his description, the lymphatic capillaries are more numerous than the blood-capillaries.

The *periosteum of bones* is provided with a rich plexus of lymphatic capillaries. They are present in several layers, of which the outermost form the richest plexus. Lymphatic capillaries have also been described accompanying the blood-vessels in the Haversian canals in bones (Rauber, Schwalbe, Budge). Nothing is known concerning the lymphatics of the bone marrow. *Cartilage* lacks both blood and lymphatic capillaries.

The capsular membranes of joints are richly provided with lymphatic capillaries (Tillmanns). They are arranged in two layers—an inner layer made up of a rich plexus of wide capillaries, lying just outside the subendothelial blood-capillaries, and an outer layer, consisting of a rich plexus in the subsynovial tissue. The lymphatic capillaries have no open connection with the joint cavity.

The membranes surrounding the *pleural*, *pericardial* and *peritoneal cavities* are richly supplied with lymphatic capillaries, which form here thick plexuses outside the endothelium. These plexuses are usually described with the underlying organ, as the subserous lymphatic capillaries of the intestine, etc. In the central tendon of the diaphragm the subperitoneal lymphatics are extremely rich. They widen out here to form very large endothelial-lined cavities which, in the spaces between the connective-tissue bundles, lie directly in contact with the peritoneal epithelium. The existence of open connections between these capillaries and the peritoneal and pleural surfaces (the "stomata" of von Recklinghausen) has recently been disproven. The capillaries on the two surfaces of the central tendon communicate freely with one another.

2. *THE LYMPHATIC VESSELS*

The lymph which enters the lymphatic capillaries passes over into collecting vessels (ducts), which carry it through the lymph-glands (nodes) to the large veins at the base of the neck. The lymph-vessels course in the loose subcutaneous tissues, in the connective tissues between muscles and organs, often accompanying the arteries and veins, sometimes forming networks around them. An idea of their arrangement can be best obtained by glancing at the illustrations of the lymphatics of special regions. In general they are made up of numerous long, narrow vessels, rarely more than half or three-fourths of a millimetre in diameter, which occasionally communicate with one another, and which radiate toward groups of lymph-glands placed in certain definite regions. In the lymph-glands the afferent lymph-vessels break up into capillaries, which again collect into efferent vessels. Several of these efferents from each lymph-gland may pass to a second lymph-gland, where they undergo a second widening into capillaries. In this way the lymph, passing through one, two, three or more lymph-nodes in succession, eventually reaches the thoracic duct, or one of the short ducts, all of which empty into the large veins at the base of the neck. The thoracic duct, which receives, at its lower end, the lymph from the lower half of the body, is the only lymphatic vessel which attains any considerable size (four to six millimetres in diameter) and is usually the only one large enough to be seen readily without injection.

In *structure* the lymphatic vessels much resemble the veins. They possess an intima, a media and an adventitia, although the line of demarcation between the different layers is not sharp. In the thoracic duct, the endothelium of the intima is succeeded by a delicate layer of fibres, mainly elastic; outside of this is the media, made up mainly of circular smooth muscle-cells, interspersed with elastic and connective-tissue fibres; then follows a layer of coarse elastic and connective-tissue fibres, which is succeeded by the adventitia, containing longitudinal and transverse bundles of smooth muscle-cells, as well as blood-vessels and nerves. The other lymphatic vessels possess the three layers, which, however, toward the capillaries, grow thinner, and eventually reach a stage in which, outside the endothelium, there are found only single muscle-cells, or muscle-cells in groups of two or three.

The lymphatic vessels are characterised by their great richness in valves, which are present throughout their entire course, from their beginnings in the capillary region to their openings into the veins of the neck. The valves are bi- or tri-cuspid, and are always arranged so as to prevent the flow of lymph back to the capillaries. They thus aid indirectly in the movement of the lymph, in that any external pressure on the vessels must always force the lymph onward.

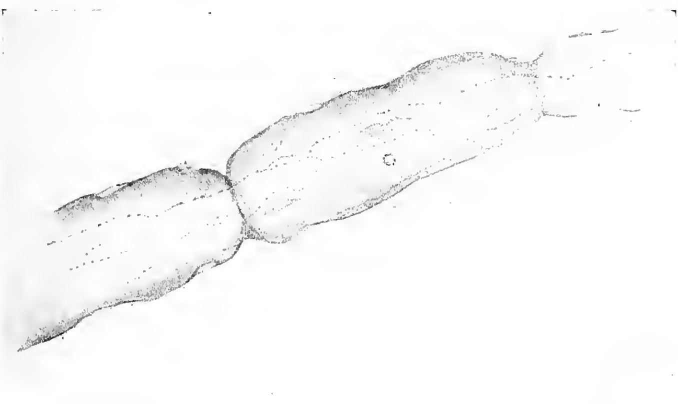
Nerves of lymphatic vessels.—That the thoracic duct and the smaller lymphatic vessels are provided with nerves has been shown by several observers. According to Kytmanoff (in dogs) the nerves to the lymphatics are mainly non-medullated, and are both motor and sensory. They form four sets of plexuses—adventitial, supramuscular, intermuscular and subendothelial. Sensory nerve-endings (fig. 550) are found in adventitia and media, in the form of free-ending threads, and bush-like endings. Motor endings are present in connection with the smooth muscle cells of the media. In the intima there is a plexus of extremely fine varicose threads. The physiological action of the nerves supplying the receptaculum chyli has been tested by Camus and Gley who found in dogs a dilatation of the receptaculum as the result of electrical stimulation of the splanchnic nerve.

Movement of the lymph.—It has been estimated (Ludwig) that the amount of lymph which passes through the lymphatic ducts of a dog aggregates, during the twenty-four hours, one-third the body-weight. In the thoracic duct the lymph is under a sufficient pressure to burst the duct behind a ligature. In the absence of any especial propulsive organ, such as the heart for the blood-circulation, what are the forces which move the lymph? There must be recognised primary and accessory forces. As accessory forces there are the movement of the muscles and the general pressure of the organs on the lymph-ducts. Since these are provided with valves, all preventing the lymph from flowing backward, any such pressure causes the lymph to move onward. As accessory agents must also be reckoned the smooth muscle and elastic tissue which is present in the walls of the lymph-vessels and in the lymph-gland. That these forces, however, are not primary is shown by numerous facts. There is an active circulation in the lymphatics of

Fig. 550.—A. The Adventitial and Supra-muscular Nerve Plexuses, together with Sensory Endings in the Thoracic Duct of a Dog. (Methylene-blue method.) B. Nerve-fibres on the Endothelium of a Lymphatic Capillary of a Dog. (After Kytmanoff.)

A

B



embryos long before valves develop. In many lower animals no valves develop save at the entrance of the lymphatics to the veins. That neither valves nor muscular movements are essential is shown by the fact that, in the tails of frog larvæ, where no valves are present and where the muscle movements have been completely paralysed by an anesthetic, the circulation of lymph continues unchecked.

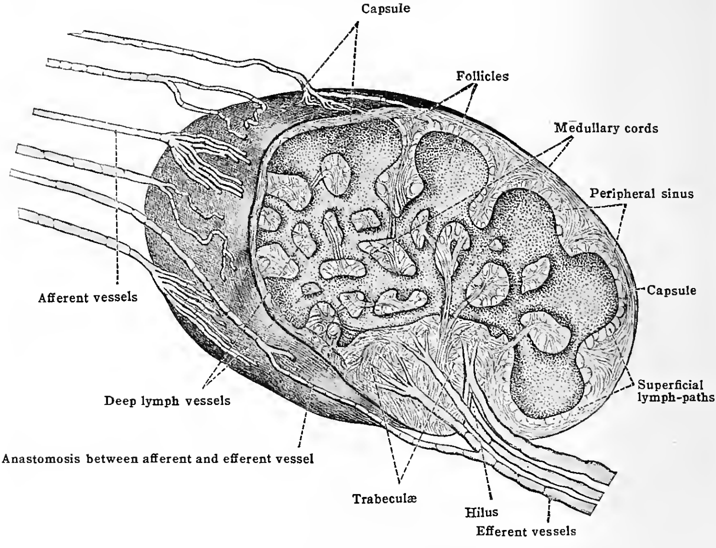
The primary cause, therefore, for the movement of lymph is to be sought in the capillary region, in the force produced by the passage of lymph through the endothelial wall, whether this process be a filtration and diffusion—in which case the causes would lie in the pressure and molecular condition of the tissue fluid outside the lymphatic—or whether it be an active secretion by the endothelium—in which case the driving force would be this secretory power of the endothelium.

3. THE LYMPHOID ORGANS

Closely associated with the lymphatic capillaries and vessels is a group of glandular structures known as lymphoid organs. They consist, essentially, of groups of round lymphoid cells, lying in a meshwork of reticulum fibres, and having often a definite relationship to the blood or lymph vessels.

The group of lymphoid organs includes, in addition to the lymph-glands [lymphoglandulæ] or lymph-nodes, which are particularly related to the lymphatic vessels, the spleen, thymus and bone-marrow, which are also largely made up of lymphoid tissue. The spleen and thymus, however, are considered separately with the Ductless Glands.

Fig. 551.—Diagram of a Lymph-node. (After Toldt, "Atlas of Human Anatomy, "Rebman, London and New York.)



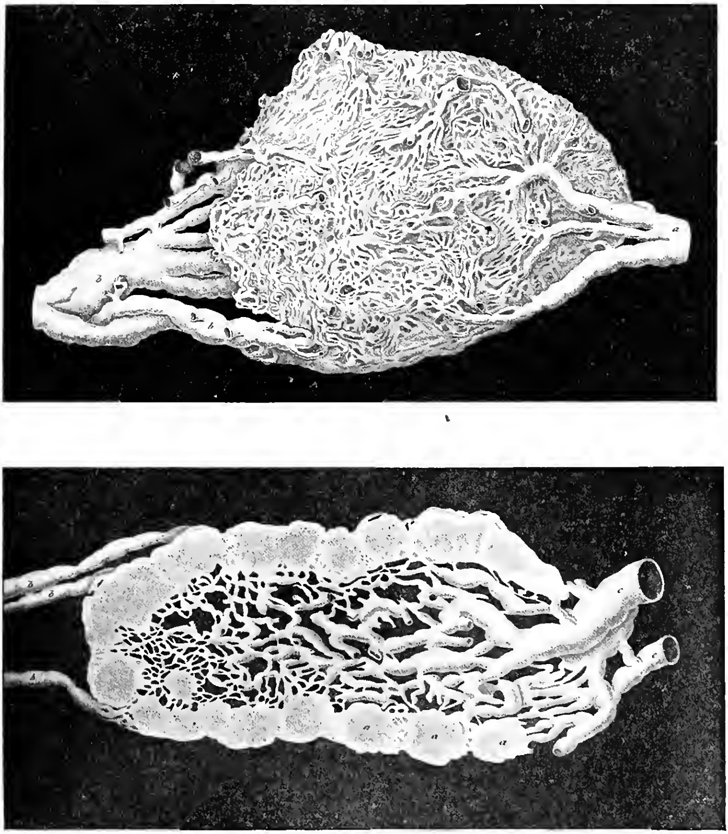
In their most simple form, the lymphoid organs form mere irregular accumulations or patches of lymphoid cells, which have been termed lymphoid infiltrations. Such patches are frequent in mucous membranes especially along the intestinal tract (fig. 549) and the air-passages in the lungs.

Larger accumulations of lymphoid cells produce definite round nodules, which may occur singly, as *solitary follicles* or in groups, as *aggregated follicles* (Peyer's patches) (fig. 548). In the solitary follicle the lymphoid cells are arranged concentrically, with a region in the centre where the cells are less closely packed together. This is called the germinal centre, and contains numerous cells undergoing mitotic division. The solitary follicle contains blood-capillaries. Lymph-capillaries, however, do not enter the follicle but form a rich plexus about it.

The **lymph-glands** or nodes (fig. 551) are larger lymphoid structures, which are developed along the course of the lymph-vessels. They vary much in size, shape, and colour, and may occur singly or in small or large groups. The *size* varies from the size of a pin-head to that of an olive, or larger. In *shape* they may be spherical, oval, or flattened on one or more sides, according to their relations to other organs. Each gland has an indentation or hilus, where the arteries enter, and where the veins and efferent ducts emerge. Their *colour* depends upon position and state of function. The glands along the respiratory tract are black, due to the presence of carbon granules. The mesenteric glands are milk-white during digestion, and other nodes are pale and translucent when their sinuses are filled with fluid, and pink or even red when red-blood cells are present in the sinuses. The lymph-gland is made up of four distinct elements: lymphoid elements, lymphatic capillaries, supporting structures, and blood-vessels.

The *lymphoid elements* (fig. 551) are arranged as follicles and as cell-strings. The follicles lie around the circumference of the gland, and form the cortex [substantia corticalis]. The cell-strings or medullary cords are irregular cords of cells which extend from the follicles through the central or medullary portion [substantia medullaris] of the gland. The follicles and medullary cords are made up, as are the solitary follicles, of round lymphoid cells.

Fig. 552.—Surface View and Section of a Lymph-node showing the Peripheral and Central Sinuses. (After Teichmann.)



The *lymphatic vessels* (fig. 551) enter the lymph-gland as several vasa afferentia, and leave it, at the hilus, as the vasa efferentia. The vasa afferentia spread out in the cortical portion of the gland into an extremely rich plexus of wide capillaries which surround the follicles, forming the peripheral sinus. The capillaries do not enter the follicle. This plexus continues, around the follicles, into the medullary portion where it forms again a rich plexus, the medullary sinus, in the spaces around the medullary cords (fig. 552). At the hilus the medullary capillaries collect into larger vessels and emerge as the vasa efferentia.

The *supporting structures* consist of a fibrous capsule surrounding the gland, from which trabeculæ or septa pass in, around and between the follicles and cords. From the septa, a fine reticulum passes into the follicles and cords, where it forms a rich dense meshwork, in the interstices of which lie the lymphoid cells. The capsule and trabeculæ are made up of white fibres, elastic fibres and smooth muscle-fibres.

The *blood-vessels*, which enter and leave at the hilus, send branches into the follicles and into the medullary cords.

The enormous widening of the lymph-stream in the lymph-node from the vasa afferentia to the capillaries—like a brook widening out into a pond—causes a very great diminution in the rate of flow of the lymph. Thus there is present in the gland a very slowly moving stream of lymph, which is separated from the lymphoid tissue outside by a single layer of flattened endothelial cells. There is thus possible an easy interchange of substances, and an opportunity for the passage, through the endothelium, of wandering cells. While the entire mode of functioning of the lymph-gland is not clear, it is known that lymphocytes, formed here, enter the lymph-stream, and that substances such as, for instance, carbon granules, or leucocytes laden with bacteria, are checked in their course by the lymph-gland.

Arrangement.—The lymph-glands are so arranged throughout the body that all the lymph which enters the lymphatic capillaries must pass through one or more lymph-glands on its way to the veins.

It is possible that this rule may have exceptions, although none have yet been definitely proved. Thus, some of the small lymphatics which join the thoracic duct may enter it without having passed through a gland. Moreover, there is often found (fig. 551) a direct anastomosis between an afferent and an efferent lymphatic vessel.

Most of the glands are collected in certain regions, where they form centers toward which the lymphatic vessels radiate. Such groups are termed regional glands. The glands forming such a group are connected with one another by numerous anastomoses, which are termed lymphatic plexuses [plexus lymphatici]. In addition to the regional glands there are many isolated glands which lie along the course of the lymph-vessels, and through which pass the vessels draining a much more limited capillary area. Such glands are termed *intercalated* glands.

4. *THE DEVELOPMENT OF THE LYMPHATIC SYSTEM*

Our knowledge of the lymphatic system has been very greatly increased during the past ten years by studies on its mode of development. Previous to 1902 nothing definite was known about the primary development or the mode of growth of the lymphatic system. It was concluded by some (Budge, Gullard and Saxer) that the lymphatics arise from undifferentiated mesenchyme cells; Ranvier believed that they arise from veins by budding of the endothelium; while Sala described them as arising partly from the mesenchyme and partly from venous endothelium.

Regarding the mode of growth and spreading of the lymphatics, various theories were likewise held. Kölliker, His, Goethe and, later, Sala held that growth takes place by the successive addition of mesenchyme cells; Langer, Rouget, and Ranvier maintained that growth takes place by sprouting of the endothelium (fig. 553). S. Mayer thought that new lymphatics are derived from transformed blood-capillaries.

Miss Sabin in 1902 gave the first clear picture of the mode of origin and growth of the lymphatic system, and our present knowledge is largely based upon her discoveries. She showed by injections of embryo pigs that the lymphatics of the skin appear first in four regions of the body—two on each side at the base of the neck, and two in the inguinal region—in the form of sacs which are connected with the veins. From these four regions the lymphatics spread out step by step over the skin of the entire body, in the form of a richly anastomosing capillary plexus. Since the publication of Miss Sabin's paper, numerous studies have been made on the mode of development of lymphatics in many different animals, including man. The results of these studies indicate that the lymphatic endothelium first appears in the form of buddings-out from the veins in certain well-defined regions of the embryo. As to the exact manner of this primary origin views differ. Miss Sabin, in her first paper, held that it arises by budding from the veins. F. T. Lewis held that it is formed by the transformation of plexuses of blood-capillaries. This view was accepted by Miss Sabin, and verified by Huntington and McClure. Stromsten recurred to Sala's view that the first lymphatic endothelium arises in part from venous endothelium, and in part from the mesenchyme cells. Hoyer and his pupils find that the first lymphatics arise as buds from the veins. This has also been found (1912) by E. R. and E. L. Clark in chick embryos.

Thus far six regions have been found, in which lymphatics develop from the veins—in the neck, on each side, at the angle formed by the internal jugular and subclavian veins; in the pelvis, on each side, along the iliac veins; and two unpaired sets in the region of the renal veins, one ventral to the aorta, the mesenteric, and one dorsal to the aorta, retroperitoneal. In these six regions the lymphatics soon coalesce to form large sacs, the jugular, iliac, mesenteric and retroperitoneal. The sacs are later broken up into the primary sets of lymph-nodes. The receptaculum chyli develops in the region of the retroperitoneal sac.

From these primary anlages derived from the veins the lymphatics spread out into the various organs and tissues of the body. The cutaneous lymphatics spread out from the two jugular and two iliac regions (Sabin), the lymphatics of the intestine from the mesenteric sac (Heuer).

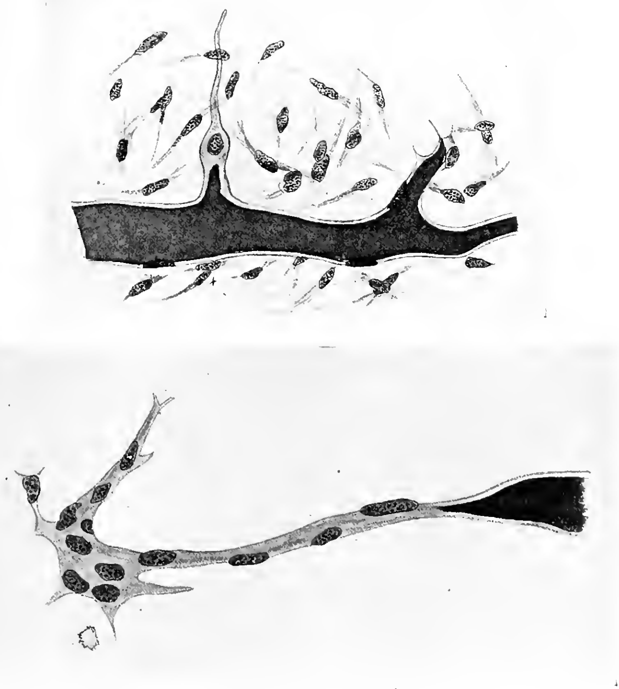
The method by which this extension of the primary lymphatics occurs is still in dispute, but there seems to be conclusive evidence that it takes place by the sprouting of the endothelium (fig. 553); that the endothelium of the lymphatics, derived from the veins, is a specific, independent tissue, and that all new lymphatic endothelium is formed from lymphatic endothelium, and not from blood-vessels or mesenchyme cells. This view is supported especially by the work of Sabin, MacCallum, Hoyer and his pupils and E. R. Clark.

On the other hand, F. T. Lewis has suggested that the spreading of lymphatics occurs by the transformation of blood-vessels into lymphatics; while Huntington and McClure and their pupils maintain that it occurs by the continued transformation of mesenchyme cells.

The lymphatics growing from the various primary centres meet and anastomose with one another, and gradually lose all connections with the veins save those at the base of the neck Sylvester has found, however, that in South American monkeys the connections with the veins in the region of the renal veins are maintained in the adult. Valves do not appear in the lymphatic vessels until quite late, in human embryos about 5 or 6 cm. long. (Sabin.)

The *lymphatic nodes* do not make their appearance until the system of vessels is well established. They are at first represented by masses of lymphoid tissue in the meshes of a lymphatic network. Later the lymphoid mass breaks up into smaller portions, into which the blood-vessels and branches from the surrounding network penetrate; and each mass, together

FIG. 553.—THE SPROUTING OF LYMPHATIC CAPILLARIES IN THE PIG. (After MacCallum.) The lymphatics are injected and the sprouts are both single cells and clumps of cells.



with the portions of the network surrounding it, becomes enclosed in a connective-tissue capsule. The original lymphoid tissue becomes transformed into the medullary cords and cortical nodules of the node, while the enclosing lymphatic capillaries form its peripheral lymph-sinus.

The earliest nodes appear in the places occupied by the primary lymphatic plexuses or sacs (Miss Sabin, F. T. Lewis, Jolly), and have been termed the "primary nodes" (Miss Sabin). Secondary and tertiary sets of nodes develop later at places of confluence of many lymphatics (cf. A. H. Clark.)

Regeneration and new growth of lymphatic vessels and glands.—While blood-vessels are known to possess throughout life the capacity for regeneration and new growth, this process in lymph-vessels has been very little studied. Yet enough has been learned from the work of Coffin and Evans to justify the statement that lymphatic vessels also possess the capacity for new growth. Evans made the interesting observation that lymphatic vessels grow into a tumor of connective-tissue origin (a round-celled sarcoma), while they fail to grow into a tumor of epithelial origin (an experimentally-produced peritoneal carcinoma in mice).

The question as to whether lymph-glands may form anew is not yet entirely settled. The study of the problem is extremely difficult, because very small lymph-nodes may be normally present in a certain region, yet they may escape observation until they become hypertrophied under certain conditions. A. W. Meyer in a careful experimental study found no evidence of new-formation of lymph glands. On the other hand, there is considerable evidence for the new-formation of lymph-glands under pathological conditions.

The hæmolymph nodes.—In addition to the ordinary lymph-nodes, there occur along the course of certain veins small nodes which are either red or brown in colour, according to their state of functional activity. These have been termed **hæmolymph nodes.** The red nodes closely resemble in structure an ordinary lymph-node, except that the sinuses are filled with blood, while the brown nodes show not blood, but blood pigment, both free in the sinuses and in the phagocytic cells of the sinuses. In certain respects these nodes resemble the spleen, there being a reduction of the medullary cords and an increase in the amount of the sinuses, which resemble those of the spleen-pulp rather than the more open lymphatic sinuses; and their trabeculæ are also like those of the spleen in having numerous smooth muscle-cells. Some of these hæmolymph nodes have lymphatic

FIG. 554.—A DEVELOPING HÆMOLYMPH NODE.

vessels, but whether, as in the spleen, these are limited to the capsule, or whether they open into the blood-sinuses, making true hæmolymph nodes, is not yet clear.

A difficult point in connection with the structure of the hæmolymph nodes is the relation of the blood-sinuses to the blood-vessels. The greater weight of evidence seems to favour the view that the sinuses are connected with the veins rather than that the arteries open directly into them, although one observer fails to find any connection between the blood-vessels and the central sinus (Schumacher). In fig. 554 is shown a hæmolymph node in the neck of a pig 24.5 cm. long. This stage marks the first appearance of the hæmal node in the neck, and shows the node in its simplest form, the follicle and its peripheral blood-sinus (Miss Sabin).

There are wide variations in the **distribution** and number of the hæmolymph nodes; indeed sufficient observations have not yet been made to determine their complete distribution. They have been divided into three groups, the prævertebral, the renal, and the splenic. In one subject, in which they were very numerous, they occurred at the root of the lung, near the bronchi and bronchial vessels, a few near the œsophagus, a continuous prævertebral chain in the abdomen extending from the diaphragm to the upper two or three sacral vertebræ, as well as a few along the cœliac axis and its branches, the superior mesenteric, renal, and iliac vessels (Lewis).

Schumacher, from a study of lymph-glands and hæmolymph glands of various stages, concludes that the hæmolymph glands are not to be considered as organs *sui generis*, but that they represent rudimentary forms of ordinary lymph-glands, which have lost their connections with the lymphatic vessels. Further investigations are needed to clear up this subject.

II. SPECIAL ANATOMY OF THE LYMPHATIC SYSTEM

The lymphatic system will be considered by regions as follows: A, head and neck; B, upper extremity; C, thorax; D, abdomen and pelvis; E, lower extremity.

A. THE LYMPHATICS OF THE HEAD AND NECK

The lymphatics of the head and neck may be divided into two sets. One set is superficial, draining the entire skin surface, and has its nodes, for the most part, in the neck, the principal group lying along the external jugular vein. The other set is deeper and drains the mucous membrane of the upper part of the digestive and respiratory tracts, together with the deep organs, such as the thyreoid gland and the tendons of the muscles. The nodes of this set are deeply placed, being situated along the carotid arteries, with outlying retro-pharyngeal nodes.

1. THE SUPERFICIAL NODES OF THE HEAD AND NECK

Lymph-nodes appear first in the neck in the process of development. In the pig the first node to appear develops from the lymph heart, which is in the supraclavicular triangle behind the sterno-cleido-mastoid muscle. From here ducts grow across the muscle and give rise to a chain of nodes along the external jugular vein. This chain is to be considered as the main chain of superficial nodes in the neck. From it lymphatic vessels grow over the back of the head, the side of the head, the face, and the front of the neck, and in their course groups of secondary nodes develop. The nodes of the main chain are known as the superficial cervical nodes, and are from four to six in number. The secondary groups are—(1) the occipital; (2) the posterior auricular; (3) the anterior auricular; (4) the parotid; (5) the submaxillary, with the facial as a tertiary set, and (6) the submental.

1. **The occipital nodes** [lymphoglandulæ occipitales].—The lymphatics of the skin of the back of the head collect into a few trunks that either empty into from one to three small nodes near the occipital insertion of the semispinalis capitis muscle, or pass by the secondary group and empty directly into the upper nodes of the main superficial cervical chain (fig. 555).

2. The **posterior auricular nodes** [lgl. auriculares posteriores].—A portion of the temporal part of the scalp, together with the posterior surface of the ear, except the lobule, and the posterior surface of the external auditory meatus, drain into two small nodes on the insertion of the sterno-cleido-mastoid muscle. The efferent vessels of these nodes pass to the upper part of the superficial cervical chain.

3. The **anterior auricular nodes** [lgl. auriculares anteriores] are few in number—from one to three—and are situated immediately in front of the tragus of the ear. They receive vessels from the anterior surface of the auricle and the external auditory meatus, from the integument of the temporal region and the lateral portion of the eyelids. Their efferents pass to the parotid and superior deep cervical nodes.

4. **The parotid nodes.**—The parotid group of nodes is considerably larger than the two preceding, containing from ten to sixteen nodes, and the group drains a more complex area. It receives vessels from the adjacent surface of the external ear, the external auditory meatus, the skin of the temporal and frontal regions, and the eyelids and nose. The deeper nodes of this set receive vessels from the parotid gland.

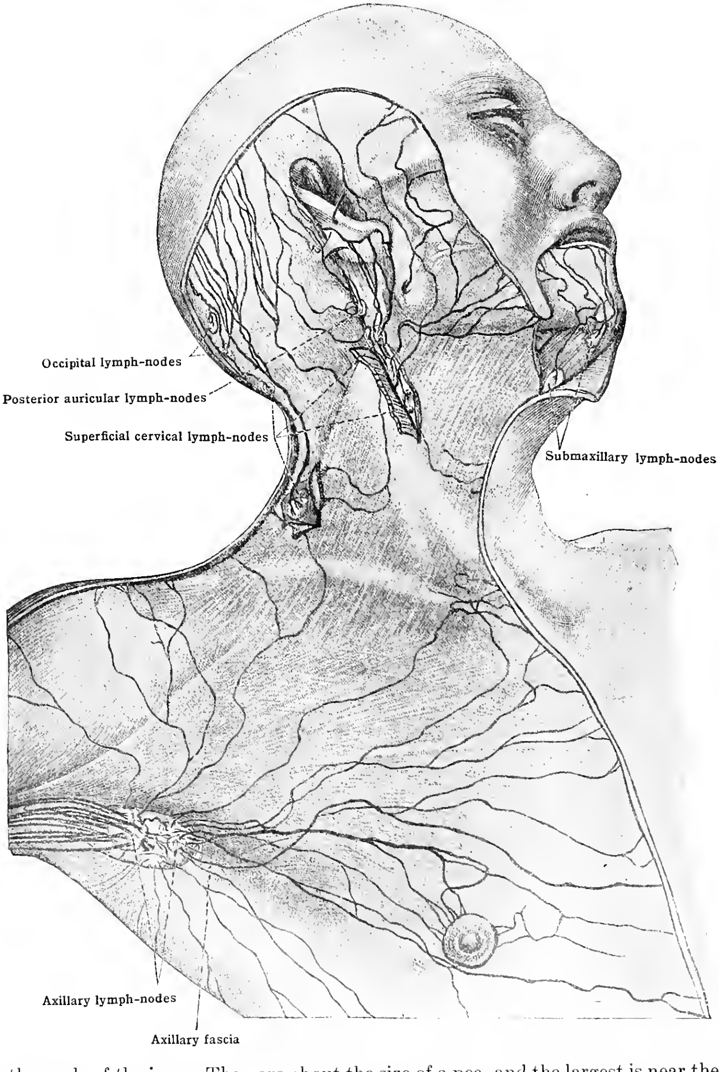
In the embryo these nodes lie in the pathway of the lymph-vessels that grow to the scalp; many of these vessels, however, pass the parotid group and empty into the superficial cervical chain. The nodes of the parotid group lie embedded in the substance of the parotid gland, and their efferents pass to the submaxillary and the superior superficial and deep cervical nodes.

As "inferior auricular nodes" Bartels designates one or two small glands of the parotid group which lie below the ear, and receive afferent vessels from the lower part of the ear.

5. **The submaxillary** [lgl. submaxillares] **and facial** [lgl. faciales profundæ] **nodes.**—The submaxillary (perhaps better "mandibular") group consists of a

chain of from three to six nodes, resting on the submaxillary (salivary) gland, along the inferior border of the mandible. They lie usually on the submaxillary gland, but may extend from the insertion of the anterior belly of the digastric to

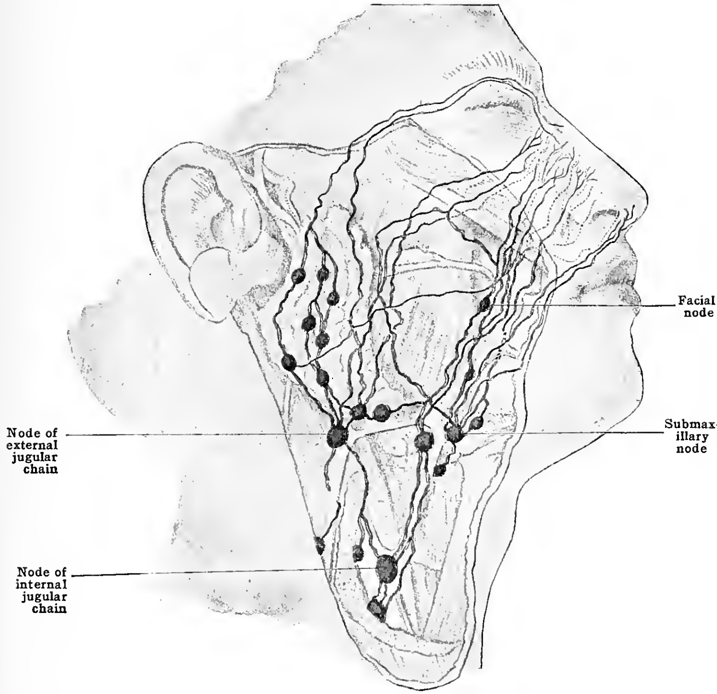
Fig. 555.—The Lymphatics of the Head and Neck. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



the angle of the jaw. They are about the size of a pea, and the largest is near the point where the external maxillary (facial) artery crosses the mandible. The submaxillary nodes, together with the next group, the facial, drain a complex area, including not only skin, but mucous membrane. They receive lymph-vessels from the nose, cheek, upper lip, the external part of the lower lip, together with almost all those from the gums and teeth and from the anterior third of the lateral portions of the tongue. In agreement with the fact that these nodes, though lying superficially and draining the skin, drain also the mucous membrane, their vessels empty not only into the superficial cervical chain, but also into the deep carotid chain.

The **facial nodes** are evidently outlying nodes of the submaxillary group. They are in two main sets—(1) the **supra-maxillary set,** which consists of from one to thirteen nodes, resting on the mandible near the point where it is crossed by the external maxillary (facial) artery. (2) The **buccinator set,** lying on the

FIG. 556.—LYMPHATICS OF THE OUTER NOSE AND FACE. (After Küttner.)



line connecting the lower margin of the ear and the angle of the jaw. Of these latter nodes, some lie near the point where the parotid duct perforates the buccinator muscle; the others are farther forward, between the external maxillary artery and the anterior facial vein. Additional nodes belonging to the group may occur near the nose and in the suborbital region. These facial nodes receive afferents from the outer surface of the nose, the lips, eyelids, cheek, temporal part of the face, the mucosa of the mouth, the teeth of the upper jaw, the gums, the tonsils, and the parotid gland. Their efferents pass to the submaxillary and parotid nodes.

6. The **submental nodes** [lgl. submentales], usually two in number, lie in the triangle bounded by the anterior bellies of the two digastric muscles and the hyoid bone (fig. 559). They are usually near the median line, and drain the skin of the chin, the skin and corresponding mucous membrane of the central part of the lower

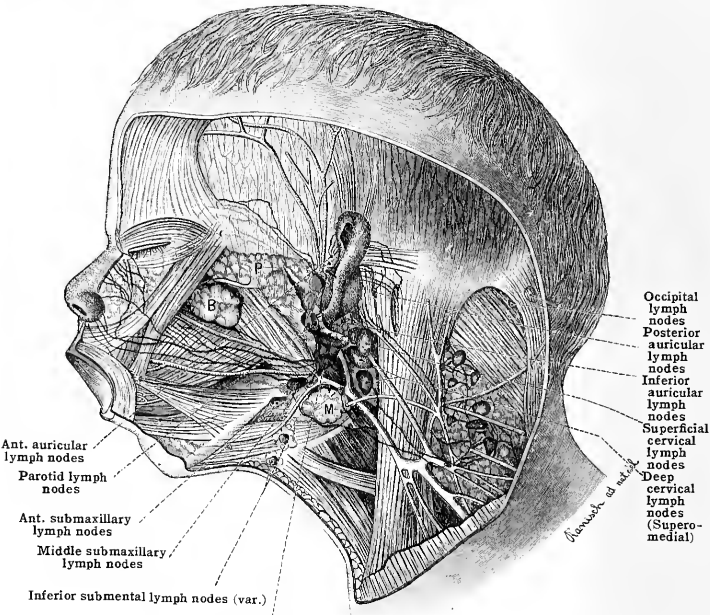
lip and jaw, the floor of the mouth, and the tip of the tongue. The efferent vessels pass either to the submaxillary nodes or to the deep cervical chain.

2. THE LYMPHATIC VESSELS OF THE FACE

The different parts of the face and their lymphatic relation to these groups of superficial nodes will now be considered.

The **lymphatics of the scalp** form a rich network in the neighbourhood of the vertex, from which vessels pass in various directions. From the frontal region a

FIG 557.—LYMPHATIC NODES AND VESSELS OF THE EAR, EYELIDS, NOSE AND LIPS. New-born child. P, parotid. M, submaxillary gland. B, buccal fat ("sucking pad"). Supero-lateral deep cervical lymph nodes are not labelled. (After Bartels.)

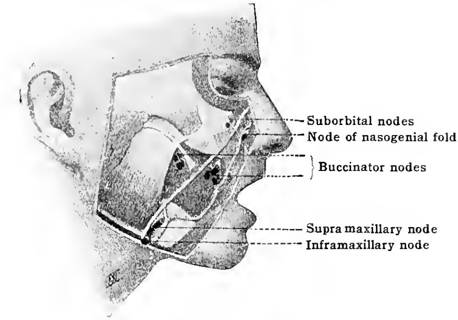


number of ducts pass downward and backward to the parotid nodes; those from the parietal and temporal regions pass to the anterior auricular, parotid, and posterior auricular nodes; and those from the occipital region pass partly to the occipital nodes and partly to the superior deep cervical group, while a single large vessel descends along the posterior border of the sterno-mastoid muscle to terminate in one of the inferior deep cervical nodes.

The lymphatics of the eyelids and conjunctiva.—The capillary plexus of the eyelids and the conjunctiva is an abundant one, and at the free border of the eyelids becomes extremely close. The lymphatics from the lateral three-fourths of the lids pass to the anterior auricular and parotid groups of nodes, while those from the medial one-fourth pass obliquely across the cheek with the facial vein to terminate in the facial and submaxillary nodes (figs. 556, 557, 561).

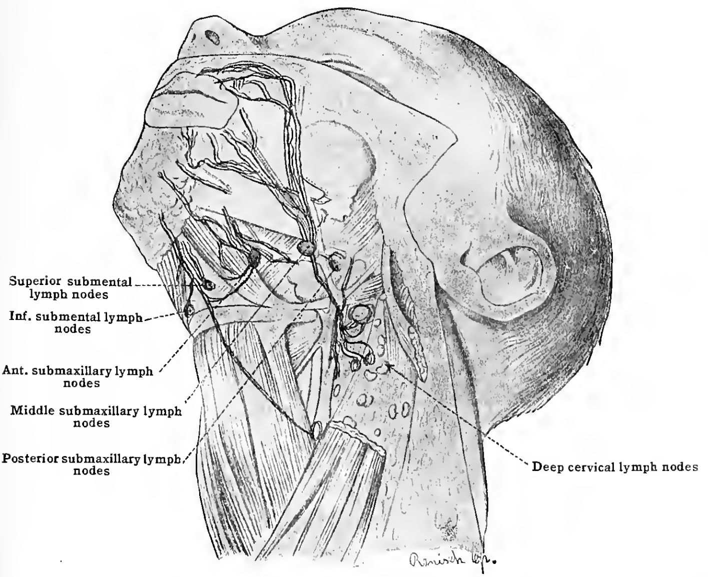
The lymphatics of the nose.—The lymphatics of the nose (fig. 556) form a network which is coarse at the root of the organ, but dense over the alar region. The vessels run in three sets—(1) one set passing over the eye to the parotid nodes; (2) a set passing under the eye to the same nodes; and (3) the most important group, consisting of from six to ten trunks, passing to the facial and submaxillary nodes. There are some anastomoses between the capillaries of the skin and those of the mucous membrane of the nose.

FIG. 558.—THE FACIAL NODES. (After Buchbinder.)



The lymphatics of the lips (fig. 559).—The capillary plexuses of the skin and mucous membrane are continuous at the free border of the lips. The vessels of the upper lip, of which there are about four on each side, pass to the submaxillary

FIG. 559.—THE LYMPHATICS OF THE LIPS. Newborn child. (From Bartels after Dorendorf.)



nodes. From the lower lip the trunks from near the angle of the mouth pass to the submaxillary nodes, while those from the centre of the lip pass to the submental nodes.

There are from two to four subcutaneous vessels and from two to three submucous vessels on either side. The collecting trunks passing to the submaxillary nodes do not anastomose, and the same is true of the submucous vessels of the lower lip. The subcutaneous vessels, on the other hand, passing to the submental nodes, anastomose freely, an important fact in connection with the extension of cancer of the lower lip.

The lymphatics of the auricle and external auditory meatus.—The lymphatic plexus in the auricle, external auditory meatus, and the outer side of the tympanic membrane is an abundant one. An anastomosis has been described between a scanty plexus on the inner side of the tympanic membrane and the plexus on the outside. The collecting vessels pass to three sets of nodes:—(1) those from the external and internal surface of the auricle and the posterior part of the external auditory meatus pass to the posterior auricular nodes; (2) those from the lobule, the helix, a part of the concha and the outer portion of the external auditory meatus pass to the inferior auricular and superficial cervical chain; some of the vessels from the first and second areas also run to the deep cervical group; (3) an anterior group from the tragus and part of the external auditory meatus consisting of from four to six trunks, pass to the anterior auricular nodes, which are connected with the parotid nodes.

3. THE DEEP LYMPHATIC NODES OF THE HEAD AND NECK

The **deep cervical chain** is the largest mass of nodes in the neck. It consists of from fifteen to thirty nodes, which lie along the entire course of the carotid artery and internal jugular vein. This chain receives vessels from all the superficial nodes, also directly from the skin, as well as from the entire mucous membrane of the respiratory and alimentary tracts in the head and neck. Thus it drains both the superficial and the deep structures.

For convenience of description this long chain, though usually continuous, is divided into two groups—(1) a superior group, lying above the level at which the omo-hyoid muscle crosses the carotid artery, and (2) an inferior or supra-clavicular group, lying below that level.

(1) **The superior deep cervical nodes** [lgl. cervicales profundæ superiores].—This group of nodes extends from the tip of the mastoid process to the level at which the omo-hyoid muscle crosses the common carotid artery. The *dorsal* and smaller nodes of the chain lie on the splenius, levator scapulæ, and scalene muscles. They drain the skin of the back part of the head, both indirectly and directly, and receive (1) efferents from the occipital and posterior auricular nodes, (2) a large vessel from the skin of the occipital part of the scalp, (3) some trunks from the auricle, and (4) cutaneous and muscular vessels from the neck.

The **ventral nodes** of the chain lie on the internal jugular vein. They drain the face both directly and indirectly, as well as the deeper structures of the head and neck. They show especially well in fig. 563 in connection with the tongue.

(2) The **inferior deep cervical** [lgl. cervicales profundæ inferiores] or supra-clavicular nodes lie in the supra-clavicular triangle. In the upper part of the triangle the nodes rest on the splenius, the levator scapulæ, and the scalene muscles, while at the base of the triangle they are related to the subclavian artery and the nerves of the brachial plexus. They drain a wide area, receiving vessels from the head, neck, arm, and thoracic wall. They are connected with the superior deep cervical chain, and receive afferents from the axillary nodes, and, in addition, they receive vessels directly from the back of the scalp, from the skin of the arm, and from the pectoral region. Thus it will be seen that a large part of the lymph of the head and neck, as well as some from the arm and thorax, passes through these nodes. Their efferents unite to form the jugular trunk, which ends at the junction of the internal jugular and subclavian veins.

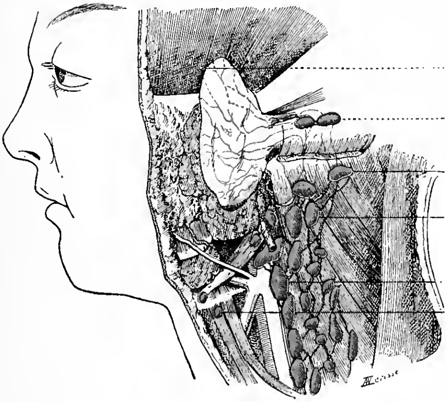
In the descriptions of the deep lymphatic vessels certain additional groups of nodes will be considered, which may be regarded as outlying groups from the deep cervical chain.

4. THE DEEP LYMPHATIC VESSELS OF THE HEAD AND NECK

The lymphatics of the brain.—It is now recognised that there are no lymphatics in the brain and cord, so that the function of absorption must be accomplished by means of the veins. There is an abundant exudation of lymph around the nervous system into the subdural space, which is connected with the central canal of the nervous system, and which is to be considered as a zone in which the tissue-spaces are especially large. Along the arteries of the brain the adventitia is loose and open, possessing tissue-spaces which have received the confusing name of perivascular lymphatics. It would be better to name them perivascular tissue-spaces.

The lymphatics of the eye.—No lymphatic vessels have as yet been discovered either in the eyeball or in the orbit. In both, however, there are abundant tissue-spaces, the most noteworthy of the orbit being the **interfascial space (space of Tenon)**, which communicates by a space between the optic nerve and its sheath with the subarachnoid spaces of the cranial cavity. In the eyeball the tissue-spaces are abundant, even if the vitreous and aqueous chamber be omitted from the category. Numerous spaces exist in the chorioid coat, especially in the lamina supra-chorioidea, and in the sclerotic, both sets communicating by perivascular spaces surrounding the venæ vorticosæ with the interfascial space. In the cornea there are abundant lacunæ, united by their anastomosing canaliculi, to form a network of lymph-spaces which come into close relation with the conjunctival lymphatics at the corneal margin.

Fig. 560.—The Deep Cervical Chain. (After Poirier.)



The conjunctiva, being a portion of the integument, does possess lymphatic vessels (fig. 562), arranged in a double network whose collecting vessels accompany those of the eyelids, and terminate with them in the submaxillary, anterior auricular, and parotid nodes.

The Lymphatics of the Digestive Tract in the Head and Neck

The lymphatics of the gums.—The lymphatics from the mucous membrane of the gums pass to the submaxillary nodes. The capillary plexus is abundant; the collecting vessels arise from it on the inner surface of the gum, and pass between the teeth to reach a common semicircular collecting vessel on the outer surface. Lymphatics have recently been demonstrated in the pulp of the tooth (Schweitzer).

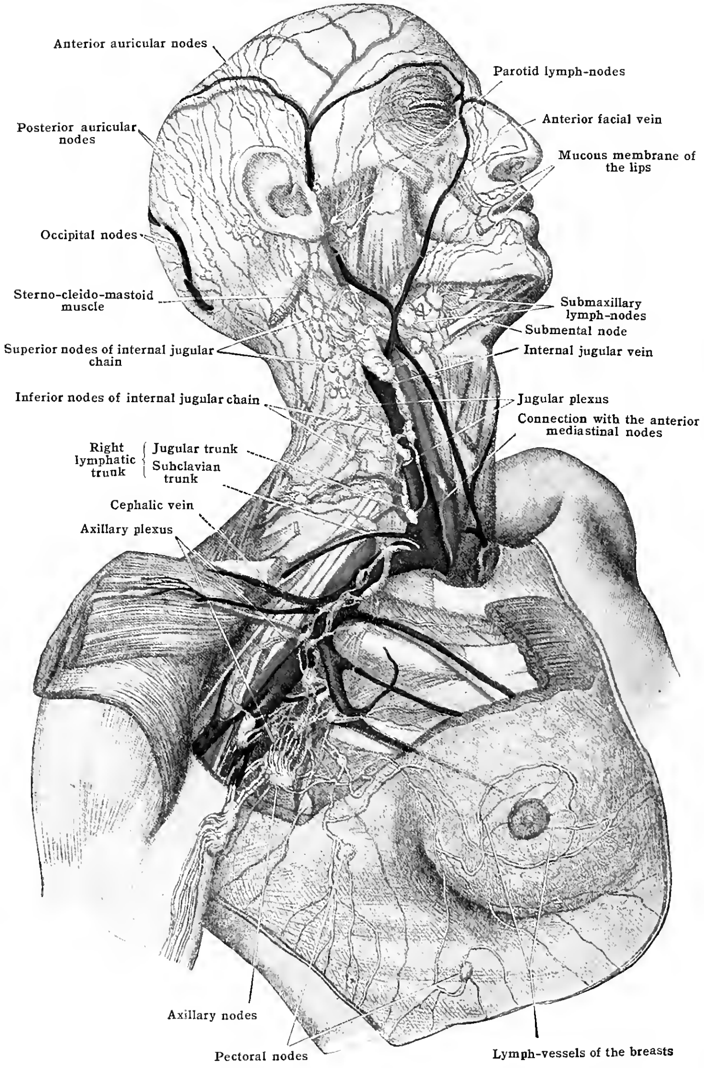
The lymphatics of the tongue.—There is a rich lymphatic plexus throughout the entire extent of the submucosa of the tongue, but that portion lying in the basal part of the tongue seems to be more or less independent of the rest. According to Aagaard the tongue muscles are provided with lymphatics which are drained by the ducts of the submucosal plexuses. There are four groups of collecting vessels—(1) apical; (2) marginal; (3) basal; and (4) central.

(1) The *apical vessels* are usually four in number, two on each side. One pair perforates the mylo-hyoid muscle and ends in a supra-hyoid median node, while the other pair pass to the deep cervical chain. The latter are long, slender vessels, which run along the frenum of the tongue to the surface of the mylo-hyoid muscle, cross the hyoid bone just behind the pulley of the digastric, and then run downward in the neck to a node of the deep cervical chain, just

above the omo-hyoid. It will be noted in fig. 563 that the most anterior vessels end in the lowest nodes, while those from the back of the tongue end in higher nodes.

(2) The *marginal vessels* are from eight to twelve in number. They all pass to the superior

FIG. 561.—LYMPHATICS OF THE HEAD, NECK, AND AXILLA. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



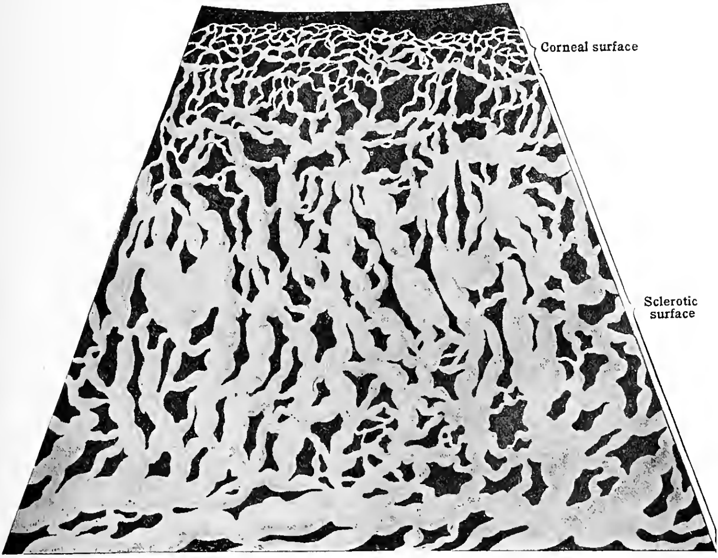
deep cervical nodes, a part of them passing external to the sublingual gland, while the larger number pass internal to it. There is one large and constant node at the point where the digastric muscle crosses the jugular vein, to which a large number of the vessels converge.

(3) The *basal vessels* are seven or eight in number, and drain the basal portion of the tongue. Some end in the large node just mentioned, while others run backward close to the median line, where they anastomose, as far as the glosso-epiglottidean fold, when they separate and join the tonsillar vessels to pass outward to the superior deep cervical nodes.

(4) The *central vessels*, arising from the central portion of the tongue, pass backward in the median line on the ventral surface of the tongue. They lie upon the mylo-hyoid muscle, cross the hyoid bone, and end in the superior deep cervical chain.

The lymphatics of the palate.—The lymphatics from the palate pass to the deep cervical chain. The trunks from the hard palate run in the submucosa as far as the last molar tooth, where they pass in front of the anterior pillars of the fauces and end in the superior deep cervical nodes beneath the digastric muscle. In the soft palate the capillary plexus is very rich, reaching a maximum in the uvula. From the inferior surface of the soft palate and the pillars of the fauces vessels pass directly to the superior deep cervical chain, but some of the vessels

FIG. 562.—THE LYMPHATICS OF THE CONJUNCTIVA. (After Teichmann.)



from the upper surface of the soft palate run forward with the pharyngeal vessels and end in the retro-pharyngeal nodes. It will be seen from fig. 564 that the retro-pharyngeal nodes are simply outlying nodes from the deep cervical chain.

The lymphatics of the pharynx.—As has just been stated, there are certain outlying nodes of the deep cervical chain which lie behind the pharynx. They receive some of the ducts from the submucosa of the roof of the pharynx, but many of the pharyngeal vessels pass by these nodes and end directly in the superior deep chain. The tonsil is especially rich in lymphatics, and its ducts, together with those from the middle and inferior portions of the pharynx, end in the superior deep cervical chain. The lymphatics of the Eustachian tube run to the lateral retro-pharyngeal lymph-nodes or, passing these, to the deep cervical nodes.

The lymphatics of the nasal cavities.—The mucous membrane of the nose contains a rich lymphatic plexus whose main ducts pass to the retro-pharyngeal nodes. An anterior set, however, anastomoses with the subcutaneous vessels, and through these their lymph is conveyed to the facial and submaxillary nodes. The posterior vessels run either to the deep cervical chain or to the retro-pharyngeal nodes. Key and Retzius have shown that an injection of the lymphatics of the nose may be made by injecting the subarachnoid spaces at the base of the brain, although there is presumably no direct connection between the spaces and the lymphatic vessels. The lymphatics of the nasal sinuses end in the retro-pharyngeal nodes.

Fig. 563.—The Lymphatics of the Tongue. (Poirier and Charpy.)

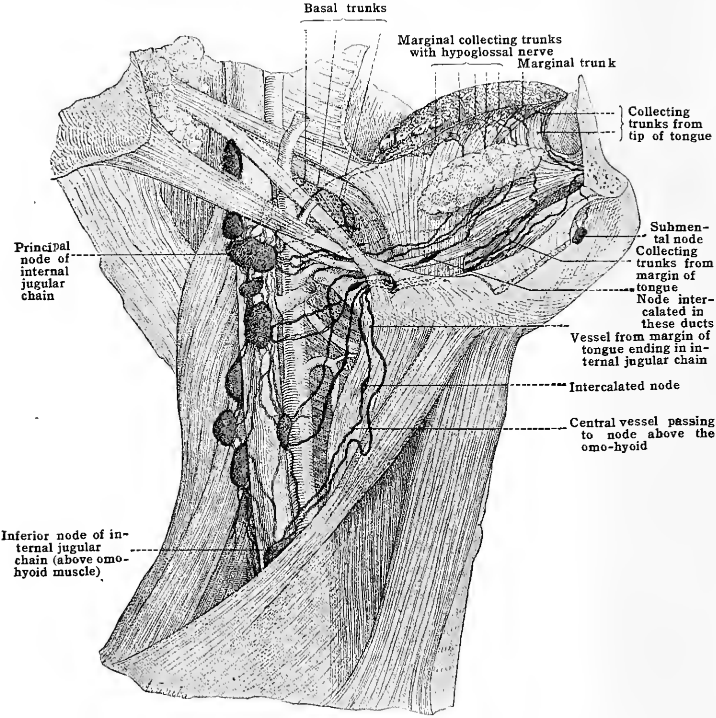


Fig. 564.—The Lymphatics of the Pharynx. (After Poirier and Cunéo.)

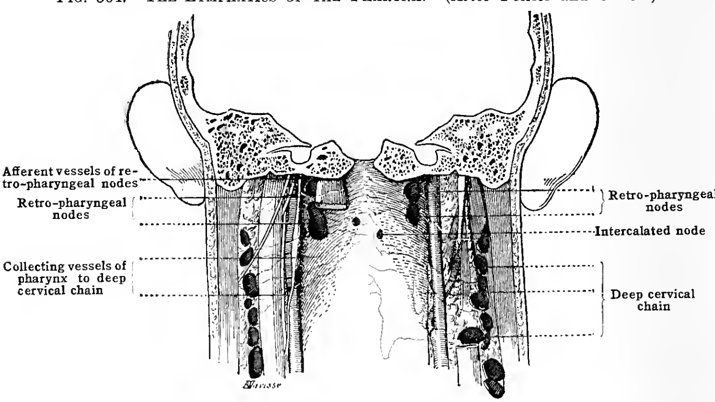


The lymphatics of the larynx.—The larynx is, for the most part, drained by the deep cervical nodes, although its lymph may also pass through certain outlying nodes situated upon its ventral surface. The mucous membrane is divided into two zones by the ventricular folds, the mucous membrane of these structures possessing but a scanty lymphatic plexus. The vessels from the upper part of the larynx, four or five in number, pass to the nodes of the superior deep cervical chain, situated near the digastric muscle; those from the lower part pass to the lower nodes of the same chain, some even descending as far as the supra-clavicular nodes. The lymphatics of the trachea pass, on each side, to the paratracheal and inferior deep cervical nodes.

The lymphatics of the thyreoid body.—The lymphatics of the thyreoid body pass either to the small nodes situated in front of the larynx and trachea, or to nodes of the deep cervical chain, a part of them ascending and a part descending.

It will thus have been seen that the lymphatics of the mucous membrane of the head and neck all end in the deep cervical chain of nodes or in the outlying nodes from it. Some of the vessels pass by the outlying nodes, but since the nodes of the chain are so closely connected, the lymph must pass through several nodes before entering the veins. The main tonsils, the numerous lingual and pharyngeal tonsils, together with small lymph-follicles in the submucosa of the respiratory tract, represent lymph-nodes in the capillary zone.

B. THE LYMPHATICS OF THE UPPER EXTREMITY

1. THE LYMPHATIC NODES OF THE UPPER EXTREMITY

The lymph-nodes of the arm lie, for the most part, in the axilla, where there is a large group of nodes which receive almost the entire drainage of the arm and the thoracic wall. In addition, there is in the arm a set of outlying superficial nodes, the superficial cubital (supra-trochlear), while small isolated nodes are often intercalated along the course of the deep lymphatic vessels which accompany the radial, ulnar, anterior interosseus and brachial arteries, the cephalic vein, and the deep cubital vessels.

(1) The antibrachial nodes are very small, pin-head sized nodes which are intercalated along the deep lymphatics which accompany the radial, ulnar, anterior and posterior interosseus arteries.

(2) The deep cubital nodes [lgl. cubitales profundæ] are also very small nodes, one or two in number, intercalated along the ducts, near the deep vessels at the bend of the elbow.

(3) The **superficial cubital node** [lgl. cubitales superficiales] (or supratrochlear) is situated three or four centimetres above the medial epicondyle of the humerus. It lies in the superficial fascia on the medial side of the basilic vein near the place where it passes through the deep fascia. It is usually single, but may be absent or represented by a chain of from two to five nodes. Its efferents follow the basilic vein.

(4) The **delto-pectoral nodes** are very small intercalated nodes from one to three in number, and are situated in the groove between the deltoid and pectoral muscles. Their vessels follow the cephalic vein.

(5) The **axillary nodes** [lgl. axillares], from twelve to thirty-six in number, may be divided into groups according to the areas which they drain (fig. 566). In addition to the upper extremity, they receive lymphatic drainage from the thoracic walls, including dorsal, lateral and ventral (mammary) regions.

(1) The *subclavian group* consists of four or five nodes, situated in the apex of the axillary fossa. They receive the efferent vessels of all the other groups, and their efferent vessels in turn unite to form a single trunk, the subclavian, which empties into the thoracic duct on the left side and on the right side either into the vein directly or else after uniting with the jugular trunk. (See pp. 726-728.)

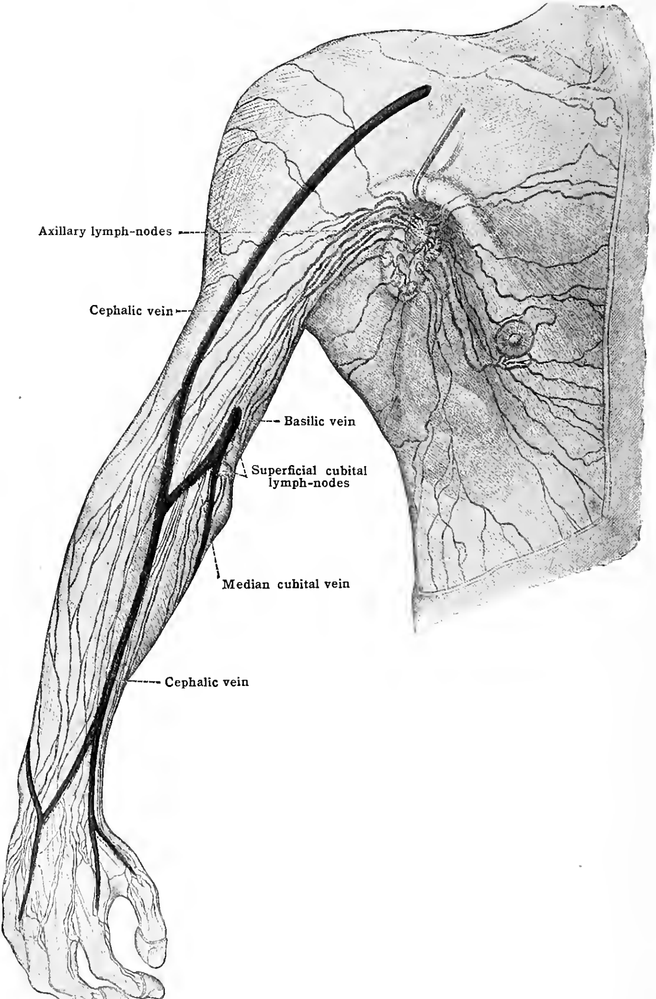
(2) *The central group.* A little lower along the axillary artery is a group of three to five nodes, which makes a second centre for the vessels of the other groups, and sends its efferents to the subclavian group. It will be clear from the figure that the separation of groups 1 and 2 is arbitrary.

(3) *The brachial group.*—This consists of four or five nodes, and, as its position toward the junction of the axillary and brachial arteries indicates, is the main station for the lymphatics of the arm proper. It receives almost all the superficial and deep lymphatics of the arm, and its efferents pass to the central and subclavian groups, although a few pass directly to the

suprascapular group. Small, outlying nodes of this group may be intercalated along the vessels following the brachial artery throughout its course.

(4) *The subscapular group* [lgl. subscapulares].—In this group are six or seven nodes, which follow the subscapular artery and its branch, the circumflex (dorsal) scapular. Belonging

FIG. 565.—THE LYMPHATICS OF THE UPPER EXTREMITY. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



to it there are usually two or three small nodes on the dorsal surface of the scapula, in the groove which separates the teres major and minor. This group receives vessels from the dorsal surface of the thorax, as well as from the arm, and its efferents pass to the brachial group.

(5) *The anterior (pectoral) group* [lgl. pectorales].—This group consists of four or five nodes which lie along the lower border of the pectoralis major and drain the mammary gland and front of the chest. Their efferent vessels pass to the central and subclavian groups.

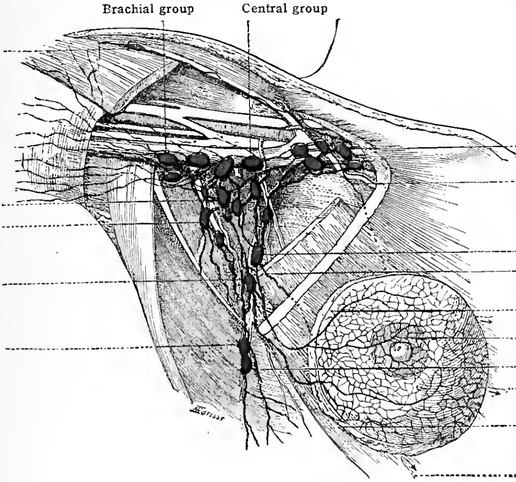
(6) The *posterior pectoral group* [lgl. pectorales] consists of small nodes situated on the inner wall of the axilla, along the course of the long thoracic artery. They receive afferents from the lateral integument of the thorax and drain into the nodes of the central group.

2. THE LYMPHATIC VESSELS OF THE UPPER EXTREMITY

The lymphatic vessels of the upper extremity are divided into two sets—a superficial and a deep set.

The superficial vessels.—The superficial lymphatic vessels of the arm course in two layers, the one quite subcutaneous, the other next the deep fascia, with frequent anastomoses between the two sets. The majority of these vessels remain superficial throughout the arm, but some of them pass through the deep fascia in the upper arm especially where the basilic vein pierces the deep fascia,

Fig. 566.—The Axillary Lymph-nodes. (After Poirier and Cunéo.)



to join the deep lymphatics accompanying the brachial artery. The general distribution of the superficial lymphatics and their relations with the lymph-nodes are shown in figs. 565 and 567.

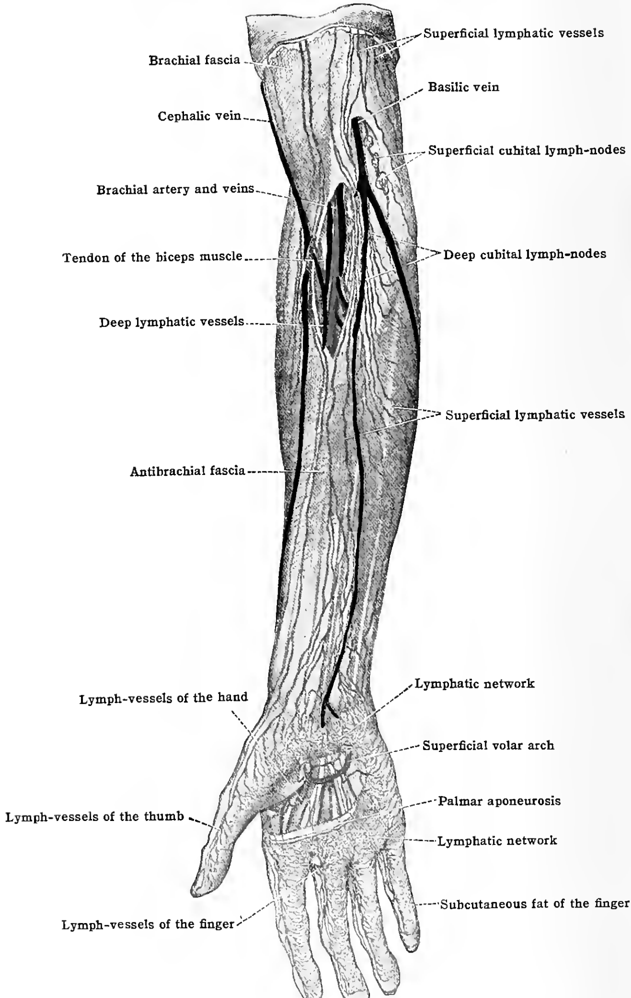
The capillary plexus is most dense in the palmar surfaces of the fingers, where the meshes are so fine that they can only be seen with a lens. On the dorsal surface of the fingers and hand the plexus is less dense. From the plexus on the palmar side of the fingers vessels come together at the base of the fingers where they pass dorsally to be joined by the dorsal vessels of the finger. They now follow two rather distinct curves: (1) those from the thumb and index finger and a part of the middle finger pass upward along the radial side of the forearm, course medially over the lower part of the biceps muscle, and empty into the axillary lymph-nodes. One or two vessels follow the cephalic vein and, after traversing the delto-pectoral node, pierce the costo-coracoid membrane to enter the subclavian nodes, or pass over the clavicle into the inferior deep cervical nodes. (2) Those from the rest of the fingers course for a short stretch on the dorsum of the forearm, when they turn toward the ulnar side, wind around to the volar side and either continue superficially along the upper arm to the axillary nodes, or pass into the superficial cubital node, or, joining the efferents from these nodes, pass through the deep fascia to unite with the deep lymphatics. (3) A set of vessels from the palm of the hand passes upward along the volar side of the forearm. Anastomoses are frequent between these groups of lymphatic vessels, particularly in the cubital region.

It will thus be seen that the superficial cubital nodes receive lymph from the ulnar digits and from the palm of the hand, but not from the thumb and forefinger.

The superficial lymphatics from the rest of the arm join these three main groups at various levels.

The deep vessels.—The deep lymphatic vessels of the upper extremity drain the joint capsules, periosteum, tendons, and (if the recent work of Aagaard is correct) the muscles. They collect into vessels which, in general, accompany the arteries, in the forearm, the radial, ulnar, anterior and posterior interosseous, and in the arm the brachial. Above the elbow they are joined by numerous super-

Fig. 567.—The Lymphatics of the Forearm. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



ficial lymphatic vessels including efferents from the superficial cubital nodes. Along their course in the forearm are intercalated small nodes (pin-head size), radial, ulnar, anterior and posterior interosseous (Mouchet) and deep cubital; and, in the arm, small brachial intercalated nodes. The deep vessels in the main enter the brachial group of axillary lymph-glands which lie behind the large vessels and nerves, the efferents from which nodes pass either into the lower deep cervical lymph-nodes or directly into the subclavian trunk.

The lymphatics of the *shoulder-joint* have recently been described by Tananesco. He finds a ring of lymphatics in the joint capsule, whose efferents, in the main, following the arteries, run to the central and subclavian groups of axillary nodes.

C. THE LYMPHATICS OF THE THORAX

The lymphatics of the thorax will be considered under the following divisions: the superficial vessels, the deep nodes, and the deep vessels.

1. THE SUPERFICIAL LYMPHATIC VESSELS OF THE THORAX

The superficial lymphatics of the thorax pass almost exclusively to the axillary nodes, and may be regarded as forming three sets, a ventral, a lateral, and a dorsal. The **ventral set** drains the thoracic integument, which extends form the median line and the clavicle over to the lateral border of the chest, and includes the vessels of the mammary gland, which will, however, be described separately. The majority of the vessels from this area end in the anterior pectoral group of axillary nodes, a few, which arise beneath the clavicle, passing to the supraclavicular nodes, and a few perforating the intercostal spaces and ending in the chain of nodes along the internal mammary artery.

It has been shown that an injection into the subcutaneous plexus near the median line passes to the opposite side, and that, in addition to the anastomosis between the networks of the two sides of the thorax which this result manifests, there may also be a few collecting trunks crossing the median line, and, furthermore, anastomoses occur between the superficial networks of the anterior thoracic and abdominal walls. Thus while the main channel of lymphatic drainage is through the axilla, there are minor accessory channels to (1) the supraclavicular nodes, (2) to the axilla of the opposite side, (3) to the internal mammary chain, and (4) in isolated cases even to the inguinal nodes. These accessory channels may become more open in cases of obstruction to the main channel.

The **lateral set** of superficial thoracic lymphatics is much less extensive than the anterior, and its collecting vessels pass upward to open into the posterior pectoral group of axillary nodes.

The **dorsal set,** which occupies the subcutaneous tissue of the *dorsal* thoracic wall, sends its vessels to the subscapular group of axillary nodes.

The Lymphatics of the Mammary Gland (Figs 566, 568)

The lymphatic network over the peripheral portions of the mammary gland is like that of the rest of the thoracic wall. In the areola, however, the capillaries are far more abundant, forming a double subareolar plexus. The superficial plexus is so dense that its meshes can be seen only with a lens. The deeper plexus not only drains the superficial plexus, but receives the vessels from the mammary gland itself, and from it arise two large trunks, one from the inferior and one from the superior part of the plexus. These two vessels pass to one or two of the nodes belonging to the anterior pectoral group of axillary nodes. In addition there may be—(1) one or two vessels passing to the nodes along the axillary artery; (2) in rare cases a vessel passing directly to the subclavian nodes. There is also a definite channel from the medial margin of the gland to the internal mammary nodes, the ducts following the perforating branches of the internal mammary vessels, and it may be noted that the crossed anastomosis and that with the abdominal network, mentioned in connection with the superficial thoracic vessels, may, on occasions, serve as channels for the mammary drainage.

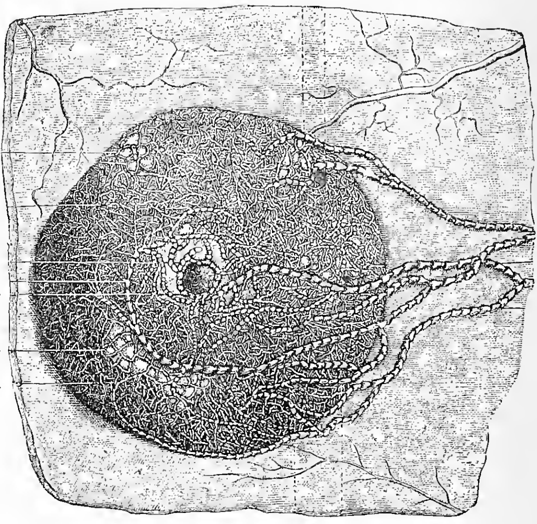
There is also clinical evidence indicating that lymphatic vessels from the lower and medial aspect of the mammary gland may pass through the abdominal wall in the angle between the xiphoid process and the costal cartilages, establishing a communication with the lymphatics of the abdomen in the diaphragmatic region.

Lymphatics of the thoracic muscles.—The recent studies of Aagaard make it probable that muscles are provided with lymphatics. Whether his findings will be substantiated or not, however, it is unquestioned that lymphatic vessels course through the pectoral muscles—some passing to the axillary, others to the subclavian, and still others to the internal mammary chain of nodes. This would suffice to explain the fact that cancer of the breast may extend into and through the pectoral muscles.

2. THE DEEP LYMPHATIC NODES OF THE THORAX

The lymphatic nodes of the thoracic cavity may be divided into the parietal and the visceral. The **parietal nodes** are arranged in two sets, the internal mammary chain and the intercostal nodes (fig. 570). Along the **internal mammary** artery are from four to six small nodes, [lgl. sternales] which receive ducts from the anterior thoracic and the upper part of the abdominal walls, from the anterior diaphragmatic nodes which drain the liver, and from the medial edge of the mammary gland. The efferent vessels usually unite with the vessels of the anterior mediastinal and bronchial nodes, to form the broncho-mediastinal trunk, which may join the thoracic duct on the left and the jugular or subclavian trunk on the right or may empty separately into the subclavian vein on both sides.

Fig. 568.—Lymphatics of the Subareolar Plexus of the Breast. (After Sappey.)



The **intercostal nodes** [lgl. intercostales] lie along the intercostal vessels, near the heads of the ribs. There are usually one or two in each space, and occasionally a node is placed where the perforating lateral artery is given off. They receive afferents from the deeper part of the thoracic wall and costal pleura. Their efferents enter the thoracic duct, those from the nodes of the lower four or five interspaces uniting usually to form a common duct on each side, but more marked on the left side, which descends to the receptaculum chyli.

The efferent lymph-vessels from the upper intercostal nodes often unite into common trunks which drain several interspaces, and which may pass through a large gland near the thoracic duct before emptying into it. Occasionally such collecting vessels from the right side cross the mid-line behind the aorta to reach a large gland to the left of the aorta.

The **visceral nodes** of the thorax are arranged in three groups:—

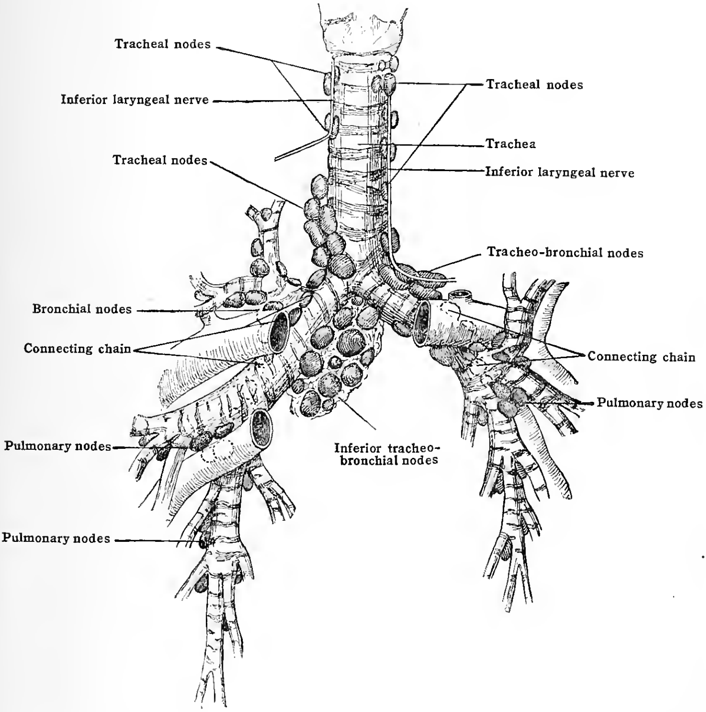
1. The **anterior mediastinal nodes** [lgl. mediastinales anteriores] are situated, as their name indicates, in the anterior mediastinum, and are arranged in an upper and a lower set. The upper set is situated upon the anterior surface of the arch of the aorta, and consists of eight or ten nodes, which receive afferents from the pericardium and the remains of the thymus gland. Their efferent vessels pass upward to join the broncho-mediastinal trunk. The lower set consists of from

three to six nodes, situated in the lower part of the mediastinum. They receive afferent ducts from the diaphragm, hence they are sometimes termed the **diaphragmatic nodes,** and also from the upper surface of the liver. Their efferents pass upward to open into the upper anterior mediastinal nodes.

2. The **posterior mediastinal nodes** [lgl. mediastinales posteriores] eight or ten in number, are situated along the thoracic aorta, and receive vessels from the mediastinal tissue and from the thoracic portion of the œsophagus. Their efferents open directly into the thoracic duct.

3. The **bronchial nodes** [lgl. bronchiales] form an extensive group lying along the sides of the lower part of the trachea, and along the bronchi as far as the hilus

Fig. 569.—The Tracheal and Bronchial Nodes. (Sukiennikow.)



of each lung, those lying in the hilus being termed the **pulmonary nodes,** and others, according to their position, lateral tracheo-bronchial, inferior tracheo-bronchial (nodes of the bifurcation) and tracheal (paratracheal). They receive the drainage of the lower part of the trachea, the bronchi, the lungs, part of the œsophagus, and, to a small extent, the heart. Their efferent vessels unite with those from the upper anterior mediastinal and internal mammary nodes to form the broncho-mediastinal trunk.

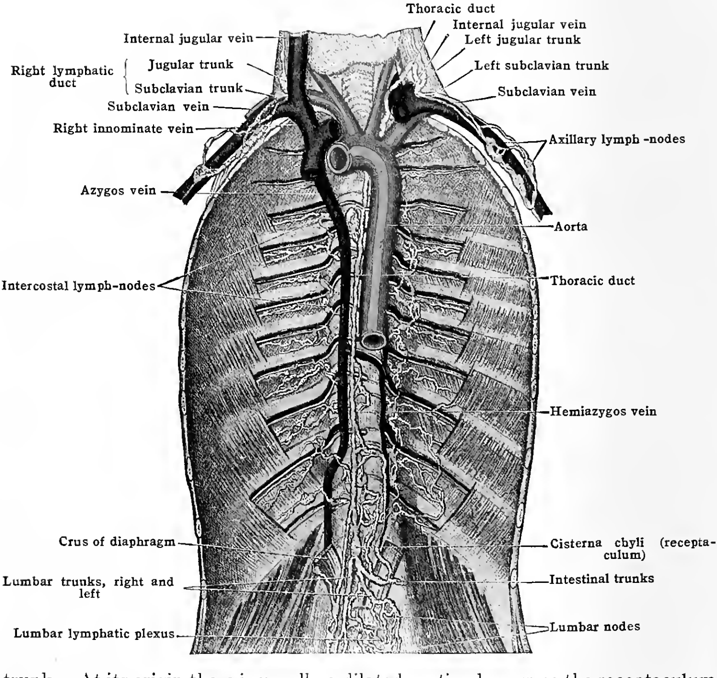
3. THE DEEP LYMPHATIC VESSELS OF THE THORAX

In following the deep lymphatics of the thorax the course of development will be followed in describing first the thoracic duct and right lymphatic ducts, second the parietal vessels, and third the visceral vessels.

The Thoracic Duct

The **thoracic duct** [ductus thoracicus] (fig. 570), which is the main collecting duct of the lymphatic system, extends from the second lumbar vertebra along the spinal column and course of the aorta to the junction of the left internal jugular and subclavian veins. It receives all the lymphatics below the diaphragm, and the deep lymphatics from the dorsal half of the chest wall; and also, when joined, near its cephalic end, by the left broncho-mediastinal, subclavian and jugular trunks, from the remainder of the left half of the body, above the diaphragm. At the caudal end the duct is formed usually by the union of three collecting ducts, one from each of the lumbar groups of nodes, and an unpaired intestinal

Fig. 570.—The Thoracic Duct. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



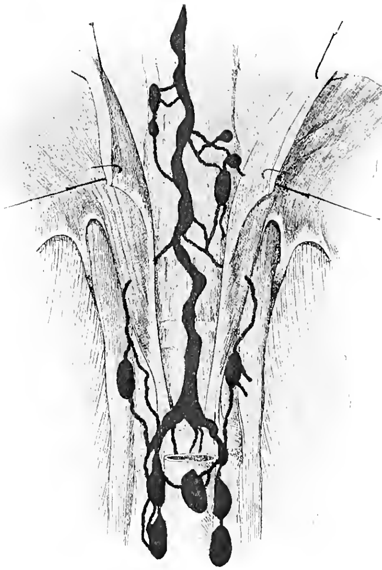
trunk. At its origin there is usually a dilated portion known as the **receptaculum [cisterna chyli]**. This usually ends opposite the body of the eleventh thoracic vertebra, and from here on the duct is from 4 to 6 mm. in diameter, until near its termination, where it is again wider.

In its cadual part, the duct lies dorsal to the aorta in the median line; it passes through the aortic opening in the diaphragm, and then inclines to the right and passes upward to about the fourth, fifth, or sixth thoracic vertebra, when it bends to the left and passes, continuing upward, over the apex of the left lung and the left subclavian artery, and in front of the root of the left vertebral artery and vein, and then curves downward to open into the left subclavian vein, close to its junction with the left internal jugular. The duct runs in the wall of the vein a short distance before ending.

Variations.—There is a wide range of variation from this usual course. The duct is frequently double throughout a part of its course, the two branches being connected by cross anastomoses, and finally uniting into a single trunk before joining the veins. It may be multiple, or a single trunk may pass in front of the aorta instead of behind. In a few instances it has been found emptying into the right instead of the left subclavian vein. There is also a wide range of variation in the height to which the duct ascends in the neck before curving downward to the vein. As regards the termination of the thoracic duct, variations are also frequent; it may bifurcate and end as two ducts. It often connects with the lowermost part of the internal jugular, or the beginning of the innominate. According to Henle, there is one undoubted case reported of a thoracic duct ending in the azygos vein near the sixth thoracic vertebra, the duct being obliterated above this point. At the terminal bend the thoracic duct receives the jugular trunk from the neck; it may also receive the subclavian and the bronchomediastinal trunks, but it is more usual for these last two to open either separately or together into the subclavian.

Variations are extremely numerous in the region of the receptaculum. Severa lobservers state that, in the majority of cases in man, no definite receptaculum exists. Bartels found one in only 25 per cent. of the cases studied. Instead, there is present a widening of each of the two lumbar trunks, with several anastomoses between them (55 per cent., Bartels), or a widening of these two stems without anastomosis (5 per cent.), or a much elongated widening arising

FIG. 571.—ABDOMINAL PORTION OF THE THORACIC DUCT. (Poirier and Cunéo.)



from the growing together of the two lumbar trunks (10 per cent.). In cases where the lumbar trunks remain separate, the intestinal trunk joins the left one.

Development.—While the exact mode of its development is still in dispute, enough is agreed upon by the various investigators to explain most of the variations in the thoracic duct. In brief, it is known that the lymphatics start in the neck as a variable number of outgrowths from the veins in the region of the junction between the later internal jugular and subclavian veins. A variable number of these connections disappear, while the various combinations of one, two, three or four which are retained furnish the numerous variations in number and position of the ducts which empty into the vein in the adult. Thus the thoracic duct may have one, two or even three openings into the veins, while the jugular, subclavian and bronchomediastinal trunks may join the thoracic duct or may enter the veins separately or in various combinations.

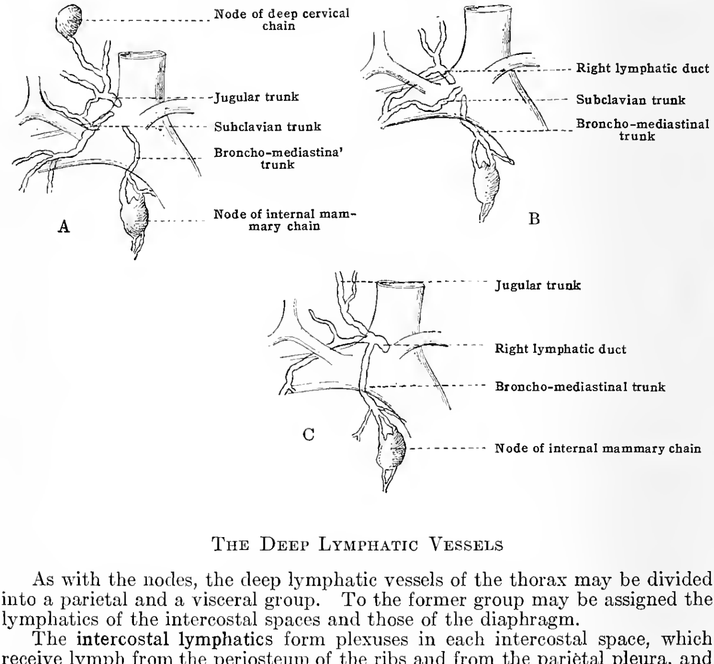
It is also known that the upper part of the thoracic duct is at first bilateral, being formed by outgrowths from the primary plexus, which meet in a common plexus around the aorta. Normally the right portion of these connections disappears, so that the thoracic duct empties into the left subclavian vein. In exceptional cases, where it opens into the right subclavian vein, there have also been present variations in the large right arterial trunk. These conditions in all probability at a certain stage in development produced a greater resistance to the lymph stream in the left than in the right vessel causing it to become obliterated so that the right instead of the left became the permanent ending of the duct.

Most of the other variations—the frequent presence of longer or shorter doublings of the duct with anastomoses between the two parts, the numerous variations in the region of the receptaculum chyli—are easily explained by the fact that the duct and receptaculum pass through a stage in development in which they form richly anastomosing plexuses around the aorta.

The Right Terminal Collecting Ducts

On the right side the jugular, subclavian, and broncho-mediastinal trunks usually open separately into the subclavian vein, the orifices of the first two being near together. When the jugular and subclavian trunks unite, the common duct is termed the right lymphatic duct; this is a rare form, and it is still more rare for the three ducts to unite to form a common stem (fig. 572). These variations have the same explanation, embryologically, as was given for the corresponding variations on the left side.

Fig. 572.—Terminal Collecting Ducts on the Right Side. (Poirier and Cunéo.)



The Deep Lymphatic Vessels

As with the nodes, the deep lymphatic vessels of the thorax may be divided into a parietal and a visceral group. To the former group may be assigned the lymphatics of the intercostal spaces and those of the diaphragm.

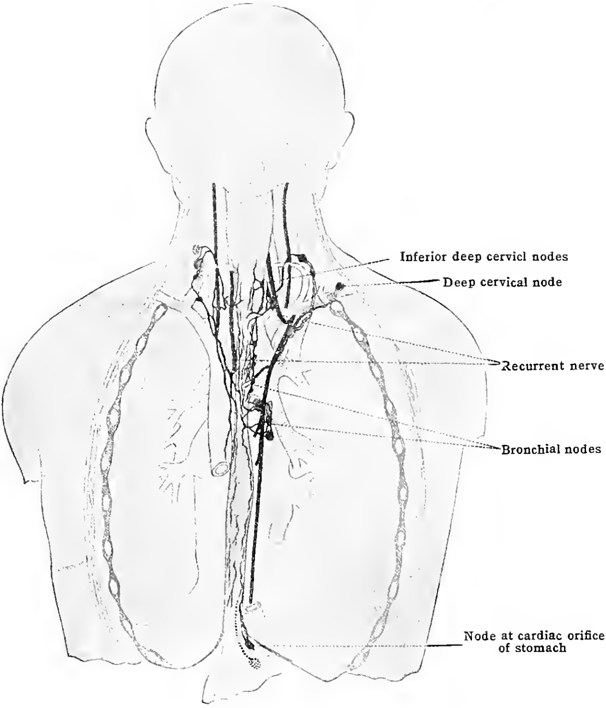
The **intercostal lymphatics** form plexuses in each intercostal space, which receive lymph from the periosteum of the ribs and from the parietal pleura, and from which the drainage is either ventral or dorsal. From the dorsal half of each space the drainage is to the intercostal nodes, while from the ventral half it is toward the internal mammary nodes.

The lymphatics of the diaphragm.—There is an exceedingly rich plexus of capillaries both on the pleural and on the abdominal surface of the diaphragm, especially in the region of the central tendon, these plexuses lying in the subserous layers and being freely connected by vessels which perforate the muscle. There is, however, only slight communication between the plexuses of the right and left sides of the diaphragm. The vessels lie between the coarse muscle bundles, forming a very characteristic picture, in which the lymphatics stream outward radially, like the spokes of a wheel. The collecting vessels empty into three groups of small nodes on the convex surface. The *ventral group* lies ventral to the central tendon. Two or three nodes in the centre of this group receive afferents from the liver and none from the diaphragm, but the rest receive vessels from the ventral surface of the diaphragm and the efferents of all pass to the lower set of anterior mediastinal nodes.

The *middle group* consists of from three to six nodes, which lie, on the left side, near the point where the phrenic nerve enters the diaphragm; on the right side, near the vena cava.

The *dorsal group* of four or five nodes is placed between the pillars of the diaphragm. The vessels from the lateral and dorsal groups pass to the posterior mediastinal nodes, and also to the upper cœliac nodes, which likewise receive the drainage from the dorsal part of the abdominal surface of the diaphragm.

Fig. 573.—The Lymphatics of the Œsophagus. (After Sakata.)



To the visceral group of thoracic lymphatics belong the vessels of the thymus, the lungs, the heart, and the œsophagus.

The **lymphatics of the thymus** drain, according to Severeanu, into three sets of glands, an anterior, a ventral and a dorsal group. The *anterior* set, one gland on each side, lies lateral to the cephalic end of the thymus, and drains into the jugular or subclavian trunk. The *ventral* set includes 4–6 of the anterior mediastinal lymph-glands. The *dorsal* set, 2 on each side, is made up of anterior mediastinal glands lying between the thymus and the pericardium.

The **lymphatics of the lungs** are arranged in two sets. A *deep set* takes its origin in plexuses which surround the terminal bronchi and follows the course of the bronchi, the pulmonary artery, and the pulmonary vein to the pulmonary nodes at the hilus, whence the stream passes to the main bronchial nodes (fig. 569), especially to those situated in the angle formed by the bifurcation of the trachea, and thence to the broncho-mediastinal trunk. A *superficial set* arises in a network situated upon the surface of the lung beneath the visceral layer of the pleura.

According to Miller, who has studied the lymphatics of lung and pleura most carefully in dog and man, the only communications between the lymphatics of the pleura and the deep lymphatics occur around the veins which reach the pleural surface. These vessels are provided with valves so that the lymph stream passes, in them, toward the pleural surface. The collecting stems of the subpleural lymphatics pass independently to the pulmonary nodes.

Lymphatics of the heart.—The superficial (subepicardial) lymphatics of the heart collect to two main stems which accompany the main coronary vessels. The right stem accompanies the right coronary artery to its origin, passes on over the arch of the aorta and empties into one of the anterior mediastinal lymph-nodes. The left stem, formed by two stems accompanying the circumflex and anterior descending branches of the coronary vein, passes behind the arch of the aorta to an anterior mediastinal lymph-gland. Two small subepicardial intercalated nodes have been described along these trunks.

Subendocardial lymphatics have been described in animals, which connect by vessels passing through the musculature with the superficial lymphatics.

Parenchymatous lymphatics have recently been demonstrated by Bock. The course of their efferent vessels has not yet been described.

The **lymphatic vessels of the œsophagus,** which will here be considered throughout its entire extent, cervical as well as thoracic, are arranged in two plexuses, one of which occurs in the mucosa and the other in the submucosa. The collecting vessels arising from the plexuses may be divided into three sets, of which the uppermost pass to outlying nodes belonging to the deep cervical chain, those from the thoracic portion of the tube pass to the bronchial and posterior mediastinal nodes, while those from its lowermost part pass to the superior gastric nodes (fig. 573).

D. THE LYMPHATICS OF THE ABDOMEN AND PELVIS

In the following section there will be described successively the lymphatic nodes of the abdomen and pelvis, the lymphatic vessels of the abdominal walls, and the visceral lymphatic vessels.

1. The Lymphatic Nodes of the Abdomen and Pelvis

The lymphatics which connect directly with the thoracic duct, though complicated, may be described briefly by saying that they follow the aorta and its branches. In the abdomen there are four main chains along the aorta—(1) the left lumbar chain; (2) the right lumbar chain; (3) the pre-aortic chain; and (4) the post-aortic chain.

The right and left lumbar nodes [lgl. lumbales], form an almost continuous chain along the abdominal aorta, resting upon the psoas muscles, some of those on the right side being ventral and some dorsal to the inferior vena cava. They receive:—(1) the efferent lymphatics of the common iliac nodes, and hence drain the leg and external genitalia; (2) the efferent lymphatics that follow the lumbar arteries and hence drain the abdominal wall; (3) the efferents that follow the paired visceral aortic branches, namely, those from the kidneys, supra-renal, and internal reproductive organs. On the right side, the lymphatics from the reproductive organs pass to the nodes ventral to the vena cava—those of the abdominal walls pass to the dorsal set, while those from the kidney pass to both sets.

The efferent vessels of the lower lumbar nodes pass to higher ones and so on up the chain, the vessels from the uppermost nodes uniting to form a single **lumbar trunk** on each side. These trunks pass to the thoracic duct, forming two of the so-called trunks of origin of that vessel (fig. 571).

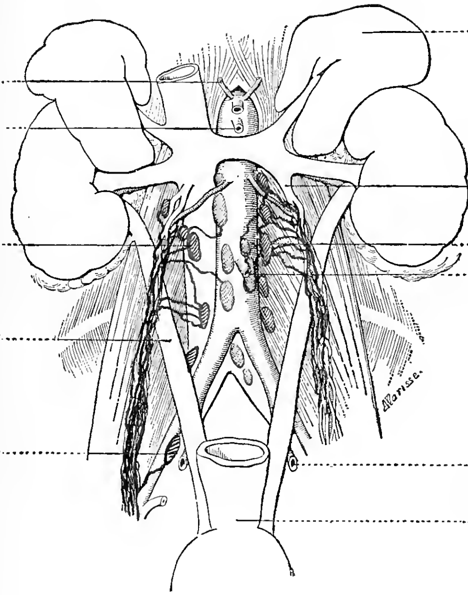
The **pre-aortic nodes** [lymphoglandulæ cœliacæ] are arranged in three groups at the root of each of the three unpaired visceral branches of the aorta—the cœliac, the superior mesenteric, and the inferior mesenteric arteries. The **cœliac nodes** are from one to three in number, and are in reality parts of chains of nodes extending along the branches of the artery and constituting the **hepatic, gastric,** and **splenic** nodes. They drain the stomach, duodenum, liver, pancreas, and spleen.

The **superior mesenteric** group is larger, and is continuous with the **mesenteric nodes** lying in the root of the mesentery. This group drains the remainder of the small intestine, the cæcum and appendix, the ascending and transverse colons, and the pancreas.

The **inferior mesenteric** group usually has two nodes, one on either side of the artery. It drains the rectum and descending and sigmoid colons. All the nodes in the mesentery and intestinal walls may be considered as outlying nodes of the pre-aortic group. They will be studied in connection with the visceral lymphatics.

The inferior mesenteric nodes drain into the neighbouring lumbar nodes, and also directly upward to the superior mesenteric nodes, and then again to the cœliac nodes. From the last a single stem, the **intestinal trunk,** arises and passes either to the right lumbar trunk or directly to the thoracic duct, forming the third of the so-called trunks of origin of the duct.

FIG. 574.—ABDOMINAL AORTIC NODES IN THE NEW-BORN. (Poirier and Charpy.)



The **post-aortic nodes** are not true regional nodes, but receive vessels from the lumbar and pre-aortic chains.

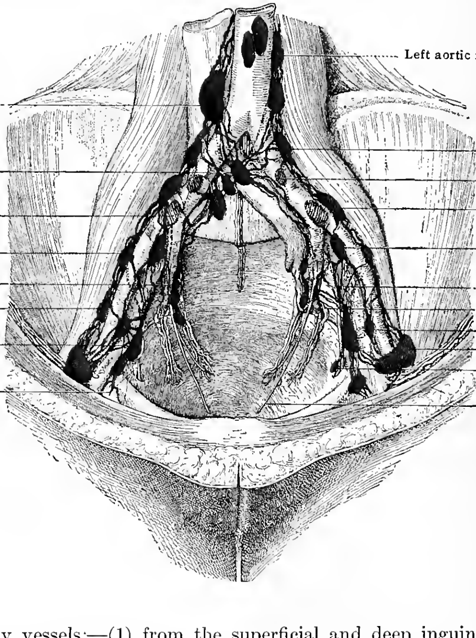
Below the bifurcation of the aorta there are three large chains, the common iliac, the external iliac, and the hypogastric.

The **common iliac nodes** [lgl. iliacæ], are in three groups (fig. 575). The *external* set consists of about two nodes, which are in reality a part of a continuous chain extending along the side of the aorta, common iliac, and external iliac arteries. A second set of two to four *posterior nodes* lies behind the artery. These two groups receive the efferent vessels of the external iliac and hypogastric chains. The *internal* set usually consists of two nodes which rest upon the promontory of the sacrum. They receive vessels from the sacral nodes, together with most of those from the pelvic viscera, namely, from the prostate, neck of the bladder, neck of the uterus, the vagina, and part of the rectum. The efferent lymphatic vessels of the common iliac nodes pass to the lumbar chain.

External iliac nodes.—These are likewise in three sets—external, middle, and internal. The *external* chain consists of three or four nodes, the lowest one being behind the crural arch. They receive:—(1) some of the vessels of the superficial and deep inguinal nodes; (2) vessels from the glans or clitoris, which come through the inguinal canal; (3) vessels from the part of the abdominal wall supplied by the deep epigastric and deep circumflex arteries, along which there may be a few outlying nodes—the **epigastric nodes.**

The *middle* chain consists of two or three nodes behind the artery. When there are three, the lowest is likewise near the crural arch. It receives vessels from the bladder, prostate, neck of the uterus, and upper portion of the vagina. The *internal* chain consists of three or four nodes, and is the continuation of the deep inguinal nodes. Its lowest nodes are likewise near the femoral ring, while the next node is large and constant, and usually lies within the pelvis. This chain

Fig. 575.—Ilio-pelvic Nodes. (Cunéo and Marcille.)



receives many vessels:—(1) from the superficial and deep inguinal nodes; (2) from the glans and clitoris through the femoral canal; (3) from the abdominal wall; (4) from the neighbourhood of the obturator vessels; (5) from the neck of the bladder, the prostate, and membranous part of the urethra; (6) from the hypogastric chain.

Thus, to sum up the nodes of the external iliac chains:—they are a part of a chain which includes the lumbar, common iliac, external iliac, and inguinal nodes. It will be noted that this extensive chain stops, for the most part, with the deep inguinal group. The external iliac nodes receive the efferents of the superficial and deep inguinal nodes; the middle and internal groups receive vessels from the pelvis. The efferent vessels of all the nodes in the chain pass to the higher nodes.

The **hypogastric nodes** [lgl. hypogastricæ].—These nodes are in groups near the origin of the branches of the hypogastric (internal iliac) artery. Thus they occur near the origin of the obturator, the uterine, or prostatic, the trunk of the inferior gluteal (sciatic) and pudic, the middle hæmorrhoidal, and the lateral sacral arteries. All the nodes are beneath the pelvic fascia, and are connected by numerous anastomoses. They receive lymphatics from the structures supplied by the corresponding arteries, namely, from the pelvic viscera, the perineum, and the posterior surface of the thigh and gluteal region. Their efferent vessels pass partly to the middle group of the common iliac nodes, and partly to the posterior nodes of the same chain.

The **sacral nodes** [lgl. sacrales].—These nodes, 5 or 6 in number, lie in the hollow of the sacrum, in or near the mid-line. They receive afferent vessels from rectum and prostate, and their efferents pass to the hypogastric and lumbar nodes.

2. THE LYMPHATIC VESSELS OF THE ABDOMINAL WALLS

The lymphatic vessels of the abdominal walls are arranged in two sets, one of which is subcutaneous and the other deep or aponeurotic. The **subcutaneous** vessels form a rich network through all the subcutaneous tissue of the abdomen, anastomosing above with the subcutaneous plexus of the thorax. The collecting vessels converge toward the inguinal region, those from the posterior wall curving forward along the crest of the ilium, and they all terminate in the superficial inguinal nodes.

The **deep** vessels drain along three principal lines. (1) A set of collecting vessels follows the line of the deep epigastric artery to terminate in the lower external iliac nodes; (2) a second set follows the deep circumflex iliac vessels to the same nodes; and (3) a third set follows the lumbar vessels to terminate in the nodes of the lumbar chain. A group of small **epigastric nodes,** which may be regarded as offsets from the iliac chain, occur on the lymph-vessels which accompany the deep epigastric vessels, not far from their termination, and a second less constant group of usually three small **umbilical nodes** occurs in the vicinity of the umbilicus in the network covering the posterior layer of the sheath of the rectus abdominis muscle.

3. THE VISCERAL LYMPHATIC VESSELS OF THE ABDOMEN AND PELVIS

The lymphatics to the viscera follow along the course of the arteries. At the point where the artery of an organ branches from the aorta there is a group of nodes which represents the main regional group, and a second chain of nodes extends along the artery. The final arrangement of nodes and ducts varies with each organ.

Though the lymphatics follow the blood-vessels, the lymphatic capillaries in the regions where their relations are known are separated from the vascular capillaries; in the intestinal villi, for example, the lymphatic capillaries are central, while the vascular capillary plexuses are peripheral. The relation of the lymphatic capillaries to the essential structures of each organ, that is to say, the arrangement of the lymphatics in the absorbing area, is not yet clear in many organs, and this is a point which can be worked out by tracing the development and gradual invasion of each organ by the lymphatics. The old theory of the origin of the lymphatics from the tissue-spaces made this problem most difficult of attack.

In almost all organs there is a peripheral or capsular lymphatic plexus, which anastomoses with the parietal lymphatics, these anastomoses being particularly well developed in the case of the liver. In addition there are one or two deep plexuses in the great majority of the organs which drain partly directly to their regional nodes and partly by way of the peripheral plexus.

The Lymphatics of the Alimentary Tract

The lymphatics of the mouth, pharynx, and œsophagus have already been described (pp. 715, 730). In general, throughout the abdominal part of the alimentary canal, the distribution of nodes is as follows:—(1) There are primary regional nodes situated at the roots of the arteries as they leave the aorta, that is to say, around the cœliac and the superior and inferior mesenteric arteries; these drain large segments of the intestine; (2) groups of definite and constant nodes placed along the branches of the arteries in the root of the mesentery; these drain a definite smaller segment of the intestine; (3) chains of nodes along the anastomotic loops of the arteries, close to the intestinal wall; these are of the type called 'intercalated nodes'; (4) solitary or compound follicles, situated within the submucosa or capillary zone of the lymphatics.

What may be taken as the typical arrangement of the lymphatic vessels in the intestine may be seen in fig. 576. There are three zones in which the capillary plexuses are spread out, namely, in the subserosa, the submucosa, and the mucosa. There is an abundant plexus of large capillaries just beneath the serosa; in the submucosa the plexus is also formed by large capillaries, while the mucosal plexus is finer. The lymph-follicles lie in the zone of the mucosal plexus, and it is from this that the central chyle vessels of the villi arise. The collecting vessels are formed by the union of vessels from the submucous and subserous plexuses. They traverse the three sets of nodes just described.

The lymphatics of the stomach (fig. 577).—The stomach differs from the rest of the alimentary canal in its blood-supply in having a ventral anastomotic loop, namely, that along the lesser curvature. Along this loop is the **superior gastric chain** [lgl. gastricæ superiores] of nodes, lying between the folds of the lesser omentum, some of them being on the posterior surface of the stomach. This is the most important group of nodes draining the stomach, and it has been shown that the lymph-vessels from the pylorus run obliquely across the stomach to the main mass of nodes near the cardia, an important point in the surgery of the pylorus. The efferent vessels of the chain pass to the cœliac nodes. The vessels of the greater curvature pass to a group of **inferior gastric nodes** [lgl. gastricæ inferiores], situated along the right gastro-epiploic artery, while those of the fundus follow the short gastric and left gastro-epiploic vessels to the nodes which lie along the splenic artery, both these sets of nodes also draining to the cœliac group. There is a zone half-way between the lesser and greater curvatures, in which the lymphatics are scanty. The lymphatics of the cardia connect with those of the œsophagus, and the mucosal plexus of the pylorus is continuous with that of the duodenum.

The lymphatics of the duodenum.—The lymphatics of the duodenum depart somewhat from the type, owing to its relations with the pancreas and the bile-ducts. The collecting vessels end:—(1) in nodes ventral to the pancreas, which follow the pancreatico-duodenal artery to the hepatic chain; (2) in nodes dorsal to the pancreas, which follow the superior mesenteric artery to the superior mesenteric nodes. There are anastomoses between the lymphatics of the duodenum and those of the pylorus, of the pancreas, and of the chain along the common bile-duct.

The **lymphatics of the jejuno-ileum** (fig. 578) have already served as the type of the arrangement of the intestinal lymphatics (see above). The mass of **mesenteric nodes** [lgl. mesentericæ] to which the lymphatics of the small intestine pass is the largest and one of the most important in the body, its individual nodes numbering anywhere from 130 to 150.

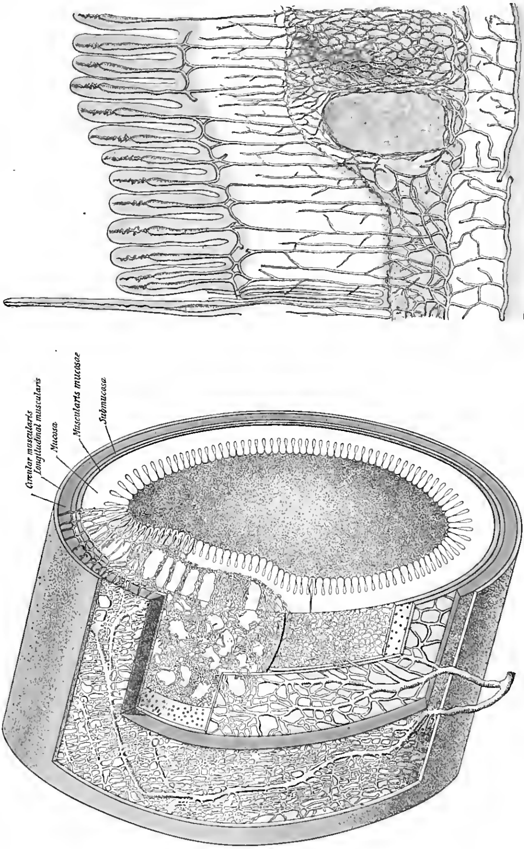
The lymphatics of the ileo-cæcal region.—The surgical importance of the lymph-nodes in connection with the appendix warrants a detailed description of them in which the observations of Brödel will be followed. The drainage of the cæcum and appendix is along the ileo-colic artery, and is carried on by three sets of collecting vessels—(1) an anterior cæcal set, which generally pass through one or more outlying nodes before reaching the ileo-cæcal mesenteric nodes; (2) a similar posterior set; and (3) an appendicular set, three to six in number, which usually pass directly to the ileo-cæcal nodes. The appendix thus has an independent drainage into one or two ileo-cæcal nodes, about 3 cm. above the ileum. The ileo-cæcal chain drains through the mesenteric nodes to the superior mesenteric group (figs. 579, 580).

The lymphatics of the large intestine.—Along the ascending colon there are but few nodes on the terminal vascular arches, but the number increases along the transverse colon, especially at its two angles. These nodes, together with those along the descending and sigmoid colons, are termed the **meso-colic nodes** [lgl. mesocolicæ], and they drain partly to the superior mesenteric and partly to the inferior mesenteric nodes, their efferents following the corresponding arteries.

The lymphatics of the transverse colon connect with those of the omentum; those of the descending colon are more scanty.

The lymphatics of the rectum and anus.—There are three lymphatic zones of the rectum and anus. (1) An **inferior zone,** corresponding to the anal integument, in which the capillary networks, both superficial and deep, are extremely abundant, and from which from three to five collecting vessels on either side pass to the inguinal region and end in the medial superficial inguinal nodes. (2) A

FIG. 576.—THE LYMPHATIC VESSELS OF THE INTESTINE. (After Mall.)

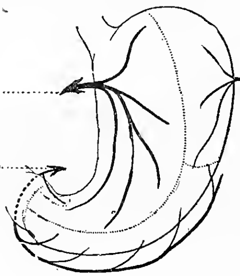


middle zone, corresponding with the transition zone of epithelium—that is, with the mucous membrane below the columns of Morgagni. Here the network is coarse, and has its meshes arranged vertically; its ducts drain partly into nodes situated along the inferior and middle hæmorrhoidal arteries, and partly pass to nodes in the meso-rectum, situated along the superior hæmorrhoidal artery and known as the **ano-rectal** nodes. (3) The **superior zone** corresponds to the remainder of the rectal mucous membrane, and contains a rich network whose collecting vessels pass to the ano-rectal glands, and thence along the superior hæmorrhoidal arteries to the inferior mesenteric nodes.

Lymphatics of the liver.—The lymphatic drainage of the liver is complicated and has great need of being entirely restudied from the standpoint of development. Its course is mainly to the cœliac nodes, but on the way it passes through a secondary group of three to six **hepatic nodes** [lgl. hepaticæ], situated along the hepatic artery. Some of these nodes are along the horizontal part of the artery, parallel to the superior border of the pancreas, while the rest follow the artery in its vertical course along with the portal vein, and become continuous at the portal fissure with two distinct chains of nodes, one of which follows the hepatic artery and portal vein, and the other the cystic and common bile-ducts. These nodes are variable, but one constant node is at the junction of the cystic and hepatic ducts. A part of the drainage of the liver is also through the **diaphragmatic nodes.**

The superficial collecting lymph-vessels of the liver have been studied by Sappey. Those from the superior surface include three sets. From the dorsal part vessels pass through the diaphragm with the vena cava, and end in the adjacent posterior mediastinal nodes. Some of these vessels from the right lobe pass in the coronary ligament to the cœliac nodes, and some from the left lobe to the superior gastric nodes. The second set of vessels from the superior surface runs over the ventral border to the hepatic nodes situated in the portal fissure. The third and most important set arises near the falciform ligament, and passes

Fig. 577.—The Lymphatic Zones of the Stomach. (Cunéo.)



partly dorsalward to the anterior mediastinal group of nodes on the upper surface of the diaphragm, and to the nodes around the vena cava, and partly ventralward to the hepatic nodes of the portal fissure.

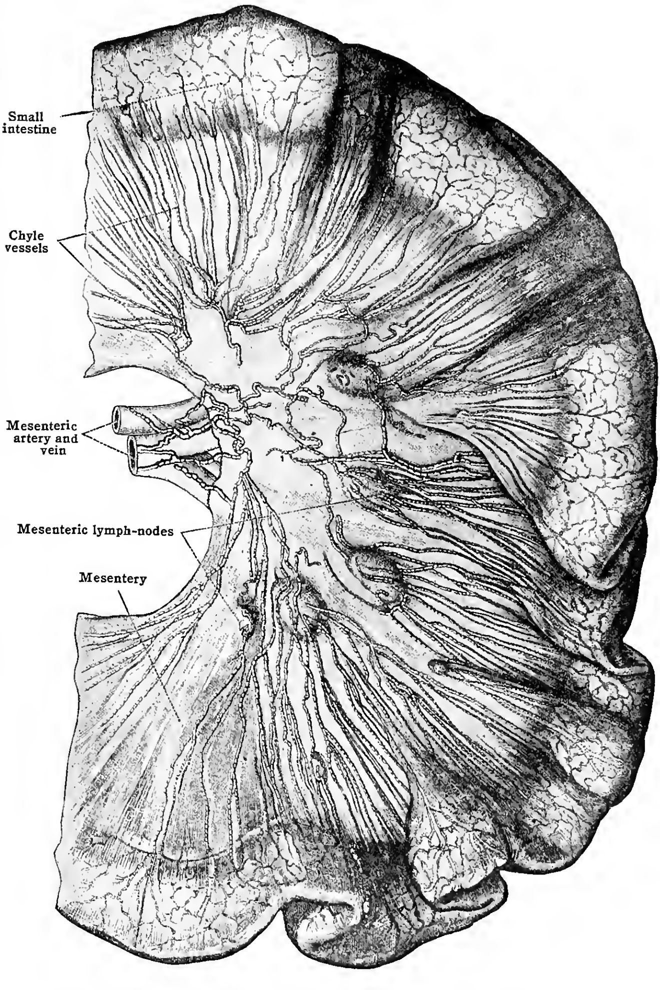
The collecting vessels of the inferior surface pass to the nodes situated in the portal fissure, either along the artery or the bile-ducts.

The lymphatics of the gall-bladder join the hepatic nodes along the cystic and common bile-ducts, and also the superior pancreatic nodes.

Lymphatics of the pancreas.—The lymph-vessels which drain the pancreas fall, according to Bartels, into four groups: left, anterior (upper), right and posterior (lower). (1) The left group drain the tail of the pancreas and pass to the splenic lymph-nodes, at the hilus of the spleen. (2) Anteriorly lymphatics pass to "superior pancreatic lymph-nodes," superior gastric and hepatic nodes. (3) To the right, lymphatics pass to "pancreatico-duodenal lymph-nodes." (4) Posteriorly lymphatics pass to the aortic, mesenteric, meso-colic, and inferior pancreatic nodes. The splenic, superior pancreatic, inferior pancreatic, and pancreatico-duodenal nodes are usually grouped together as "lymphoglandulæ pancreatico-lienales." Anastomoses exist between the lymphatics of the pancreas and those of the duodenum.

The **lymphatics of the spleen** (fig. 582) are found only in the form of a subcapsular plexus, there being no deep network (Mall). They pass to the **splenic nodes** [lgl. pancreatico-lienales], which are variable in number and are situated along the course of the splenic vessels. In addition to the spleen they drain the fundus of the stomach and a part of the pancreas.

Fig. 578.—Lymphatics of the Small Intestine. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

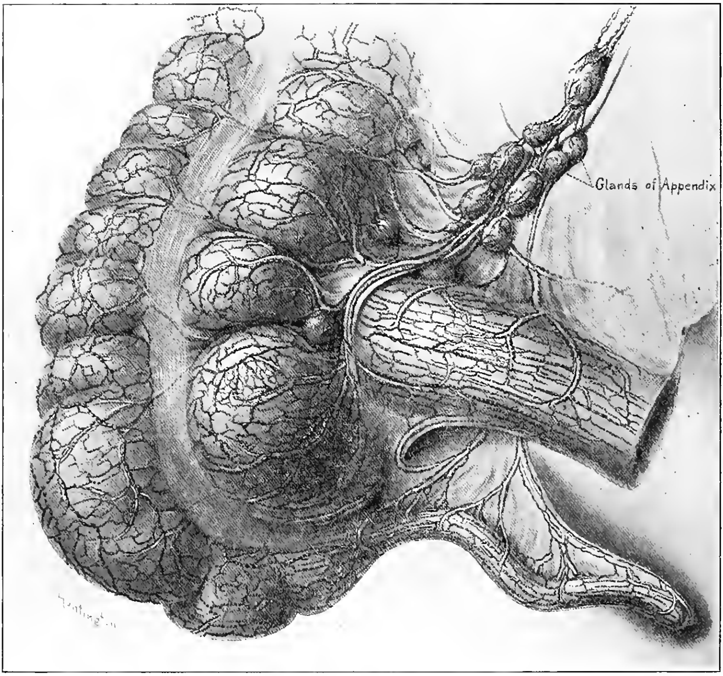


The Lymphatics of the Excretory Organs and of the Suprarenal

The lymphatics of the kidney.—The lymphatic vessels from the deep capsular and parenchymatous lymphatics of the kidney run to the nodes of the lumbar chain (fig. 583). On the right side, part of the nodes concerned lie ventral and part dorsal to the renal vein; one of the nodes lies as far caudalward as the bifurcation of the aorta; and one or two vessels may pass to pre-aortic nodes. On the left side the vessels end in four or five nodes of the lumbar group. The efferents of these nodes pass through the diaphragm and end in the thoracic duct.

The lymphatics of the Suprarenal.—The lymphatic vessels coming from the capsular and parenchymatous plexuses pass, on the right side, into two or three anterior para-aortic nodes, and a small retro-venous gland, near the pillar of the diaphragm; on the left side, into para-aortic nodes, and, in part, through the diaphragm, in company with the splanchnic nerve, to a posterior mediastinal

Fig. 579.—The Lymphatic Circulation of the Ileo-cæcal Region, Anterior View. (After Kelly.)



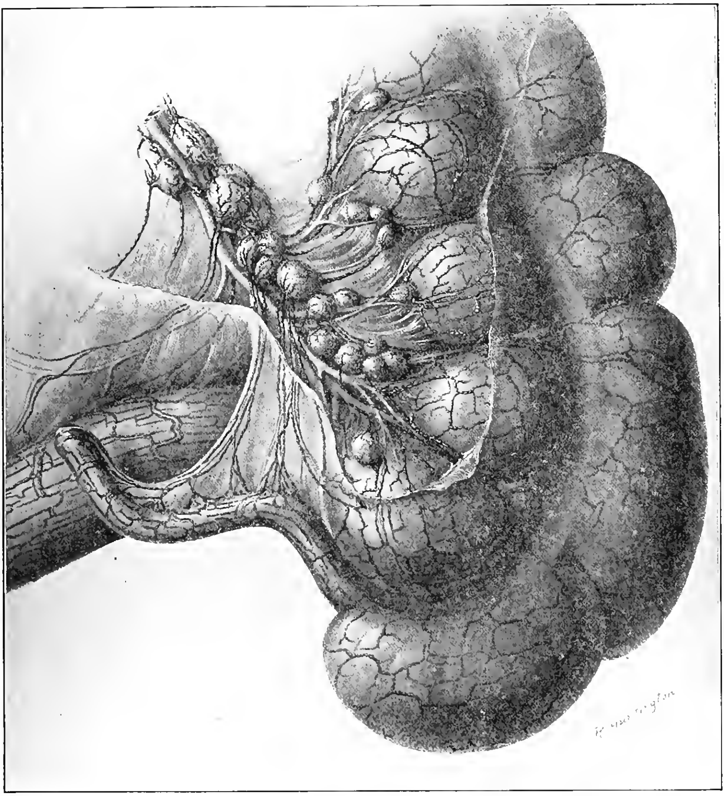
gland, lying between the ninth thoracic vertebra and the aorta. Anastomoses occur with the lymphatics of the kidney.

In addition to the capsular lymphatics proper, Kumita describes a subserous plexus, which is present over both kidney and adrenal, which anastomoses with the lymphatics of the liver and diaphragm. The efferents of this plexus collect, on the right side, to a gland placed to the right of the inferior vena cava, anterior to the right renal vein, and on the left side to a gland anterior to the left renal vein.

The lymphatics of the ureter.—Sakata has recently studied the lymphatics of the ureter. They fall into three groups: (1) An anterior (upper) group, which run to the anterior lumbar nodes, or join the renal lymphatics; (2) a middle group which pass to the posterior lumbar and interiliac nodes; (3) a posterior (lower) group which pass to hypogastric nodes and which anastomose with lymphatics of the bladder.

The lymphatics of the bladder.—The collecting vessels from the lower part of the ventral surface pass to a node of the external iliac group, situated near the femoral ring and the obturator nerve; those from the upper part of the ventral and dorsal surfaces pass to the middle node of the middle group of the external iliac chain, and from the rest of the dorsal surface they pass either to the hypogastric

Fig. 580.—The Lymphatic Circulation of the Ileo-cæcal Region Posterior View. (After Kelly.)



nodes or beyond these to the nodes at the bifurcation of the aorta (fig. 584). In this latter group end also the vessels from the neck of the bladder. Along some of the lymphatics of the bladder are intercalated lymph-nodes, which have been termed anterior and lateral vesical nodes.

The lymphatics of the prostate.—The lymphatics of the prostate have been studied in the dog by Walker and in man by Bruhns. The collecting vessels, six to eight on each side, pass along the prostatic artery to the nodes along the external border of the hypogastric artery. These nodes are connected with those along the external and common iliac arteries, and it is possible, from an injection of the prostate, to fill the entire chain of nodes as far as the renal artery. A trunk from the posterior surface runs up over the bladder and curves outward to the middle node of the middle group of the external iliac chain, and still other vessels from the posterior surface run first downward, pass around the rectum, and then ascend to the lateral sacral nodes. From the anterior surface a descending duct may follow the deep artery of the penis, and the internal pudic to the hypogastric

Fig. 581.—The Superficial Lymphatic Network of the Liver. (After Teichmann).

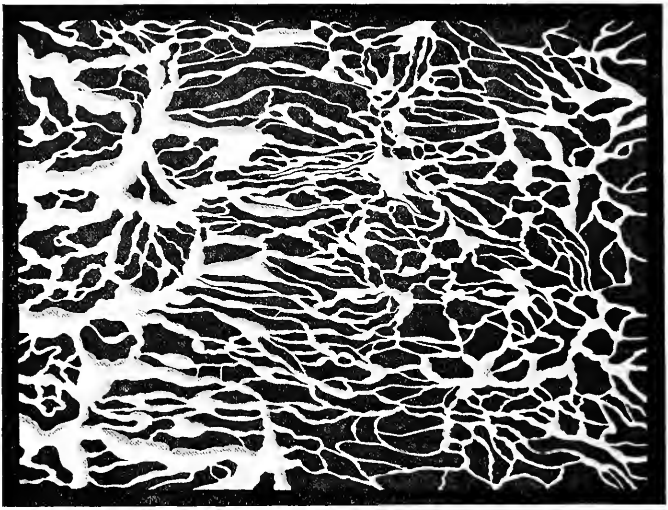


Fig. 582.—Lymphatics of the Periphery of a Pig's Spleen. (After Teichmann.)

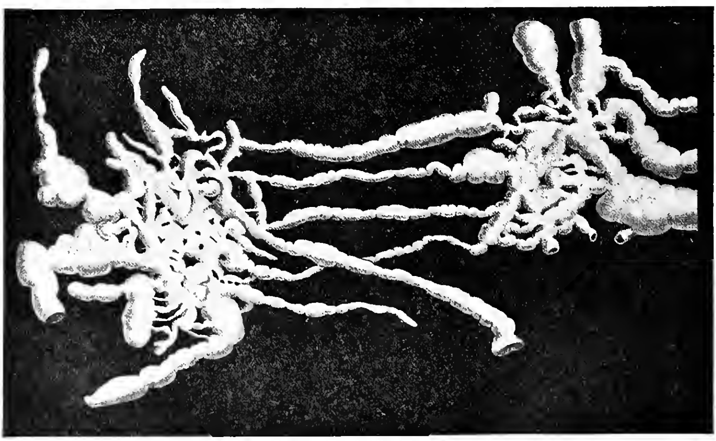

nodes (fig. 585). The lymphatics of the prostate anastomose with those of the bladder, ductus deferens and rectum.

The lymphatics of the urethra.—1. *In the Male.*—The capillary plexus of the urethra is in the mucous membrane. The collecting vessels from the mucous

FIG. 583.—LYMPHATICS OF THE KIDNEY. (After Poirier and Cunéo.)

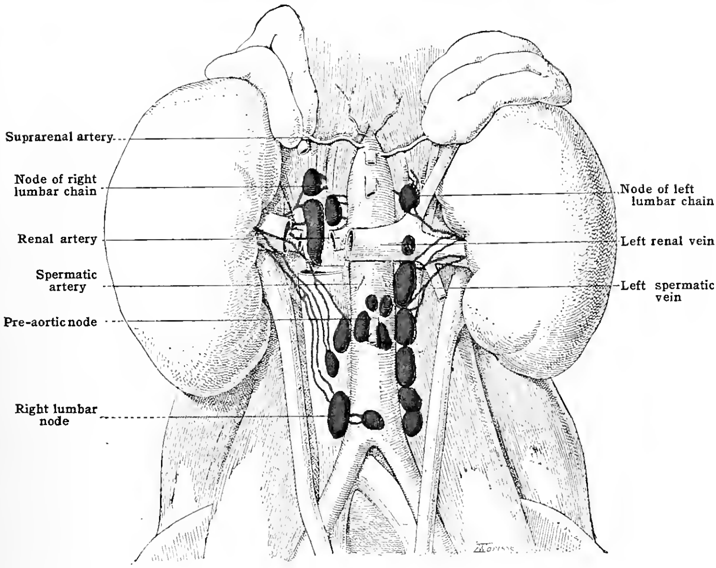

FIG. 584.—LYMPHATICS OF THE BLADDER. (After Cunéo and Marcille.)

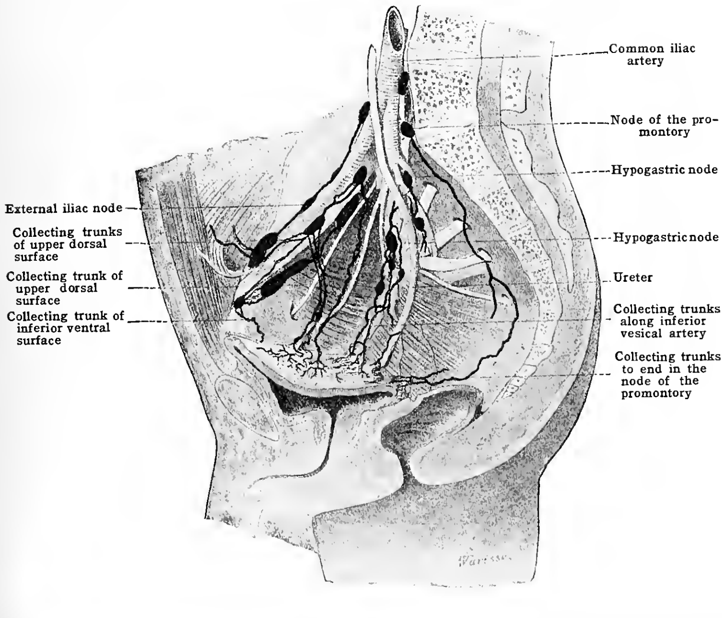
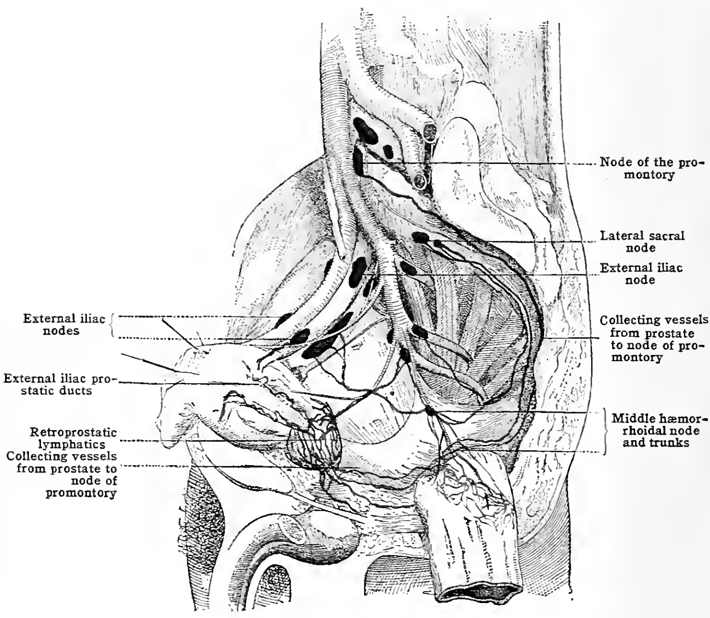


membrane of the glans follow the dorsal vein. Those from the penile and membranous portions of the urethra start from the inferior surface and curve around the corpora cavernosa, as seen in fig. 586, to join the others along the dorsal vein. These vessels run with the vein to the symphysis, where they form a plexus in which there may be some small intercalated nodes. From this plexus vessels pass in two directions:—(1) Three or four vessels, the crural trunks, pass to the deep inguinal and external iliac nodes, and (2) one vessel enters the inguinal canal and ends in one of the external iliac nodes.

The vessels from the bulbar and membranous portions either follow the internal pudic artery, or pass to the symphysis and end in the external iliac nodes, or pass onto the surface of the bladder and thence to the external iliac chain. The

Fig. 585.—The Lymphatics of the Prostate. (After Cunéo and Marcille.)



lymphatics of the prostatic portion run with the prostatic ducts. The lymphatics of the urethra anastomose with those of the bladder and those of the glans.

2. *In the female* the lymphatic vessels of the urethra end in the external iliac and hypogastric nodes.

Lymphatics of the Reproductive Organs

In the Male (figs. 585, 586, 587)

The lymphatics of the external genitalia will be first described and then those of the internal organs (fig. 589).

The **lymphatics of the scrotum** form a rich plexus which has been pictured by Teichmann (fig. 547). The collecting vessels, ten to fifteen on either side, arise near the raphe and pass to the root of the penis, where some curve lateralward to the superior medial superficial inguinal nodes; while others, coming from the lateral surface of the scrotum, pass to the corresponding inferior nodes.

FIG. 586.—LYMPHATICS OF THE PENILE AND MEMBRANOUS PORTIONS OF THE URETHRA. (After Cunéo and Marcille.)

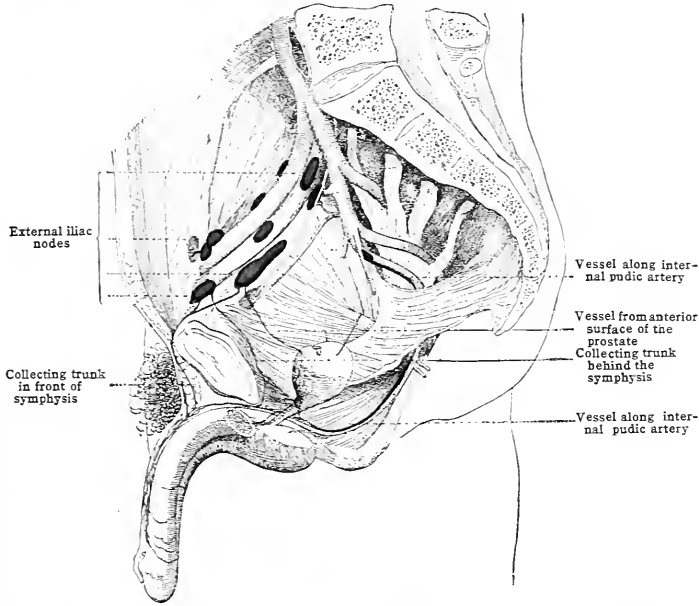


FIG. 587.—LYMPHATICS OF THE GLANS PENIS IN A NEW-BORN CHILD. (Cunéo and Marcille.)

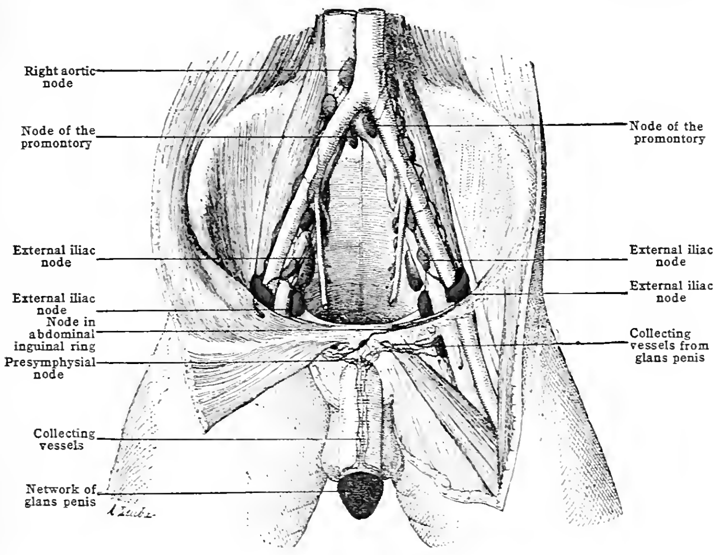
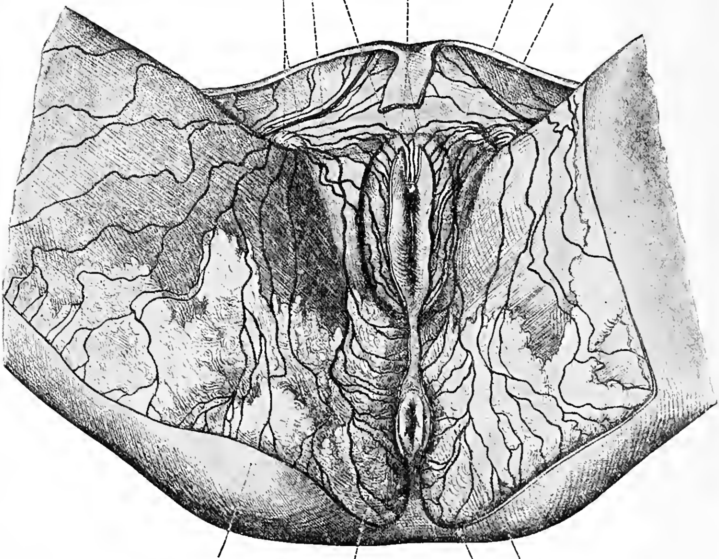


The lymphatics of the penis.—(1) The cutaneous lymphatics form a plexus from which collecting vessels follow the dorsal vein and end in the superficial inguinal nodes. (2) The lymphatics of the glans form an exceedingly rich plexus from which vessels follow the dorsal vein of the penis, as described under the urethra, and end in the deep inguinal and external iliac nodes. (3) The lymphatics of the erectile structures are little known.

The **lymphatics of the testis** are both superficial and deep, the latter being exceedingly hard to inject. The collecting vessels follow the spermatic cord and artery and end in the lumbar nodes.

FIG. 588.—LYMPHATICS OF THE PERINEUM. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The lymphatics of the ductus deferens and vesiculæ seminales.—In the ductus deferens only a superficial set has been injected, and its vessels pass to the external iliac nodes. The plexus of the vesiculæ seminales is double, superficial and deep, and its vessels pass to the external iliac and hypogastric nodes.

In the Female

(Figs. 588, 589, 590)

The lymphatics of the vulva.—Throughout the vulva there is an exceedingly rich, superficial lymphatic plexus, from which collecting vessels pass to the symphysis and there turn lateralward to the medial superficial inguinal' nodes. The fact that the capillary plexus is continuous from side to side and that there is a plexus of the vessels in front of the symphysis, makes the nodes of both sides liable to infection from a unilateral lesion.

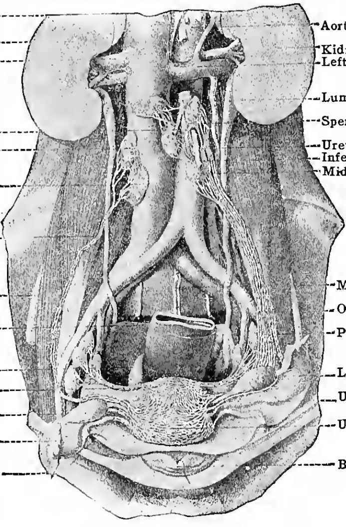
The lymphatics of the clitoris.—The lymphatics of the glans of the clitoris form an abundant network from which collecting vessels pass toward the symphysis pubis, and thence principally to the deeper inguinal nodes, one or two, however, passing through the inguinal canal to terminate in the lower external iliac nodes.

The lymphatics of the ovary.—The ovary has a remarkably rich lymphatic plexus, from which from four to six vessels leave the hilus and follow the ovarian artery to the lumbar nodes. One vessel may run in the broad ligament to the internal iliac group.

The **lymphatics of the Fallopian tube** form three capillary networks from which collecting vessels run in part with those of the ovary, and in part with the uterine lymph-vessels.

The lymphatics of the uterus.—According to Poirier, the lymphatics of the uterus arise from three capillary plexuses, a mucous, a muscular, and a peritoneal. The collecting vessels from the *body of the uterus* are in three sets:—(1) Those from the fundus, consisting of four or five vessels, run lateralward in the suspen-

Fig. 589.—Lymphatics of the Internal Genital Organs in the Female. (After Poirier.

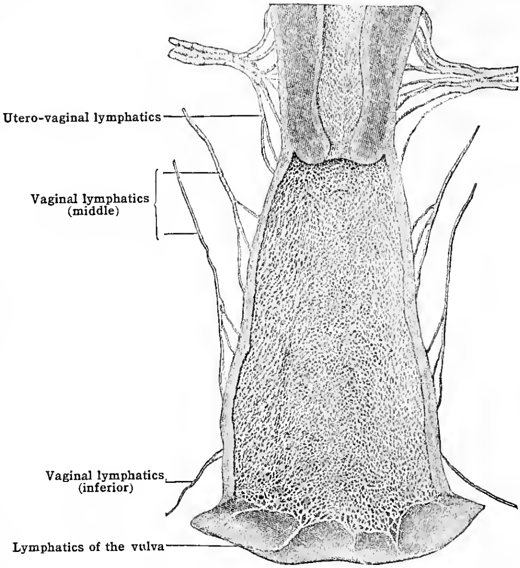


sory ligament of the ovary and follow the ovarian vessels to the lumbar and preaortic nodes. They anastomose with the lymphatics from the ovary opposite the fifth lumbar vertebra; (2) some small vessels from the fundus follow the round ligament of the uterus and terminate in the inguinal nodes; and (3) others from the body of the uterus pass laterally with the uterine vessels and terminate in the iliac nodes.

The collecting vessels from the *cervix*, five to eight in number, form a large lymphatic plexus just after leaving the cervix. From this plexus run three sets of vessels. Two or three vessels pass lateralward with the uterine artery in front of the ureter, and end in the external iliac nodes; a second set passes behind the ureter and ends in a node of the hypogastric group, and a third set from the posterior surface runs downward over the vagina and then backward and upward to end in the lateral sacral nodes and node of the promontory of the sacrum.

The lymphatics of the vagina (fig. 590).—There are two lymphatic plexuses in the vagina, a superficial and deep—the latter, the mucosal plexus, being exceedingly rich. The collecting vessels are in three groups. The superior set drains the upper third of the vagina and takes the same course as those from the lower cervical portion of the uterus; the middle set follows the vaginal artery to the hypogastric nodes; and the inferior set runs to the lateral sacral nodes and to those of the promontory. The capillary network of the lower part of the vagina is continuous with the plexus of the vulva, which drains to the inguinal nodes.

Fig. 590.—Lymphatics of the Vagina. (After Poirier.)



E. THE LYMPHATICS OF THE LOWER EXTREMITY

1. THE LYMPHATIC NODES OF THE LOWER EXTREMITY

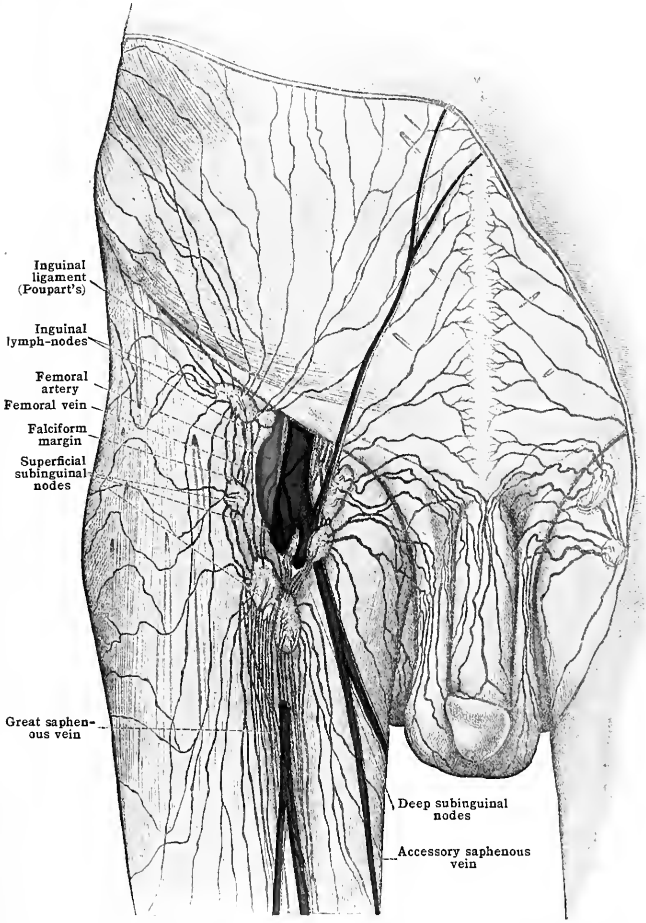
The principal group of nodes of the lower extremity is situated in the inguinal region, and hence is known as the **inguinal group.** It is in many respects similar to the axillary group, although it is not quite equivalent to it developmentally. The nodes composing it are divisible into a superficial and a deep group, the former containing many more and larger nodes than the latter. Furthermore, it is convenient to divide each of these groups into an upper and a lower set, the dividing line being an arbitrary line drawn horizontally through the point where the saphenous vein pierces the fascia of the fossa ovalis. The nodes above this line are termed collectively the **inguinal nodes,** while those below it are known as the **subinguinal nodes.**

The superficial inguinal nodes [lgl. inguinales superficiales] (fig. 591), lie along the base of the femoral trigone immediately below Poupart's ligament, superficial to the fascia lata. Their number varies from ten to twenty. They receive the subcutaneous drainage of the abdominal walls, the gluteal region, and the perineal region, and their efferents descend to the fossa ovalis, which they perforate along with the saphenous vein and terminate in the lower external iliac nodes.

The **superficial subinguinal nodes** [lgl. subinguinales superficiales], occupy the lower part of the femoral trigone and receive the entire superficial drainage of the leg, as well as a few vessels from the gluteal region and from the perineum. Their efferents pierce the fossa ovalis and pass partly to the deep subinguinal nodes and partly directly to the lower external iliac nodes.

The deep nodes.—The deep nodes are small, and vary from one to three. They lie medial to the femoral vein, the highest one (node of Cloquet or of Rosenmüller) being placed in the femoral ring and being of especial surgical

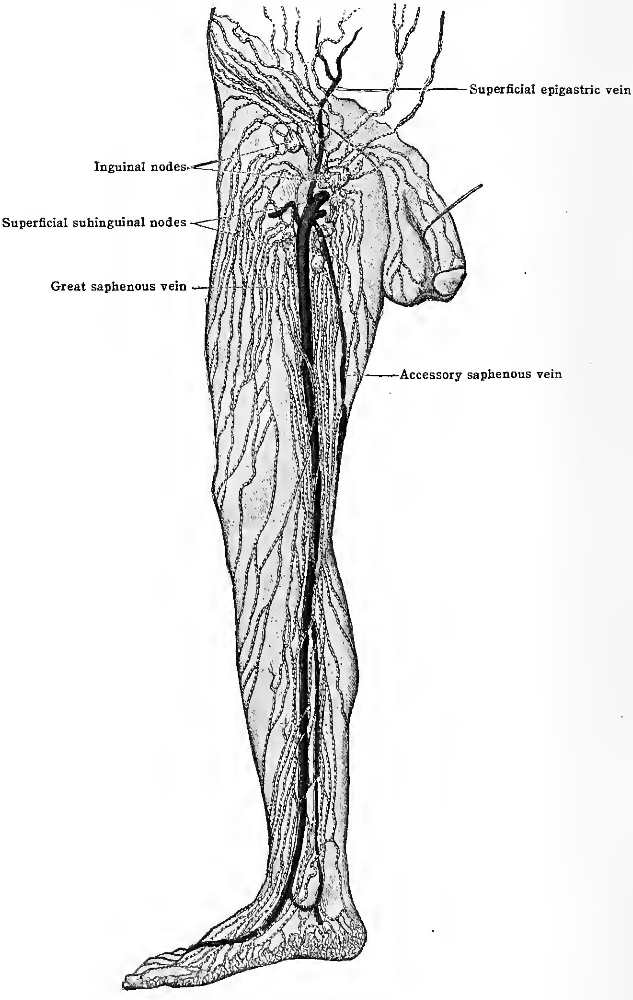
Fig. 591.—The Superficial Inguinal Nodes. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



interest in that, when enlarged, it may simulate a strangulated hernia. The lowest node is below the point where the lesser saphenous joins the femoral vein. These deep nodes receive the deep lymphatics of the leg, the vessels from the glans penis in the male, and the clitoris in the female, and some of the vessels from the superficial subinguinal nodes. Their efferent vessels enter the external iliac nodes.

In addition to the inguinal group of nodes there are some other nodes in the lower limb situated along the course of the deep vessels. Thus there is a node in the course of the anterior tibial vessels below the knee, and there is a small group of **popliteal nodes** [lgl. popliteæ], in the popliteal space, which are in the course of the lesser saphenous vessels, and receive the vessels which accompany the posterior tibial and peroneal vessels and those which drain the knee-joint.

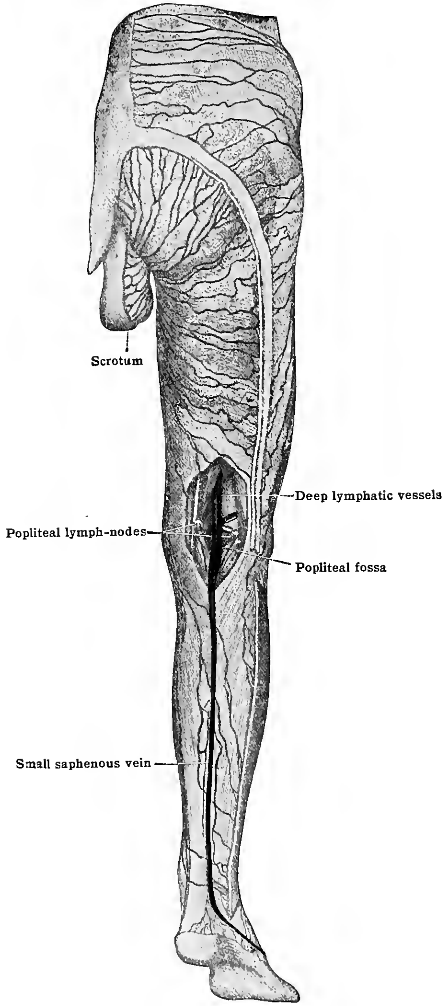
Fig. 592.—The Superficial Lymphatics of the Lower Extremity. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



2. THE LYMPHATIC VESSELS OF THE LOWER EXTREMITY

As in the upper extremity, the subcutaneous capillary plexus of the lower varies greatly in complexity, being most abundant in the soles of the feet. The collecting vessels form two main groups. The medial, larger group follows the saphenous vein, and ends in the superficial subinguinal nodes, while the lateral group curves around to join the medial, partly in the leg and partly in the thigh. Two or three vessels from the heel follow the lesser saphenous vein to the popliteal space. The vessels from the upper and dorsal part of the thigh curve around on both sides to reach the superficial inguinal nodes. The vessels of the anus and

Fig. 593.—The Lymphatics of the Back of the Lower Extremity. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



perineum, as well as those from the external genitalia, except from the glans penis or the clitoris, pass to the medial nodes of the superficial inguinal group.

The deep vessels follow the course of the arteries of the leg, those accompanying the dorsalis pedis and anterior tibial arteries coming into relation with the anterior tibial node, when it is present, and then passing backward to join the vessels which accompany the posterior tibial and peroneal arteries. These terminate in the popliteal nodes, from which efferents follow the course of the femoral artery and terminate in the deep inguinal nodes. The deep lymphatic vessels accompanying the gluteal and obturator arteries pass to the hypogastric nodes.

Lymphatics of the hip-joint.—According to Clermont, they accompany, in the main, the arteries about the joint. (1) Satellites of the anterior circumflex artery, draining almost the entire ventral surface, pass to the lateral inferior external iliac node. (2) Satellites of the posterior circumflex artery, draining the dorsal and medial surfaces, empty into the medial inferior external iliac node, occasionally into one of the deep inguinal nodes. (3) Satellites of the obturator vessel, draining the round ligament, empty into the obturator or hypogastric nodes. (4) Satellites of the inferior gluteal vessels, draining the dorsal surface, empty into three small nodes along the internal pudic and inferior gluteal arteries. Less important ("accessory") vessels are: satellites of the superior gluteal artery leading to a gluteal node; vessels from the dorsal surface which cross the lateral border of the pectineus to reach the medial inferior external iliac node; and vessels from the ventral surface, crossing parallel to the cotyloid notch, passing under the psoas to the lateral inferior external iliac or one of the deep inguinal nodes.

Lymphatics of the knee-joint.—According to Tanasesco the lymphatics draining the structures around the knee-joint in the main follow the arteries about the joint and pass largely to the more deeply placed of the popliteal nodes. Some (superficial) follow the great saphenous vein to the subinguinal nodes, and sometimes deep vessels pass the popliteal nodes and, accompanying the femoral artery, run to the deep inguinal or inferior external iliac.

SECTION VII

THE NERVOUS SYSTEM

REVISED FOR THE FIFTH EDITION

BY IRVING HARDESTY, A.B., PH.D.

PROFESSOR OF ANATOMY, THE TULANE UNIVERSITY OF LOUISIANA

THE nervous system of man, both anatomically and functionally, is the most highly developed and definitely distributed of all the systems of the body. It consists of an aggregation of peculiarly differentiated tissue-elements, so arranged that through them stimuli may be transmitted from and to all the other tissue systems or functional apparatuses. It is a mechanism with parts so adjusted that stimuli affecting one tissue may be conveyed, controlled, modified, and distributed to other tissues so that the appropriate reactions result. While protoplasm will react without nerves, while muscle will contract without the mediation of nerves, yet the nervous system is of the most vital importance to the higher organisms in that the stimuli required for the functioning of the organs are so distributed throughout their component elements that the necessary harmonious and coordinate activities are produced. For this purpose the nervous system permeates every organ of the body; nerve cell-bodies, accumulated into groups, receive impulses and give rise to the nerves which ramify and divide into smaller and smaller branches till the division attains the individual nerve-fibres of which the nerves are composed, and even the fibres bifurcate repeatedly before their final termination upon their allotted elements. So intimate and extensive is the distribution throughout that could all the other tissues of the body be dissolved away, still there would be left in gossamer its form and proportions—a phantom of the body composed entirely of nerves.

The parent portion or **axis** of the system extends along the dorsal mid-line of the body, surrounded by bone and, in addition, protected and supported by a series of especially constructed membranes or meninges, the outermost of which is the strongest. The cephalic end of the axis, the **encephalon,** is remarkably enlarged in man, and is enclosed within the largest portion of the bony cavity, the cranium, while the remainder of the central axis, the **spinal cord,** continues through the foramen magnum and lies in the vertebral canal.

The intimate connection of the axis with all the parts of the body is attained by means of forty-six pairs of nerves, which are attached to the axis at somewhat regular intervals along its extent. They course from their segments of attachment through the meninges and through their respective foramina in the bony cavity to the periphery. Of these *cranio-spinal nerves,* fifteen pairs pass through the cranium and are attached to the encephalon, and thirty-one pairs to the spinal cord. Some of the cranial nerves and all of the thirty-one pairs of spinal nerves contain both *afferent fibres,* which convey impulses from the peripheral tissues to the central axis, and *efferent fibres,* which convey impulses from the axis to the peripheral tissues. The different pairs of nerves possess the two types of fibres in varying proportions.

Upon approaching the spinal cord, each spinal nerve is separated into two roots —its posterior or *dorsal root* and its anterior or *ventral root.* The afferent fibres enter the axis by way of the dorsal roots, which are, therefore, the sensory roots, and the efferent fibres leave the axis by way of the ventral or motor roots.

As usually studied, the nervous system is referred to in two main **divisions**:—

(1) The *central nervous system,* composed of—(*a*) The spinal cord, or medulla spinalis, and (*b*) the brain or encephalon.

(2) The *peripheral nervous system,* composed of—(*a*) The cranio-spinal nerves, and (*b*) the sympathetic nervous system.

All these parts are so intimately connected with each other that the division is purely arbitrary. The cranio-spinal nerves are anatomically continuous with the central system; their component fibres either arise within or terminate within the confines of the central system, and thus actually contribute to its bulk. The sympathetic system, however, may be more nearly considered as having a domain of its own. By communicating rami, it is intimately associated with the cranio-spinal nerves and thus with the central system, both receiving impulses from the central system and transmitting impulses which enter it. But, while its activities are largely under the control of the central system, it is possible that impulses may arise in the domain of the sympathetic system and, mediated by its nerves, produce reactions in the tissues it supplies without involving the central system at all. For this reason, as well as because of the structural peculiarities of the sympathetic system, the nervous system is sometimes divided into—(1) the cranio-spinal system, consisting of (*a*) the central system and (*b*) the cranio-spinal nerves; (2) the sympathetic nervous system, consisting of its various peripheral ganglia and their outgrowths forming its plexuses.

Within and closely proximal to the central system or axis are grouped the parent cell-bodies whose processes comprise the nerve fibres of the cranio-spinal nerves. Other groups of nerve cell-bodies, distributed in the periphery without the bounds of the central system, give rise to the fibres of the sympathetic nerves and plexuses. Any group of such cell-bodies situated in the periphery, whether belonging to the cranio-spinal or sympathetic system, is known as a *ganglion.*

THE DEVELOPMENT OF THE NERVOUS SYSTEM

The essential elements of the nervous system, the nerve cell-bodies and the essential portion of all nerve fibres, central, cranio-spinal and sympathetic, develop from one of the embryonic germ layers, the ectoderm, and all arise from a given region of that germ layer. Further a small portion of the supporting tissue of the nervous system, the neuroglia, is of the same origin.

In its development the nervous system is precocious. It is the first of the functional apparatuses to begin differentiation and is the first to acquire its form. The first trace of the embryo appears on the developing ovum as the *embryonic area,* and the rapidly proliferating cells of this area shortly become arranged into the three germinal layers:—the outer layer or *ectoderm,* the middle layer or *mesoderm,* and the inner layer or *entoderm.* Early in the process of this arrangement there is formed along the axial line of the embryonic area a thickened plate of ectodermal cells, the *neural plate.* In the further proliferation of these cells, the margins of the neural plate, which lie parallel with the long axis of the embryonic area, rise slightly above the general surface, forming the *neural folds,* and the floor of the plate between the folds undergoes a slight invagination, the process resulting in the *neural groove* (fig. 595, A, A^1, B and B^1). As development proceeds and the embryonic area assumes the form of a distinct embryo, the neural folds or lips of the groove gradually converge, and beginning at the oral end, finally unite. Thus the groove is converted into the *neural tube,* extending along the dorsal mid-line and enclosed within the body of the embryo by the now continuous ectoderm above (fig 595, C^1, D and D^1).

For a time the neural tube remains connected with the inner surface of the general ectoderm along the line of fusion by a residual lamina of ectodermal cells. This lamina is known as the *ganglion crest* (neural crest). It is a product of the proliferation of the ectoderm during the process of fusion, consists of the cells which composed the transition between the closing lips of the original groove and the general ectoderm or skin, and whose fusion aided in the closure of the tube. The ectoderm soon becomes separated from the ganglion crest and the cells of the crest become distinctly differentiated from the cells of the neural tube. The essential elements of the entire nervous system together with the neuroglia are derived from the cells of the neural tube and the cells of the ganglion crest.

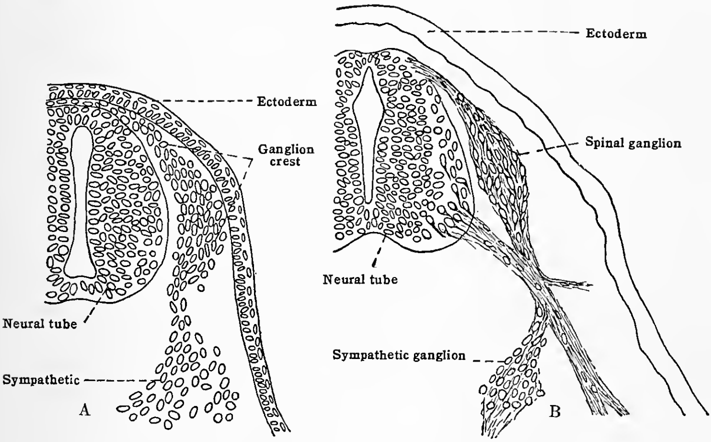
FIG. 595.—DORSAL SURFACE VIEWS OF HUMAN EMBRYOS AND DIAGRAMS OF TRANSVERSE SECTIONS ILLUSTRATING THE DEVELOPMENT OF THE NEURAL TUBE.

A, dorsal view of human embryo at beginning of infolding of neural plate to form neural groove. Amnion partly removed. (Graf Spee, from Keibel and Mall.) A^1, diagram of portion of a transverse section of an embryo as though taken through A at the line a^1. B, dorsal view of human embryo of 7 somites, neural tube not yet closed, Mall Collection. (Dandy, from Keibel and Mall.) B^1, diagram of portion of a transverse section of an embryo as though taken through B at the line b^1. C^1, diagram of portion of a transverse section of an embryo as though taken through D at line c^1. D, dorsal view of human embryo of 8 somites, 2.11 m.m. long, neural tube closed except at caudal end. (Kollmann, from Keibel and Mall.) D^1, diagram of a portion of a transverse section of an embryo as though taken through D at line d^1.

Before the caudal extremity of the tube is entirely closed, its oral end undergoes marked enlargement and becomes distended into three vesicular dilations, the anterior, middle, and posterior primary *brain vesicles.* The anterior of these primary vesicles give off a series of secondary vesicles and by these, followed by further dilations, flexures of its axis, and by means of localized thickenings of its walls, the portion of the tube included in the three primary vesicles develops into the encephalon or brain of the adult. The remainder of the tube becomes the spinal cord. This latter portion retains the simpler form. By the proliferation and migration laterally of the cells lining this portion of the tube, there results a comparatively even bilateral thickening of its walls so that the mature spinal cord retains a cylindrical form throughout its length.

The proliferating and migrating cells of the wall of the neural tube are known as *germinal cells.* The products of their division are apparently indifferent at first, but later they become differentiated into two varieties: (1) *spongioblasts,* or those cells which will develop into neuroglia, and (2) *neuroblasts,* or those which will increase in size, develop processes and become nerve cell-bodies. As described below, the processes given off by a neuroblast are of two general characters: (1) a long process or axone which goes to form nerves, nerve roots, and nerve fasciculi, and (2) dendritic processes which are numerous, branch much more frequently and extend but a short distance from the cell-body. An adult cell-body with all its processes is known as a *neurone* and the neuroblasts of the developing system become transformed into the neurones

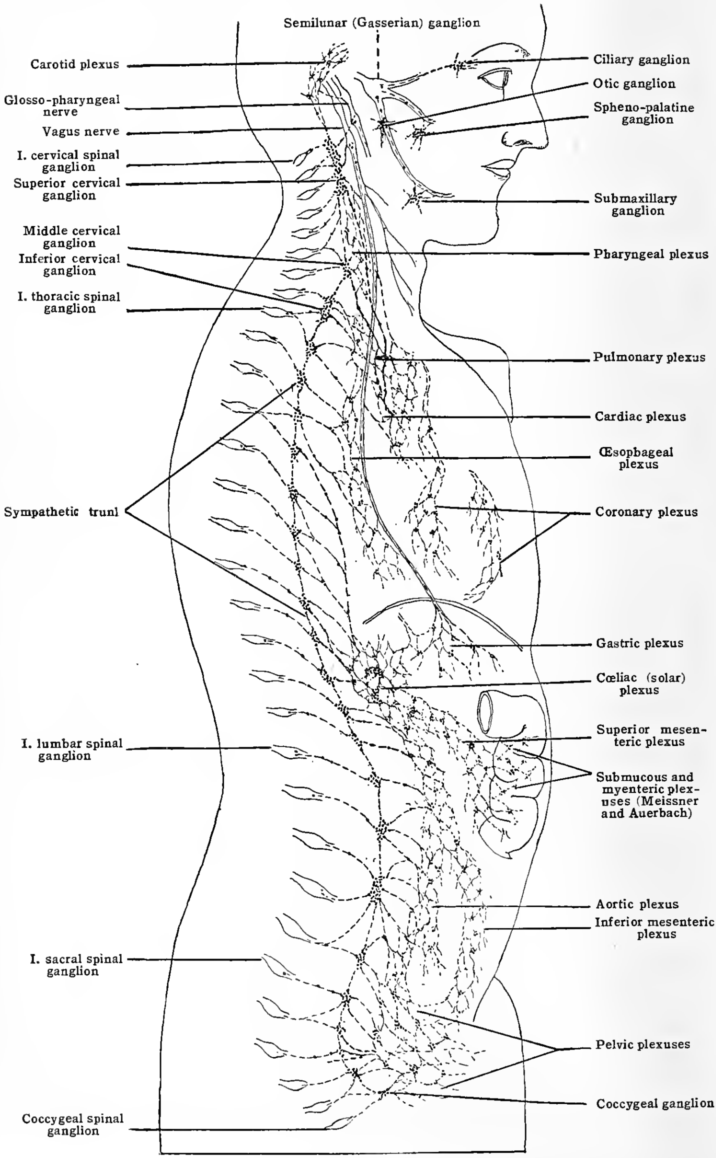
Fig. 596.—Diagrams of Transverse Sections of Embryonic Spinal Cords showing the Migration of the Cells of the Ganglion Crest to form the Spinal and Sympathetic Ganglia and the Origin of the Dorsal and Ventral Roots of the Spinal Nerves. A, a stage following D[1] of fig. 595. B, a later stage in which the ganglia and the components of the nerve are assuming their form resulting from the further migration and from processes being given off by the neuroblasts.



of the varying sizes, shapes, and arrangements of processes characteristic of different divisions and localities of the nervous system. Usually the first process to be noted is that which will become the axone or nerve fibre.

Neurones whose cell-bodies belong to the peripheral nervous system are not developed within the walls of the neural tube or central nervous system at all. These, comprising the spinal ganglion neurones and those of the sympathetic system, are derived from the cells of the ganglion crest. The wedge-shaped lamina of cells, comprising the ganglion crest, through rapid cell division, gradually extends outward and ventralward over the surface of the neural tube along either side. Soon the proliferation becomes most active in regions corresponding to the mesodermic somites or primitive body segments and this, together with the stress of the growing length of the body, results in the ganglion crest (originally a lamina) becoming segmented also. The segments or localised cell masses thus formed are the beginning not only of the spinal ganglia, but also of the ganglia of the entire sympathetic system. The cells of the crest migrate to assume a more lateral position, and then occurs a separation of their ranks. A portion of them remain in a dorsolateral position near the wall of the neural tube and develop into the neurones of the *spinal ganglia* (the sensory neurones of the spinal nerves), but others wander further out into the periphery and become the neurones of the sympathetic. Certain of those of this more nomadic group of cells settle within the vicinity of the vertebral column and by sending out their processes, form the *gangliated cord* or the proximal chain of sympathetic ganglia; others migrate further, but in more broken rank, and become the ganglia of the *prevertebral plexuses* (as the cardiac, cœliac and hypogastric plexuses), or the scattered intermediate chain of ganglia; while still others wander into the very walls of the peripheral organs and

Fig. 597.—Diagram Showing the Chief Paths of Migration of the Cells from the Ganglia of the Spinal and Cranial Nerves to form the Adult Sympathetic System (After Schwalbe, modified.)



occur singly or in groups in such plexuses as those of Auerbach and Meissner, within the tunics of the walls of the alimentary canal. Scattered along between these proximal, intermediate, and distal groups there are to be found small straggling ganglia, many of which contain so few cell-bodies that they are indistinguishable with the unaided eye. All these sympathetic neurones, however, are always either directly or indirectly anatomically associated with and

largely under the control of the neurones of the central system through central *visceral efferent fibres* passing to them by way of the rami communicantes or by way of the peripheral distribution of the spinal nerves.

The ganglia of the sensory portions of all those cranial nerves attached to the inferior of the main divisions of the brain and all the sympathetic ganglia of the head have an origin similar to that of the spinal and sympathetic ganglia in the remainder of the body.

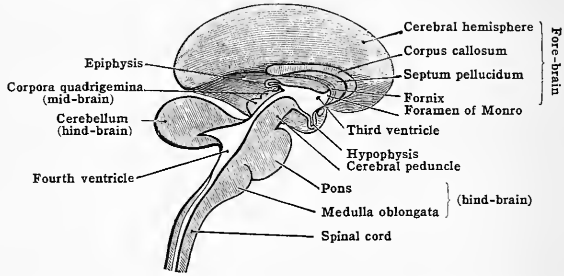
The behavior of the walls of the three primary vesicles, into which the oral end of the neural tube is converted, is much more complex than in case of the spinal cord. Their walls do not thicken uniformly and, to give rise to the form of the adult brain, the anterior and the posterior of the three vesicles give off secondary vesicles.

The walls of the posterior primary vesicle give rise to the posterior of the main divisions of the brain, the hind brain or *rhombencephalon*, the cerebellum developing from the anterior portion only of its dorsal wall, and the medulla oblongata and pons from its ventral wall. Its cavity persists and enlarges into the fourth ventricle of the adult, while the posterior portion of its dorsal wall does not develop functional nervous tissue at all but persists as a thin membrane known as the *chorioid tela of the fourth ventricle.* The cells which form the ganglia of the auditory and vestibular nerves arise from the dorsolateral regions of this vesicle.

From the middle primary vesicle comes the mid-brain or *mesencephalon*, the corprora quadrigemina [colliculi] developing from its entire dorsal wall and the cerebral peduncles occupying its ventral wall. The constriction between the middle and posterior vesicles becomes the *isthmus* of the rhombencephalon.

The anterior or first primary vesicle undergoes greater elaboration than either of the other two. At an early period it gives off a series of secondary vesicles or diverticula. First, two ventrolateral outpouchings occur, the *optic vesicles*, which later become the optic stalks and optic cups of the embryo. A medial protuberance becomes evident in its antero-dorsal wall and from each side of this quickly starts a lateral diverticulum. The two lateral diverticula thus arising from the protuberance are the beginning of the two *cerebral hemispheres* or the *telencephalon*, and the vesicular cavities contained persist as the two *lateral ventricles* of the brain. Soon, each of these vesicular rudiments of the hemispheres gives off ventrally from its anterior part a narrow tube-like diverticulum, each continuous into the parent primary vesicle. These are the olfactory vesicles which are transformed into the *olfactory bulbs* and *olfactory tracts* of the adult encephalon. (See fig. 598, B. and C.) As development proceeds, the cavities of the olfactory vesicles become occluded in man. However, in many of those animals

Fig. 601.—Diagram of Mesial Section of the Human Brain showing the Segments and the Flexures and the Expansion of the Cerebral Hemispheres over the Other Portions of the Brain. The Thalamus is not shown.



in which the olfactory apparatus attains greater relative development than in man, these cavities persist as the olfactory ventricles. The cavities of the optic vesicles never persist as ventricles in the adult. They form stalks which represent the future courses of the *optic nerves*, while from their extremities are developed the retinæ, portions of the ciliary bodies and portions of the iris of the ocular bulbs.

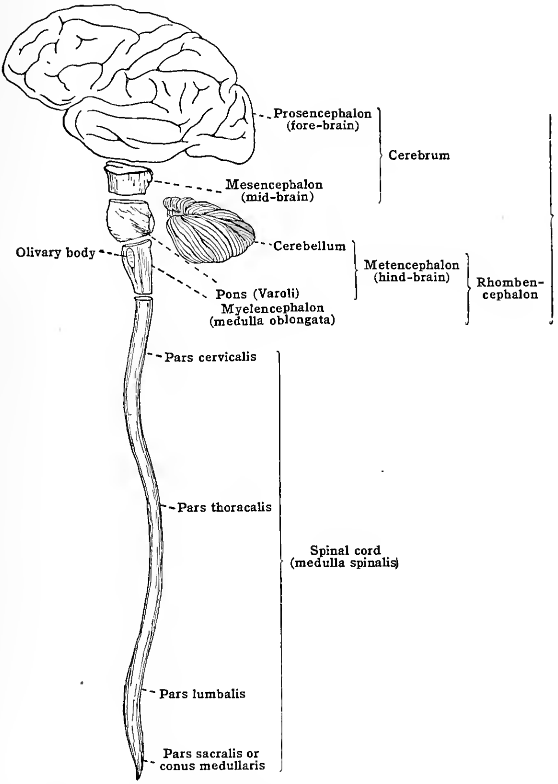
In addition to that which forms the cerebral hemispheres, the remaining portion of the anterior primary vesicle becomes the *diencephalon* or inter-brain. The lateral walls of this part thicken to form the *thalami*, the posterior end of its dorsal wall gives off a secondary vesicle which becomes the pineal body or *epiphysis*, and from its ventral wall projects the infundibular recess which becomes the posterior lobe of the *hypophysis* with its infundibulum and tuber cinereum.

The adult human brain is characterised by the preponderant development of the cerebral hemispheres. The secondary vesicles forming these expand till, held within the cranial cavity, the hemispheres come to extend posteriorly completely over the thalamencephalon and the mesencephalon and even overlap the cerebellum to its posterior border. Their cavities, which persist from their origin from the anterior primary vesicle, are correspondingly large (the lateral ventricles) and comprise two of the *four ventricles* of the adult brain. The *third ventricle* becomes a narrow cavity situated between the two thalami. It represents the original cavity of the anterior primary vesicle from which the structures above mentioned arose as secondary vesicles. It remains continuous with the lateral ventricles by the two *inter-ventricular foramina*, known also as the *foramina* of *monro*, one into each cerebral hemisphere. The *fourth ventricle* of the adult represents the cavity of the posterior primary vesicle and comes to lie between the cerebellum and medulla oblongata, since the cerebellum likewise extends posteriorly from its region of origin. The cavity of the middle primary vesicle becomes the *cerebral aqueduct*, or aqueduct of Sylvius, passing under the corpora quadrigemina and connecting the fourth or posterior ventricle with the third.

Development of the nerve fibres.—All axones begin as outgrowths or processes of the cytoplasm of neuroblasts. Most of such processes are sent out at a very early stage in the development of the nervous system and extend to the tissues they are to innervate when these tissues are as yet quite near the neural tube. Then, as the structures of the body elaborate and assume their final forms and positions more remote from the central nervous system, the axones terminating in them must necessarily grow and be drawn out with the structures. At need, later axones are sent out by neurones developing later to supply the growth demands. Such axones follow the general paths made by those already extending to the tissues requiring them. Being processes of the cytoplasm of the cell-body, the growth and life of all axones (and dendrites) is under the control of the nucleus in the cell-body. They grow by absorbing nourishment, or having added to them substances, from the tissue stroma through which they pass, which stroma may be either ectodermal or mesodermal in origin.

The great majority of axones in the central nervous sytem and all in the peripheral system have sheaths about them. The sheath is an acquired structure and is not added till a relatively late period of development. These sheaths are of two general varieties, sheaths con-

Fig. 602.—Diagram illustrating the Gross Divisions of the Central Nervous System.



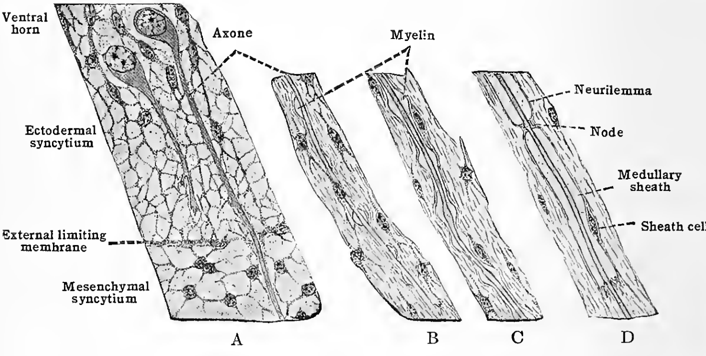
sisting merely of a fibrous coat with the nuclei belonging to it, and sheaths in which there has been added a coating of fat or myelin, *medullary sheaths.* A *nerve fibre* consists of an axone and its sheath whether medullated or non-medullated.

In the embryo, axones are given off from the developing neurones at a time when the entire ectodermic neural tube and embryonic ganglia and the mesodermic tissue surrounding them are each void of definite cell boundaries, each being a continuous mass of nucleated protoplasm, a *syncytium.* From these syncytia are developed the fibrous connective tissues of the later framework supporting the nervous system. Of this, the fibrous tissue, *neuroglia,* is derived from the ectodermal syncytium, while the white and elastic fibrous tissues are derived from the mesodermal or mesenchymal syncytium. Before any connective tissue fibrils are developed in either syncytium, before and at the time of the ingrowth of blood-vessels into the developing ganglia and the neural tube from the mesenchyme about them, there occurs an invasion of the mesenchymal syncytium into the ectodermal syncytium. This invasion occurs both as independent ingrowths and fusions at the periphery of the neural tube and by the mesenchymal tissue being carried in by the ingrowing blood-vessels. After the mixture of the nuclei resulting from this fusion of the syncytia from the two sources, nuclei of mesodermal origin cannot be distinguished from those of ectodermal origin. Further, axones outgrowing from the embryonic ganglia and neural tube carry with them adhering portions of the ectodermal syncytium into the surrounding mesenchymal (fig. 603).

As development proceeds further, each syncytium becomes resolved into a reticulum of granular endoplasmic processes, containing the nuclei, with transparent exoplasm occupying its meshes. Fibrils soon form in the exoplasm and from these develop the connective-tissue fibres, whether neuroglia in the central nervous system or mesenchymal fibrous tissue both without and within it. Certain of these fibrils of course surround the axones imbedded among them and from condensations of such fibrils are derived the fibrous sheaths of the axones, the sheath nuclei being acquired from the adjacent nuclei of the original syncytium. These sheaths become more dense or pronounced as the axones extend and the fibrous tissue increases with growth, but there are always present fine marginal fibrils by which the sheaths grade into the looser fibrous tissue about them. It is generally believed that the tissue giving rise to these

Fig. 603.—Drawings Illustrating the Origin of the Axone and the Development of the Medullary Sheaths.

A, ventral portion of transverse section of an embryonic spinal cord involving portion of periphery of future ventral horn and part of the mesenchymal (mesodermal) syncytium outside the external limiting membrane of the cord. B, later stage of ventral root (peripheral) axone with myelin droplets adhering to it and fibrillated stroma surrounding it. C, stage in which myelin droplets, supported by fibrils of stroma, have increased and accumulated to form a practically continuous myelin or medullary sheath. D, final stage with medullary sheath of even thickness, showing a node, and showing a neurilemma, sheath nucleus and fibrous framework of the myelin ("neurokeratin") derived from the fibrils of the original stroma.



axone sheaths is of mesodermal origin. However, in amphibian larvæ, Harrison has shown that some sheath nuclei at least are derived from the nuclei of the ectodermal syncytium of the ganglion crest, and Neal has noted in elasmobranchs the fact that nuclei migrate from the ventral wall of the neural tube along with the axones growing out to form the ventral roots of the spinal nerves. Whether all or any of these nuclei are originally ectodermal, and, if so, whether such ectodermal tissue gives rise to all axone sheaths, especially in the higher animals, are questionable contentions.

Axones possessing only fibrous sheaths comprise the non-medullated nerve fibres. The majority of the sympathetic fibres are of this variety, and Ranson has found numerous non-medullated fibres present in the spinal nerves. The generally accepted form of non-medullated sympathetic fibres may be seen in fig. 609, C.

Medullated fibres are those which possess an investing coat of fat or myelin in addition to the fibrous sheath. Most of the fibres in the central nervous system and most of those belonging to the cranio-spinal nerves proper acquire myelin sheaths. Myelin begins to appear upon axones shortly after the beginning development in the syncytium of the fibrils of the fibrous connective tissue, and thus after the beginnings of what will become the fibrous sheaths. The fibrous portions of the sheaths in the central nervous system develop less rapidly and are far more scant than those of the medullated fibres of the peripheral nerves. Probably because of this, it has been claimed that myelin begins to appear on the axones of the central system before the appearance of the fibrous sheath. In man, the first appearance of myelin occurs at about the fourth month, but myelinisation is not completed till after birth. The cranio-spinal nerves contain completely medullated fibres before the central system does.

Myelin first appears as small droplets adhering to the axone at irregular intervals. These droplets increase in size and number and gradually accumulate to form a practically continuous sheath of fat immediately investing the axone. They probably result from the coalescence of finer droplets floating in the surrounding fibrillated stroma. However, collecting upon the axone, the myelin retains the form of an emulsion, and as it increases in amount it incloses the adjacent fibrils which serve as a framework supporting the droplets of the emulsion in its meshes. Thus supported, the increasing myelin does not inclose the adjacent nuclei and endoplasm of the original syncytium. Probably because of the fibrous support of the myelin thus obtained, medullating fibres may be often seen presenting the beaded appearance shown in fig. 603, C, instead of an even distribution of the emulsion after it has become continuous along the axone. The "beads" probably represent the uneven beginning of the accumulation indicated in B of this figure. Increasing further, the myelin becomes a cylinder of even thickness, the adjacent nuclei being pressed away against its surface and the adjacent fibrils also condensed upon it.

There is good reason to believe that the fibrous portion of the sheath, the *primitive sheath* or *neurilemma*, of the medullated axone arises as a condensation of the fibrils of the surrounding stroma during development, that the sheath cells represent certain of the nearest nuclei incorporated from the original syncytium, and that the so-called *neuro-keratin* of the myelin represents the fibrous framework of the myelin inclosed by it during its accumulation upon the

axone. The theory that the myelin arises as a differentiated portion of the axone and the theory that it is formed by the neurilemma have been advanced. That it is accumulated from the immediately surrounding fluid of the stroma and adheres to the axone, added droplets coalescing there, in preference to other tissue elements because of some physical or chemical peculiarity of the axone, is more probably correct.

As the medullary sheath approaches completeness, constrictions may be observed at more or less regular intervals at which the myelin emulsion is absent. There are the *nodes of Ranvier*. The process by which they arise is not clearly understood. While the fibre is growing in length, new myelin is added at the nodes. The internodal segments of the sheath increase in length with age, and each segment may possess from one to several sheath nuclei.

In adolescence, fibres whose medullary sheaths are in various stages of completeness may be found both in nerve bundles in the central system and in the cranio-spinal nerves, and in both, the sheaths of some axones certainly never acquire myelin. Also, in the adult, fibres whose medullary sheaths present the beaded appearance may be observed, probably representing cases of arrested accumulation of myelin. According to Westphal there is a slight increase in the thickness of the sheath with age. Larger axones acquire thicker sheaths of myelin than smaller ones. Some fibres of the sympathetic system are medullated but in such the myelin sheath is relatively thinner than in the cranio-spinal system. Beaded sheaths are frequent in sympathetic rami, though non-medullated fibres are most abundant.

FUNDAMENTALS OF CONSTRUCTION

The functionally mature nervous system consists of peculiarly differentiated essential cell elements held in place by two forms of supporting tissue and supplied with abundant blood-vessels.

The nervous element is distinguished from all other units of the structure of organs in that its cell-body gives off outgrowths or processes of peculiarly great length and characteristic form. Knowledge of the possible lengths and complexity of these processes is comparatively recent and, to include them together with their parent cell-body, which has long been known as the *nerve cell*, the term neurone is used. The **neurone**, therefore, may be defined as the nerve cell-body with all its processes, however numerous and far reaching they may be. As a class of tissue elements, all neurones possess characteristics distinguishing them from other tissue elements, but the varieties within this class vary greatly. They vary in form both according to function and according to their locality in the nervous system. They vary in different animals, those in the higher animals being more complex in form. Fig. 604 gives illustrations of the external form of the cell-body of a few of the types found in the human nervous system.

The cell-body of the neurone gives off two general types of processes, dendrites and axones:

(1) The dendritic processes or **dendrites.** These are the more numerous, the shorter, and the more frequently branching processes. They branch dichotomously and with rapid decrease in diameter as they branch. They serve to increase the absorbing surface of the cell-body for purposes of nutrition. Nerve impulses transmitted to the neurone are received by them and, therefore, they also serve to increase the recipient surface of the neurone. They never acquire medullary sheaths. Since they convey impulses toward the cell-body, they are known as *cellipital processes.* Their absorbing and receptive surfaces are further increased by the presence of thickly placed, very minute projections known as "pin-head processes" or *gemmules.*

(2) The **axone** (neuraxis). Each neurone possesses properly but one of these processes. It arises from the cell-body more abruptly and quickly becomes smaller in diameter than are most dendrites before the latter decrease by branching. It is the longest process, in most cases very much longer than dendrites. Computation shows that some axones may contain nearly 200 times the volume of the parent cell-body of the neurone. Occasionally the axone gives off a few small branches near the cell-body. These are known as *collaterals* and are given off at practically right angles instead of dichotomously. Regardless of its branching, the axone maintains a practically uniform diameter throughout its long course. Its usual nervous function is to convey the impulses away from the cell-body, either to transmit them to other neurones by contact upon their dendrites, etc., or to appropriate elements of the other tissue systems of the body. Thus the axones are the *cellifugal processes.* There is one well-known partial exception to this, namely, a part of the axone of the spinal ganglion type of neurone, the peripheral sensory neurone. The axone of this bifurcates a short distance from the cell-body into a peripheral and a central branch. See fig. 604, A, and fig. 610. The peripheral branch collects sensory impulses from the tissues of the body, the skin, etc., and, in conveying them to the central system, must necessarily convey them toward the cell-body as far as the point of bifurcation. Thence the impulse goes on in the central branch, still toward the central system but now, in conformity, away from the cell-body of the neurone. While the continued vitality of the axone is dependent upon the cell-body, in the peculiar case of the spinal ganglion neurone the impulse does not necessarily pass through the cell-body. Experiments with the lower animals have shown that the impulses pass in the fibre from the peripheral tissues to the central system when the cell-body has been cut away.

Terminations of axones.—At its final termination, well beyond its collateral branches and usually a considerable length from its cell-body, the axone practically always divides into two or more *terminal branches*, and each of these breaks up, now dichotomously, into numerous terminal twigs. These terminal twigs are known as *telodendria.* Telodendria vary in number and character of form according to the tissues in and upon which they terminate. Functionally, they are of three classes: Those terminating upon and in the other (peripheral) tissues of the body are either (1) *sensory* or (2) *motor.* In order to transmit impulses from one neurone to another, telodendria of the axone of one neurone are placed in contact with the dendrites or cell-body of another neurone forming (3) *synapses.* Upon approaching its termination, every axone loses its sheath, its telodendria being necessarily bare.

Sensory or afferent axones, receiving impulses from the skin or other epithelial surfaces, break up into very numerous telodendria each of which terminates directly upon the surface of the epithelial cell, such as the cells of the germinative (Malpigin) layer of the skin or those of its basal or columnar layer. Such telodendria are known as *free terminations.* Free terminations are also to be found in the connective tissues of the body. A second variety of peripheral termination of afferent axones is the *encapsulated form.* These are known as 'end organs' and 'corpuscles' and are named according to their complexity and position. Three of the different forms of them are shown in fig. 605, B, C, and D. These are always situated in fibrous connective tissue from which their capsules are derived. Their most elaborate form is the lamellated or Pacinian corpuscle. Besides the motor axones terminating upon the fibres of voluntary or skeletal muscle, sensory impulses are carried from this tissue and one of the forms of telodendria for this purpose terminates upon the muscle fibre. This is known as

Fig. 605.—Showing Some Varieties of Peripheral Terminations of Axones.

A. 'Free termination' in epithelium (after Retzius). B. Krause's corpuscle from conjunctiva (after Dogiel). C. Meissner's corpuscle from skin (after Dogiel). D. Pacinian corpuscle (after Dogiel). E. the 'neuromuscular spindle.' In it, the axone penetrates the sarcolemma and breaks into telodendria which coil spirally about the muscle fibre. The most extensive and elaborate form of sensory telodendria are those which spread out in plate-form upon tendons sheaths.

FIG. 606.—SCHEMES SHOWING TWO FORMS OF SYNAPSES OR THE TERMINATION OF AXONES UPON CELL-BODIES OF OTHER NEURONES.
A. In ventral horn of spinal cord. B. In spinal ganglia.

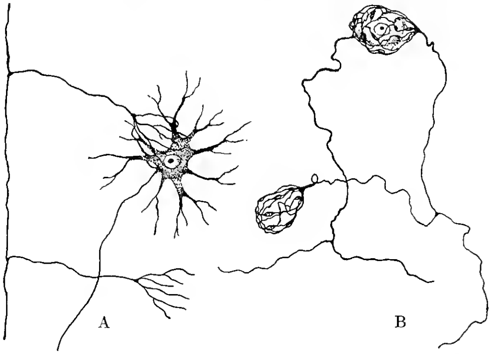

FIG. 607.—DRAWINGS ILLUSTRATING TWO GENERAL TYPES OF ARRANGEMENT OF NEUROFIBRILLÆ IN THE CELL-BODIES OF NEURONES.
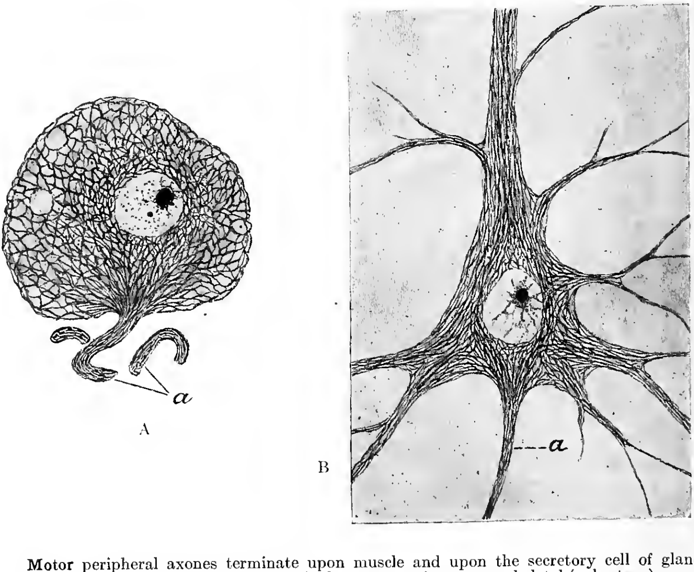
A, cell-body of spinal-ganglion neurone. B, selected "giant pyramidal cell" from cerebral cortex, human. a, axone.

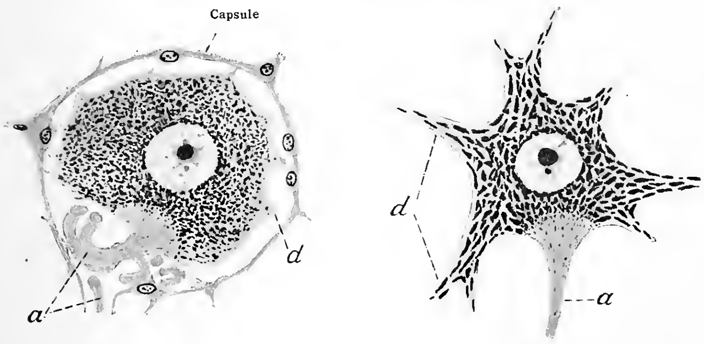


Motor peripheral axones terminate upon muscle and upon the secretory cell of glands (secretory axones). The motor cranio-spinal axones terminate upon skeletal (voluntary) muscle fibres and upon the cell-bodies of sympathetic neurones, the axones of which latter terminate upon cardiac muscle, smooth muscle fibres, and (secretory) in glands. Upon skeletal muscle, the terminal branch of the axone loses its sheath and breaks up into numerous telodendria which themselves branch and show very evident, irregnlar varicosities, the whole of which spread out in plate-form, and lie in contact with the substance of the muscle fibre. In man and all mammals, the area covered is usually somewhat oval and is marked by a granular differentiation of the muscle substance. This with the telodendria is known as a *motor end-plate*. The telodendria of sympathetic axones ending upon cardiac and smooth muscle fibres are fewer and simpler than those of cranio-spinal axones upon skeletal muscle. They consist of a few fine fibrils, with very small varicosities along them and at their ultimate terminations, which run longitudinally along the muscle fibre in close relation with its substance. Those upon gland cells are similar in character except that they often form a loose pericellular plexus about and upon the cell. The varicosities of telodendria are sometimes called *end-feet* and closer study of them has shown that they themselves consist of fine plexuses of the neuro-fibrils described below as contained in the cell-body of the neurone and extending throughout all its processes. Quite recently Boek has found that a sympathetic axone may sometimes accompany a cranio-spinal axone to an end plate on a skeletal muscle fibre.

Synapses.—Every functionally complete nerve pathway consists of two or more neurones arranged in series. Very often, the series consists of many more than two, the impulses being transmitted from neurone to neurone. The axone, bearing the impulse away from the cell-body of one neurone, gives off terminal branches, each of which loses its sheath and breaks up into telodendria which twine themselves upon the dendrites or cell-body of another neurone. The mpulse is transferred from one neurone to another by means of contact rather than by direct anatomical continuity of the parts of the two neurones. Such terminations of axones are known as synapses.

FIG. 608.—DRAWINGS ILLUSTRATING THE ABUNDANCE AND GENERAL ARRANGEMENT OF THE TIGROID MASSES IN CELL-BODIES OF NEURONES IN RESTING CONDITION.

A, cell-body from spinal ganglion. B, large cell-body from ventral horn of spinal cord. a, axone. d, dendrites.



In the terminal arrangement of the telodendria, synapses assume forms varying from compact "*pericellular baskets*" and "*climbing fibres*" to the more open arborisations composed of fewer twigs in simpler arrangements, "*end-brushes*." In case of the spinal ganglion type of neurone, the cell-body of the majority of which has no dendritic processes, the telodendria of the visiting axone form an anastomosing pericellular plexus inclosing the entire cell-body. This and the simple end-brush form of synapses are illustrated in fig. 606. It should be mentioned that, contrary to the general belief that impulses are transmitted by simple contact of the neurones in the series, it has been claimed that the ultimate twigs of the telodendria frequently penetrate the substance of the receiving cell-body and are fused in continuity. If during the processes of growth this becomes true, instead of being an appearance produced by the technique employed, it is better considered as merely an exception to the general rule.

Internal structure of the neurone.—The cell-body of the neurone consists of a large, spherical, vesicular nucleus and a cytoplasm continuous into its axone and dendritic outgrowths. Its nucleus is further characterized by having most usually but one nucleolus, large, spherical and densely staining, situated in a karyoplasm containing otherwise a remarkably small amount of chromatin. Of the cytoplasm, the two most interesting structures are its fibrillar and its granular components.

The **fibrillar structure**, known as the *neuro-fibrillæ*, represents a growth and elaboration of the spongioplasmic reticulum of the original, embryonal cell. The filaments increase in thickness during the development of the neurone, and, in the sending out of its processes, the meshes of the original reticulum become so drawn out in the processes as to give the appearance of a more or less parallel arrangement of threads. The reticular or net-like arrangement is usually more nearly retained in the cytoplasm immediately about the nucleus, since here the stress of the outgrowing processes is less directly applied. In the cell-body of the spinal ganglion type of neurone, when no dendrites are given off, the net-like arrangement is apparent throughout the cytoplasm except in that region giving rise to the axone. On the other hand, in the typical so-called "pyramidal cell" of the cerebral cortex, from which two chief processes, the axone and the apical dendrite, are given off from opposite poles, the more reticular arrangement about the nucleus is often practically obliterated by the opposing growth stress.

So manifest does the parallel appearance of the neuro-fibrillæ in the processes often become that it has been interpreted as a series of individual and independent fibrils. In the application of gold chloride and similar methods to the neurones of lower forms, the reduced reagent is often precipitated upon the fibrils in parallel, seemingly independent lines. And, assuming the existence of independent fibrils, it has been contended that the neurone is not the functional unit of the nervous system but is itself composed of numerous functional units, individual fibrils, each for the conduction of nerve impulses. More recent and trustworthy methods, however, show that the neuro-fibrillæ retain their original reticular form, the threads anastomosing in all planes, and that the meshes of the net may, in the processes, be so drawn in one direction that a parallel appearance predominates. Further, it is now held that the neuroplasm, or the more fluid substance in which the fibrils lie throughout, is capable, and probably fully as capable, of conducting impulses as the fibrils.

Of the granules in the cytoplasm, the most interesting are those first described in detail by Nissl. These are the most abundant of those in the cell-body and are known as *tigroid masses* or *Nissl bodies*. They consist of numerous basophilic granules collected into clumps or masses of varying size. They are known to disappear during fatigue of the nervous system and they are more abundant in animals after a period of rest. They are distributed throughout the cytoplasm of the cell-body with the interesting exception that they are not found in the axone nor in the immediate vicinity of its place of origin from the cytoplasm, leaving a free region known as the *axone hillock*. As accumulated masses, they show characteristic shapes and arrangement

FIG. 609.—SHOWING PIECES OF AXONES.

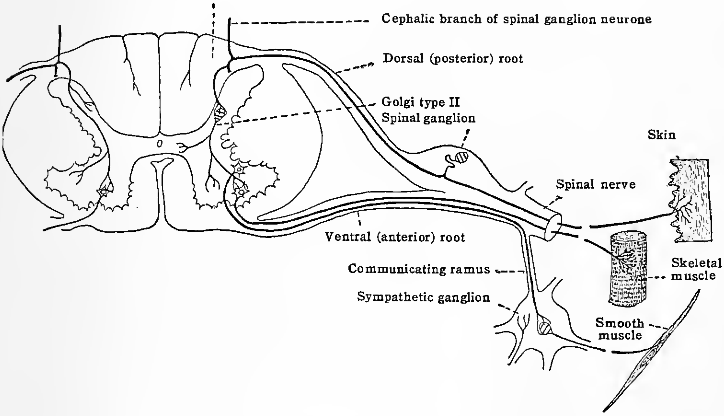
which are interpreted as signifying the shapes and arrangement of the spaces or meshes they occupy in the reticulum of the neuro-fibrillæ. In cell-bodies of the varieties found in the ventral horns of the spinal cord or in the cerebral and cerebellar cortex, for example, the masses situated immediately about the nucleus are smaller, more numerous and of irregular shape. Nearer and in the beginnings of the dendrites, they are larger and mostly of fusiform or diamond shape. Farther out in the dendrites, they become more and more thin and attenuated; and in the distant reaches of the dendrites they are invisible or absent. In the cell-body of the spinal ganglion they are of irregular shape, smaller and more numerous throughout the cytoplasm, being slightly smaller and more thickly placed in the immediate vicinity of the nucleus. In all neurones several hours post-mortem, they appear in fewer and larger masses and it was in this condition that Nissl originally described them in man. Closely examined, the masses of all sizes are found to be accumulations of finer granules. Functionally they are supposed to be of nutritive significance, substances in unstable chemical equiblibrium, energy stored in the cytoplasm, capable at need of being split into simpler forms usable in the activities of the neurone. The fact that tigroid masses are absent from the axone hillock, the axone, and the distant reaches of the dendrites may signify that the substance is chiefly present here only in the split and usable form. Also, in the axone especially, the neurofibrillæ are so closely arranged that the meshes of their net here are too small to contain masses of appreciable size. Close examination of the axone hillock and longitudinal sections of the axone in deeply stained preparations usually show a few very minute basophilic granules.

Sheaths of the axone.—The great majority of axones acquire sheaths about them which isolate and protect them in their course through other tissues or in company with other axones. A *nerve fibre* is an axone together with its sheath. In transverse sections, the axone comprises the central portion of the nerve fibre or its so-called "axis-cylinder." It is of course the essential portion of the fibre. As noted above in describing their development, nerve fibres are classified according to the character of the sheaths. Those which possess sheaths of myelin, a peculiar form of fat, are known as *medullated fibres*, and those in which the sheaths are merely membranes of condensed fibrous tissue, void of myelin, are *non-medullated fibres*. A medullated fibre also possesses a fibrous membrane outside its myelin sheath, known as the *neurilemma* or sheath of Schwann. The neurilemma is of the same origin and general structure as the sheath of the non-medullated fibre, and both possess nuclei scattered along them. Medullated fibres, at more or less regular intervals, show constrictions at which the myelin sheath ceases, but over which the neurilemma continues. These constrictions are the *nodes of Ranvier*. The myelin is in the form of an emulsion, whose fat droplets are supported in a fine fibrous reticulum (neurokeratin), while the neurilemma without serves to hold it in place. The neurilemma possesses from one to three or four sheath nuclei between adjacent nodes of Ranvier.

There is no sharp line of separation between medullated and non-medullated fibres, for in any locality there may be found axones in all degrees of medullation. Most of the fibres

Fig. 610.—Diagram of Transverse Section of Spinal Cord with Roots of Spinal Nerve and Neighbouring Ganglia Attached, Illustrating Simplest Forms of Neurone Chains.



belonging to the sympathetic system (processes of sympathetic neurones) are non-medullated, but both partially medullated and completely medullated sympathetic fibres may be found. (See fig. 609.) The myelin sheaths of completely medullated sympathetic fibres are always thinner and less well developed than those of medullated cranio-spinal fibres. Most of the fibres belonging to the cranio-spinal nerves and to the central nervous system are medullated, but among the fibres belonging to either there are to be found numerous non-medullated fibres. As indicated in fig. 609, nodes of Ranvier are absent in the medullated fibres of the central system.

In all the higher vertebrates, the myelin sheath always begins on the axone a short distance from its parent cell-body. The neurilemma of the medullated and the fibrous membrane of the non-medullated fibre are each faintly continuous with the fibrous connective tissue surrounding it, and, in the cranio-spinal and sympathetic ganglia, in which each cell-body of the neurone has a fibrous capsule about it, the fibrous membrane or the neurilemma, as the case may be, is directly continuous into the capsule of the cell-body. Upon approaching its final termination, in other tissues or upon the dendrites or cell-body of other neurones, the nerve fibre always loses its sheath, the telodendria of the axone always being bare when placed in contact with the other element. In losing the sheath, the myelin sheath, if present, always ceases and the fibrous membrane becomes continuous with the tissue investing the receiving element, whether the capsule of the ganglion cell, the sarcolemma of the skeletal muscle fibre. the corium of the skin, or the connective-tissue capsule of the encapsulated terminal corpuscle,

The connective tissue of the nervous system is of two main varieties—*white fibrous connective tissue* and *neuroglia*. White fibrous tissue alone supports and binds together the peripheral system, and it is the chief supporting tissue of the central system. As connective tissues, these two varieties are quite similar in structure, each consisting of fine fibrillæ, either dispersed or in bundles, among which are distributed the nuclei of the parent syncytium. In both tissues nuclei are frequently found possessing varying amounts of cytoplasm which has not yet been transformed into the essential fibrils.

In addition to its enveloping membranes, the three meninges, which are of white fibrous tissue, the white fibrous tissue supporting the central system within is quite abundant. It is all sent in from without, either as ingrowths of the developing pia mater, the most proximal of the membranes, or is carried in with the blood-vessels, of the walls of which it is an abundant component. Practically, the neuroglia as a connective tissue proper differs from white fibrous tissue only in origin and in its chemical or staining properties. Based upon the latter, there are methods of technique by which the two may be distinguished. White fibrous tissue is derived from the middle germ layer or the mesoderm, while neuroglia comes from the ectoderm. The epithelium lining the central canal of the spinal cord and the ventricles of the encephalon, with which the canal is continuous, is the remains of the mother tissue of the neuroglia, and in the adult is the only vestige representing its origin. The cells of this epithelium are known as *ependymal cells*, and they are usually classed as a variety of neuroglia.

Axones, with their medullated or non-medullated sheaths (nerve fibres) comprise all nerves in the periphery and all nerve tracts in the central system.

White substance [substantia alba] ("white matter") consists of a portion of nervous tissue in which medullated fibres predominate. The myelin sheaths, being in the form of a fat emulsion, reflect the entire spectrum and thus appear white.

Grey substance [substantia grisea] ("grey matter") is a portion of nervous tissue in which medullated axones do not predominate. Thus sympathetic ganglia and sympathetic nerves may be grey, though the term is usually applied to grey portions of the central system, such as the cerebral cortex, the central grey column of the spinal cord, etc. Such grey regions contain more cell-bodies of neurones than other regions, though at least half of their volume may consist of neuroglia, white fibrous connective tissue, blood-vessels, and axones of both varieties.

Neurone chains.—As noted above, the numerous neurones comprising the nervous system are functionally and anatomically related to all the other tissues of the body and to each other. A functionally complete *nerve pathway* extends from the tissue in which the nerve impulse is aroused to the tissue in which a resultant reaction occurs. It is known that the simplest possible of such paths necessarily comprises at least two neurones. The great majority involve a greater number. The axone of one neurone bearing impulses from the peripheral tissue transfers the impulses to the dendrites or cell-body of another by synapsis, and the axone of this, in the same way, transfers them to another and so on till the final neurone receives the impulses and the telodendria of its axone transfer the impulse to the tissue element which reacts in response to the stimulus brought. Neurones are thus linked together in chains. A neurone chain may be defined, therefore, as a number of neurones associated with each other in series to form a functionally complete nerve pathway. Examples of the simplest forms of neurone chains as contained in the spinal cord are illustrated in fig. 610. An impulse aroused in the skin is borne by the spinal ganglion neurone to the spinal cord where, in the left half of the figure, telodendria of one of the terminal branches of its axone form synapses with a neurone in the ventral horn, and the axone of this bears the impulse out of the spinal cord to transmit it probably direct to skeletal muscle. This arrangement involves but two neurones and is supposed to be relatively rare. In the right half of the figure, a third neurone is seen interposed. This is a neurone, numerous in grey substance everywhere, whose axone is relatively short and branches frequently, making possible several synapses in the near neighbourhood of its parent cell-body. Its type is referred to as the *Golgi neurone of type II*. This interposed, gives a chain of three neurones between the origin of the impulse in the periphery and the contraction of muscle in response. Simple chains like these can result only in reflex activities and such chains are often called *reflex arcs*. Another chain is indicated in the figure in which the reflex action involves involuntary or smooth muscle. This must involve at least one sympathetic neurone, and, should the Golgi neurone of type II form synapses with the ventral horn neurone involved, a chain composed of four neurones results. In the more extensive and complex neurone chains, such as those in which the impulse from the skin, as above, ascends to the cerebral cortex and the resultant muscular contraction is thrown under cerebral control, each of the several neurones or links in the series is not only referred to by name according to the position of its cell-body, but each is often called according to its order in the series, as "neurone of first order," "second order," "third order," etc.

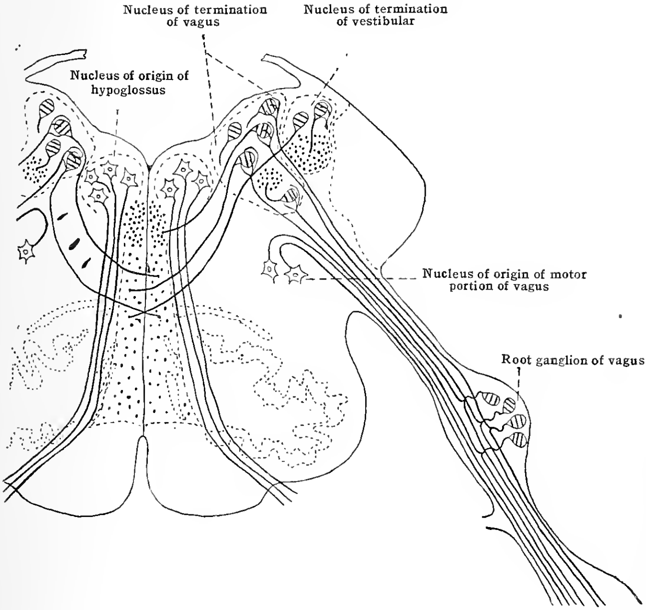
A given axone may break into a considerable number of branches each of which forms synapses with a different second neurone, or, if peripheral, the telodendria of each branch may terminate upon a separate peripheral tissue element. Thus, a given impulse aroused in a peripheral tissue element may be transmitted to an ever increasing number of neurones, and the initial neurone may comprise the first link in a number of neurone chains. Such is quite general in the structural plan of the nervous system throughout. It is thought possible to consider each neurone interposed in a chain as a separate source of energy, a sort of relay in the nerve path; that the impulse passing through the axone is gradually weakened in overcoming resistance, but, when transferred to another neurone, it incites a splitting into usable form of the substance represented by the tigroid masses and thus a liberation of energy or a reinforcement of the impulse. Further, thus is made possible the economy of one neurone serving as a link in a number of neurone chains.

The axones (nerve fibres) taking part in the various neurone chains course in bundles of varying size, the larger of which have names. And there is a general tendency with axones of the same function and the same origin to course in company with each other. A fibre bearing impulses from the peripheral tissues to the central system is an *afferent fibre* or sensory fibre. A fibre bearing impulses out of the central system to peripheral tissues is an *efferent fibre* or motor fibre. Efferent fibres which bear impulses to skeletal muscle are known as *somatic efferent fibres*, while those which terminate upon the cell-bodies of sympathetic neurones and thus bear impulses destined for smooth muscle, cardiac muscle and glands (secretory) are *visceral* or *splanchnic efferent fibres*.

A nerve is a closely associated aggregation of parallel nerve fibres coursing in the *periphery*. It may be spinal, cranial or sympathetic according to its attachment or according to the origin of the majority of its fibres. It may contain several functional and structural varieties of fibres. The spinal nerves contain all structural varieties. **Nerve roots** are those bundles of fibres which join to form a nerve. Most of the cranial nerves have but one root of origin. Nerve roots, in their turn, are formed by the junction of smaller *root-filaments*. *Nerve branches* result from the division of the nerve, the separation of its component fibres into separate bundles. Some branches are of sufficient size and significance to be called nerves and given separate names. The smaller branches are called *rami*, twigs, etc.

In the *central system*, a given bundle of fibres is called a **fasciculus**, while two or more adja-

FIG. 611.—DIAGRAM OF TRANSVERSE SECTION OF MEDULLA OBLONGATA, ILLUSTRATING NUCLEI OF TERMINATION AND NUCLEI OF ORIGIN.



cent fasciculi coursing parallel to each other comprise a **funiculus**, a bundle of bundles. The central nervous system is bilaterally symmetrical throughout its length. A bundle of fibres arising from cell-bodies situated on one side and crossing the mid-line transversely to terminate in the opposite side is a **commissure.** The commissures vary greatly in size and contain fibres crossing in both directions. Scattered fibres which cross the mid-line are *commissural fibres*. Fibres of varying length, arising from cell-bodies situated in one locality of the central system, which do not cross the mid-line, but terminate in other localities of the same side, above and below the level of their origin or in a different region of the same level, form **association fasciculi.** The shortest association fasciculi, not extending beyond the bounds of a given division of the central system, are known as **fasciculi proprii.** When bundles of the same origin, functional direction and significance, running one on either side of the mid-line, cross the mid-line they are said to decussate and the crossing is known as a **decussation.** In the decussations, the direction of the crossing is oblique rather than transverse.

The cell-bodies of neurones whose axones go to form certain nerve roots, fasciculi and certain commissures show a tendency to accumulation in localized masses. In the *peripheral* system, such an accumulation of cell-bodies is known as a **ganglion**; in the *central system* such is distinguished as a **nucleus.** Thus, there are the *sympathetic ganglia* which give rise to sympathetic nerves and sympathetic roots of nerves; and on the beginning of each spinal nerve there is a *spinal ganglion* which gives rise to the afferent fibres of its dorsal root and in its nerve trunk. There are *ganglia on* the *cranial nerves* which give rise to the afferent or sensory axones in them and which are of the same significance as the spinal ganglia. Every ganglion, therefore, has connected with it bundles of nerve fibres. Some of these fibres bear impulses from neighboring ganglia or from the tissues of the neighboring organs and transmit them to the cell-bodies of the ganglion; others arise from the cell-bodies in the ganglion and bear impulses to the central system or, in case of the sympathetic, to other ganglia or to the tissues of the peripheral organs. Necessarily, the larger the ganglion, the larger will be the bundles of fibres connected with it.

Nuclei may be considered in two general classes: (1) Recipient nuclei or nuclei of termination, and (2) Nuclei of origin.

A nucleus of termination is an accumulation of cell-bodies in which the axones of a given fasciculus or of a nerve root terminate, that is, cell-bodies which, by synapses, receive the impulses borne by the terminating axones. In most cases the impulses transferred to a nucleus so named are sensory in character. The nucleus may be considered as a defined region in which neurones of the next order are interpolated in a given nerve pathway or system of neurone chains. Fasciculi in the spinal cord which bear impulses to the cerebrum have their nuclei of termination in the medulla oblongata, and the sensory or afferent axones of the cranial nerves find their nuclei of termination upon entering the central system.

A nucleus of origin is an accumulation of cell-bodies of neurones which give origin to the axones going to form a given nerve root or a fasciculus. Strictly speaking, a nucleus of termination for one nerve tract is the nucleus of origin for another, the next link in the neurone chain. However, the term is commonly used to distinguish a group of cell-bodies giving rise to a motor nerve tract. Thus each motor cranial nerve has its nucleus of origin within the central system. The central grey substance of the spinal cord is in the form of a column continuous throughout the length of the cord and so the cell-bodies in the ventral horns of this column which give rise to the motor or afferent roots of the spinal nerves are not considered as grouped into nuclei of origin, one for each of the motor roots.

The **dorsal root** of each spinal nerve is afferent or sensory in function and its axones arise as processes of cell-bodies comprising the spinal ganglion of the nerve. The afferent or sensory fibres of the cranial nerves arise as processes of cell-bodies comprising the ganglia of the cranial nerves, which ganglia are, in development and character, exactly homologous to the spinal ganglia.

The **ventral root** of each spinal nerve is efferent or motor in function and its fibres arise as processes of cell-bodies situated in the ventral horn of the grey substance of the spinal cord. The efferent or motor fibres of the cranial nerves arise as processes of cell-bodies accumulated as nuclei of origin in the grey substance of the encephalon, and homologous with those cell-bodies of the ventral horns of the spinal cord which give origin to the ventral-root fibres.

The general relation of the cerebrum (which includes the mesencephalon) to the remainder of the nevous system is a *crossed relation*. Neurone chains from the general body to the cerebrum, via the spinal nerves and cord and via the cranial nerves and medulla oblongata and pons of one side, cross the mid-line to terminate in the opposite side of the cerebrum. Axones, and neurone chains, arising in response in one side of the cerebrum, likewise usually decussate in descending to terminate in the respective regions of the opposite side.

Many of the names given nervous structures, prior to 1850 especially, instead of suggesting something of their functional or anatomical significance, indicate nothing more than active imaginations for accidental resemblances between the various structures of the nervous system and objects in ordinary domestic environment. Also, quite often the name given a structure is merely the name of some anatomist associated with it. The much needed elimination of these old non-descriptive names is proving a very slow process. Attempts have often increased the difficulty by making necessary the use of several names for a given structure instead of one. The most recent and concerted attempt, the nomenclature known as the BNA (anatomical names chosen by a commission appointed for the purpose which convened in Basle in 1895), has been adopted by modern text-books. It is here used in the form of the English equivalents of the Latin terms, except in cases of those Latin terms which have become so commonly used as to be considered words incorporated into the English language. The BNA has retained many of the old names and, since a name should indicate something of the locality and significance of the structure to which it is applied, it is not yet wholly satisfactory throughout. In applying the names of a few fasciculi, the BNA in the following pages is slightly modified by so compounding the name that the first word in the compound indicates the locality of origin of the fasciculus and the second, the locality of its termination. Thus, "*Dorsal spino-cerebellar fasciculus*" indicates the more dorsally coursing of the fasciculi which arise from cell-bodies in the spinal cord and terminate in the cerebellum. This principle applies to many of the BNA names without change, as "*lateral cerebro-spinal fasciculus.*"

THE CENTRAL NERVOUS SYSTEM

The central nervous system [systema nervorum centrale] or organ is an aggregation of nuclei, fasciculi and commissures—a large axis of grey and white substance situated in the dorsal mid-line of the body—and the bundles of fibres connecting it with the tissues of other systems and with the peripheral ganglia are of necessity correspondingly large. So numerous are the axones connecting it and so intimately are its neurones associated that a disturbance affecting any one part of the system may extend to influence all other parts. The enlarged cephalic extremity of this central axis, the brain or **encephalon,** is a special aggregation of nuclei and masses of grey substance, many of which are much larger than any found in the periphery.

In the study of the central nervous system its enveloping membranes or meninges are met with first, and logically should be considered first, but since a comprehensive description of these membranes involves a foreknowledge of the various structures with which they are related, it is more expedient to consider them after making a closer study of the entire system they envelop.

For convenience of study, the central nervous system is separated into the gross divisions, spinal cord and brain (encephalon) as illustrated in fig. 602. Each of these divisions will be subdivided and considered with especial reference to its anatomical and functional relations to the other divisions and the inter-relations of its component parts.

I. THE SPINAL CORD

The spinal cord [medulla spinalis] is the lower (caudal) and most attenuated portion of the central nervous system. It is approximately cylindrical in form and terminates conically. Its average length in the adult is 45 cm. (18 in.) in the male and 42 cm. in the female. It weighs from 26 to 28 grams or about 2 per cent. of the entire cerebro-spinal axis.

After birth it grows more rapidly and for a longer period than the encephalon, increasing in weight more than sevenfold, while the brain increases less than half that amount. Its specific gravity is given as 1.038.

The line of division between the spinal cord and the medulla oblongata is arbitrary. The outer border of the foramen magnum is commonly given, or, better, a transverse line just below the decussation of the pyramids. Lying in the vertebral canal, the adult cord usually extends to the upper border of the body of the second lumbar vertebra. However, cases may be found among taller individuals in which it extends no farther than the last thoracic vertebra. With increase in stature, its actual length increases, but the extent to which it may descend the vertebral canal decreases. Up to the third month of intra-uterine life it occupies the entire length of the vertebral canal, but owing to the fact that the vertebral column lengthens more rapidly and for a longer period than does the spinal cord, the latter, being attached to the brain above, soon ceases to occupy the entire canal. At birth its average extent is to the body of the third lumbar vertebra.

External Morphology of the Spinal Cord

In position in the body, the spinal cord conforms to the curvatures of the canal in which it lies. In addition to the bony wall of the vertebral canal, it is enveloped and protected by its three membranes or meninges, which are continuous with the like membranes of the encephalon: first, the **pia mater,** which closely invests the cord and sends ingrowths into its substance, contributing to its support; second, the **arachnoid,** a loosely constructed, thin membrane, separated from the pia mater by a considerable **subarachnoid space;** third, the **dura mater,** the outermost and thickest of the membranes, separated from the arachnoid by merely a slit-like space, the **subdural space.**

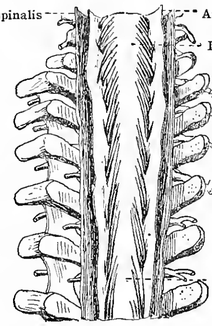
The intimate association of the central system with all the peripheral organs is attained chiefly through the spinal cord, and this is accomplished by means of thirty-one pairs of spinal nerves, which are attached along its lateral aspects. The nerves of each pair are attached opposite each other at more or less equal intervals along its entire length, and in passing to the periphery they penetrate the meninges, which contribute to and are continuous with the connective-tissue sheaths investing them. Each nerve is attached by two roots, an afferent or **dorsal root,** which enters the cord along its postero-lateral sulcus, and an efferent or **ventral root,** which makes its exit along the ventro-lateral aspect.

With its inequalities in thickness and its conical termination the spinal cord is subdivided into four parts or regions:—(1) The **cervical portion,** with eight pairs of cervical nerves; (2) the **thoracic portion,** with twelve pairs of thoracic nerves; (3) the **lumbar portion,** with five pairs of lumbar nerves; and (4) the **conus medullaris,** or sacral portion, with five pairs of sacral and one pair of coccygeal nerves. From the termination of the conus medullaris, the pia mater continues below in the subarachnoid space into the portion of the vertebral canal not occupied by the spinal cord, and forms the non-nervous, slender, thread-like terminus, the *filum terminale.* This becomes continuous with the dura mater at its lower extremity.

In the early fœtus the spinal nerves pass from their attachment to the spinal cord outward through the intervertebral foramina at right angles to the long axis of the cord, but, owing to the fact that the vertebral column increases considerably in length after the spinal cord has practically ceased growing, the nerve-roots become drawn caudad from their points of attachment, and, as is necessarily the case, their respective foramina are displaced progressively downward as the termination of the cord is approached, until finally the roots of the lumbar and sacral nerves extend downward as a brush of parallel bundles considerably below the levels at which they are attached. This brush of nerve-roots is the *cauda equina*. The dura mater, being more closely related to the bony wall of the canal than to the spinal cord, extends with the vertebral column and thus envelops the cauda equina, undergoing a slightly bulbous, conical dilation which decreases rapidly and terminates in the attenuated canal of the coccyx as the coccygeal ligament.

The enlargements.—Wherever there is a greater mass of tissue to be innervated, the region of the nervous system supplying such must of necessity possess a greater number of neurones. Therefore, the regions of the spinal cord associated with the skin and musculature of the regions of the superior and

FIG. 612.—DORSAL VIEW OF PORTION OF SPINAL CORD IN POSITION IN VERTEBRAL CANAL



inferior limbs are thicker than the regions from which the neck or trunk alone are innervated. Thus in the lower cervical region the spinal cord becomes broadened into the *cervical enlargement*, and likewise in the lumbar region occurs the *lumbar enlargement*. The spinal nerves attached to these regions are of greater size than in other regions.

The **cervical enlargement** [intumescentia cervicalis] begins with the third cervical vertebra, acquires its greatest breadth (12 to 14 mm.) opposite the lower part of the fifth cervical vertebra (origin of the sixth cervical nerves), and extends to opposite the second thoracic vertebra. Unlike the lumbar enlargement, its lateral is noticeably greater than its dorso-ventral diameter.

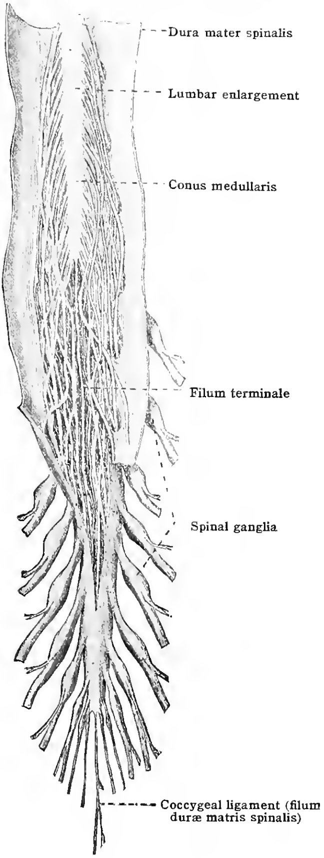
The **lumbar enlargement** [intumescentia lumbalis] begins gradually with the ninth or tenth thoracic vertebra, is most marked at the twelfth thoracic vertebra (origin of the fourth lumbar nerves), and rapidly diminishes into the conus medullaris.

Both the lumbar and thoracic regions are practically circular in transverse section. Neither diameter of the lumbar is ever so great as the lateral diameter of the cervical enlargement. The thoracic part attains its smallest diameter opposite the fifth and sixth thoracic vertebræ (attachment of the seventh and eighth thoracic nerves.)

The enlargements occur with the development of the upper and lower limbs. In the embyro they are not evident until the limbs are formed. In the orang-utan and gorilla the cervical enlargement is greatly developed; the ostrich and emu have practically none at all.

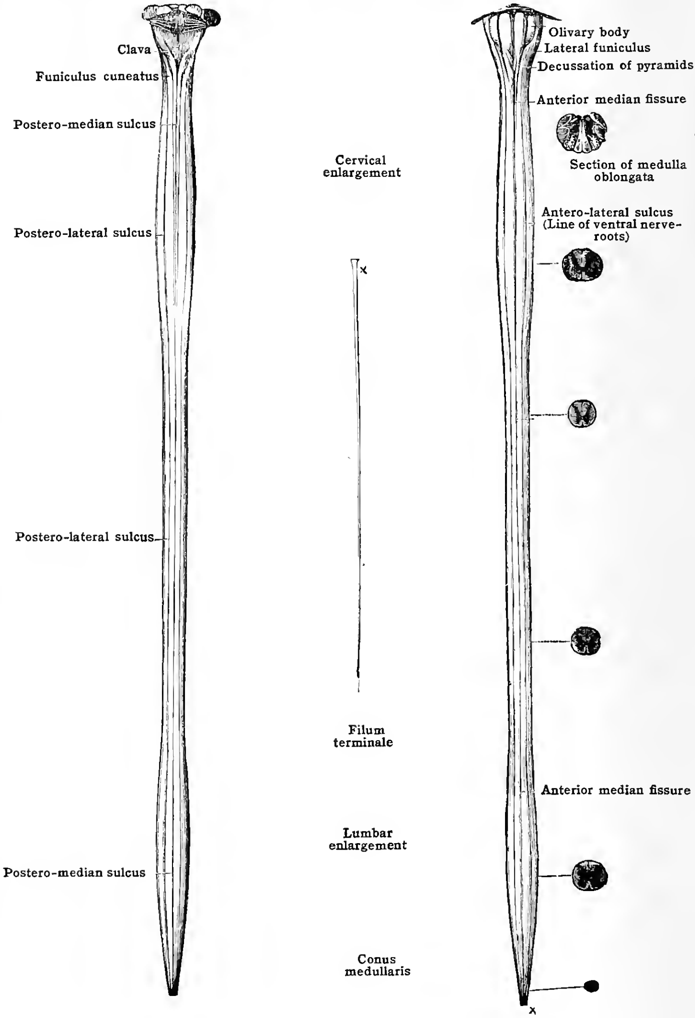
Surface of the spinal cord.—The cord is separated into nearly symmetrical right and left halves by the broad **anterior median fissure** into which the pia mater is duplicated, and opposite this, on the dorsal surface, by the **posterior median sulcus.** Along the lower two-thirds of the cord this sulcus is shallowed to little more than a line which marks the position of the posterior median septum; in the medulla oblongata it opens up and attains the character of a fissure. Each of the two lateral halves of the cord is marked off into a posterior, lateral, and anterior division by two other longitudinal sulci. Of these, the **postero-lateral sulcus** occurs as a slight groove 2 to $3\frac{1}{2}$ mm. lateral from the posterior median sulcus, and is the groove in which the root filaments of the dorsal roots enter the cord in regular linear series. The ventral division is separated from the lateral

Fig. 613.—Drawing from Specimen showing Cauda Equina, the Roots of Certain of the Spinal Nerves which form it, and its Accompanying Dura Mater. (Dorsal aspect.)



by the **antero-lateral sulcus.** This is rather an irregular, linear area than a sulcus. It is from 1 to 2 mm. broad, and represents the area along which the efferent fibres make their exit from the cord to be assembled into the respective ventral roots. This area varies in width according to the size of the nerve-roots, and, like the postero-lateral sulcus, its distance from the mid-line varies according to locality, being greatest on the enlargements of the cord. In the cervical region, and along a part of the thoracic, the posterior division is subdivided by a delicate longitudinal groove, the **postero-intermediate sulcus,** which becomes more evident toward the medulla oblongata and represents the line of demarcation between the fasciculus gracilis and the fasciculus cuneatus. Occasionally in the upper cervical region a similar line may be seen along the ventral aspect close to the anterior

Fig. 614.—Posterior and Anterior Views of the Spinal Cord. (Modified from Quain.)



median fissure. This is the **antero-intermediate sulcus,** forming the lateral boundary of the ventral cerebro-spinal fasciculus.

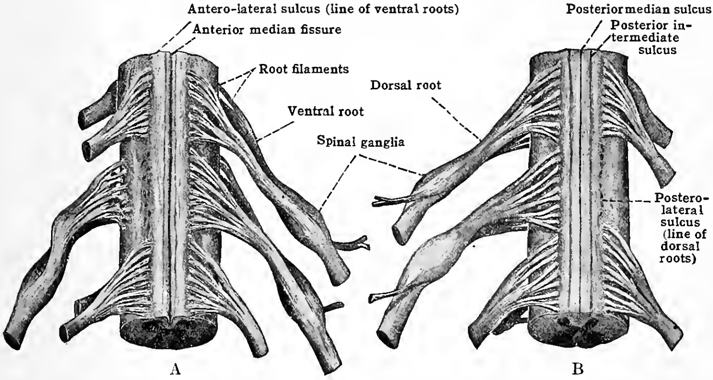
Collectively, the entire space between the posterior median sulcus and the line of attachment of the dorsal roots is occupied by the **posterior funiculus;** the lateral space between the line of attachment of the dorsal and that of the ventral roots, by the **lateral funiculus;** and the space between the ventral roots and the anterior median fissure, by the **anterior funiculus.** Each of these funiculi is subdivided within into its component fasciculi.

The dorsal and ventral nerve-roots are not attached to the cord as such, but are first frayed out into numerous thread-like bundles of axones which are distributed along their lines of entrance and exit. These bundles are the **root filaments** [fila radicularia] of the respective roots. The fila of the larger spinal nerves are fanned out to the extent of forming almost continuous lines of attachment, while in the thoracic nerves there are appreciable intervals between those of adjacent roots. Throughout, the intervals are less between the fila of the ventral than between those of the dorsal roots.

Internal Structure of the Spinal Cord

By reflected light masses of medullated axones appear white in the fresh, and such masses are known as **white substance.** The spinaal cord consists of a continuous, centrally placed column of grey substance surrounded by a variously thickened tunic of white substance. The closely investing pia mater sends

Fig. 615.—A, Ventral, and B, Dorsal, Views of Portion of Spinal Cord showing Modes of Attachment of Dorsal and Ventral Roots.



numerous ingrowths into the cord, bearing blood-vessels and contributing to its internal supporting tissue. The volume of white and of grey substance varies both absolutely and relatively at different levels of the cord. The absolute amount of grey substance increases with the enlargements. The absolute amount of white substance also increases with the enlargements coincident with the greater amount of grey substance in those regions. The relative amount of white substance increases in passing from the conus medullaris to the medulla oblongata, due to the fact that the ascending and descending axones associating the cord with the encephalon are the one contributed to the cord and the other gradually terminating in it at different levels along its entire descent.

The grey substance.—In the embryo all the nerve-cells of the grey substance are derived from the cells lining the neural tube, and in the adult the column of grey substance, though greatly modified in shape, still retains its position about the central canal. In transverse section the column appears as a grey figure of two laterally developed halves, connected across the mid-line by a more attenuated portion, the whole roughly resembling the letter H. The cross-bar of the H is known as the **grey commissure.** Naturally, it contains the **central canal,** which is quite small and is either rounded or laterally or ventrally oval in section, according to the level of the cord in which it is examined. The canal continues upward, and in the medulla oblongata opens out into the fourth ventricle. Downward, in the extremity of the conus medullaris, it widens slightly and forms the rhomboidal sinus or **terminal ventricle,** then is suddenly constricted into an extremely small canal extending a short distance into the filum terminale, and there ends blindly. The grey commissure always lies somewhat nearer the ventral than the dorsal surface of the cord, and itself contains a few medullated axones which vary in amount in the different regions of the cord. The medullated axones crossing the mid-line on the ventral side of the central canal form the ventral or **anterior white commissure**; those, usually much fewer in number, crossing on the dorsal side of the central canal, form the dorsal or **posterior white commissure.** These two commissures comprise fibres crossing in the grey substance as distinguished from others which cross in the white substance dorsal and ventral to them. The axones of these commissures serve in functionally associating the two lateral halves of the grey column.

Each lateral half of the grey column presents a somewhat crescentic or comma-shaped appearance in transverse section, which also varies at the different levels of the cord. At all levels each half presents two vertical, well-defined horns, themselves spoken of as columns of grey substance. The **dorsal horn** [columna posterior] extends posteriorly and somewhat laterally toward the surface of the cord along the line of the postero-lateral sulcus. It is composed of an **apex** and a **neck** [cervix columnæ posterioris].

In structure the apex is peculiar. The greater portion of it consists of a mass of small nerve-cells and neuroglia tissue, among which a gelatinous substance of questionable origin predominates, giving the horn a semi-translucent appearance. This is termed the **gelatinous substance of Rolando,** to distinguish it from a similar appearance immediately about the central canal, **the central gelatinous substance.** The apex of the dorsal horn is widest in the regions of the enlargements, especially the lumbar, and the gelatinous substance of Rolando is most marked in the cervical region. In these regions the cervix consists of a slight constriction of the dorsal horn between the apex and the line of the grey commissure. In the thoracic region, however, the base of the cervix is the thickest part of the dorsal horn. This thickness is due to the presence there of the **nucleus dorsalis,** or Clarke's column—a column of grey substance containing numerous nerve-cells of larger size than elsewhere in the dorsal horn, and extending between the seventh cervical and third lumbar segments of the cord. Tapering finely at its ends, this nucleus attains its height in the lower thoracic or first lumbar segment. About the ventro-lateral periphery of the nucleus dorsalis are scattered nerve-cells of the same type as contained in it. These cells are sometimes distinguished as **Stilling's nucleus,** though Clarke's column was also described by Stilling. They are more numerous about the lower extremity of the nucleus dorsalis, and they continue to appear below its termination in the lumbar region.

The **ventral horn** [columna anterior] of each lateral half of the grey figure is directed ventrally toward the surface of the spinal cord, pointing toward the antero-lateral sulcus. It contains the cell-bodies which give origin to the efferent or ventral root axones, and these axones make their emergence from the spinal cord along the antero-lateral sulcus. The ventral horns vary markedly in shape in the different regions. In certain segments each ventral horn is thickened laterally and thus presents its two component columns of grey substance: the **lateral horn** [columna lateralis], a triangular projection of grey substance into the surrounding white substance, in line with or a little ventral to the line of the grey commissure; and the **ventral horn proper** [columna anterior], projecting ventrally. In the mid-thoracic region the lateral horn is relatively insignificant, and the anterior horn is quite slender; in the cervical and lumbar enlargements both horns are considerably enlarged.

The grey substance is not sharply demarcated from the white. In the blending of the two there are often small fasciculi of white substance embedded in the grey, and likewise the grey substance sends fine processes among the axones composing the white substance. Such processes or grey trabeculæ are most marked along the lateral aspects of the grey figure and present there the appearance known as the **reticular formation.** The reticular formation of the spinal cord is most evident in the cervical region (fig. 616).

Minute structure.—The large cell-bodies of the ventral horn as a whole are divisible into four groups, only three of which are to be distinguished in the mid-thoracic region of the spinal cord:—(1) A *ventral group* of cells, sometimes separated into a ventro-lateral and a ventro-medial portion (see figs. 616, 619), occupies the ventral horn proper, is constant throughout the entire length of the cord, and contributes axones to the ventral root, most of which probably supply the muscles adjacent to the vertebral column; (2) a *dorso-medial group* of cells, situated in the medial part of the ventral horn, just below the level of the central canal, gives origin to axones some of which go to the ventral root of the same side, but most of which cross the mid-line viâ the anterior white commissure, either to pass out in the ventral root of the opposite side or to enter the white substance of that side and course upward or downward, associating with other levels of the cord. Some of its axones terminate among the cells of the ventral horn in the same level of the opposite side; (3) a *lateral group* of cells, sometimes separated into a dorso-lateral and a ventro-lateral portion, occupies the lateral column or horn, and is best differentiated in the cervical and lumbar enlargements. Most of the axones arising from its larger cells are contributed to the ventral root of the same side, and such axones probably supply the muscles of the extremities. Some of those from its ventral portion are distributed to the muscles of the body-wall; the dorso-lateral portion is that part of the lateral column which persists throughout the cord, and is considered as supplying the visceral efferent fibres in the ventral roots. (4) an *intermediate group*, occupying the mid-dorsal portion of the ventral horn. Axones arising from its cells are probably seldom contributed to the ventral root, but instead course wholly within the central nervous system. Some pass to the opposite side of the cord, chiefly viâ the anterior and possibly the posterior white commissure, to terminate either in the same or different levels of the grey column. Others of longer course pass to the periphery of the cord, join one of the spino-cerebellar fasciculi, and pass upward to the cerebellum.

Furthermore, there are scattered throughout the grey substance many smaller cell-bodies of neurones. These give rise to axones of shorter course, either commissural or associational proper. Of such axones many are quite short, coursing practically in the same level as that in which their cells of origin are located, and serve to associate the different parts of the grey substance of that level. Others course varying distances upward and downward for the association of different levels of the grey column.

It is evident from the above that in addition to the various nerve-cells it contains, there is also to be found a felt-work of axones in the grey substance. Many of these axones are medullated, though not in sufficient abundance to destroy the grey character of the substance. The felt-work is composed of three general varieties of fibres:—(1) The terminal branches of axones entering from the fasciculi of the white substance and forming end-brushes about the various cell-bodies in the grey substance (partly medullated); (2) axones given off from the cells of the grey substance and which pass into the surrounding white substance either to enter the ventral-roots or to join the ascending and descending fasciculi within the spinal cord (partly medullated); (3) axones of Golgi neurones of type II, which do not pass outside the confines of the grey substance (non-medullated). Some axones of any of these varieties may cross the mid-line and thus become commissural. In general all fibres of long course acquire medullary sheaths a short distance from their cells of origin, and lose them again just before termination.

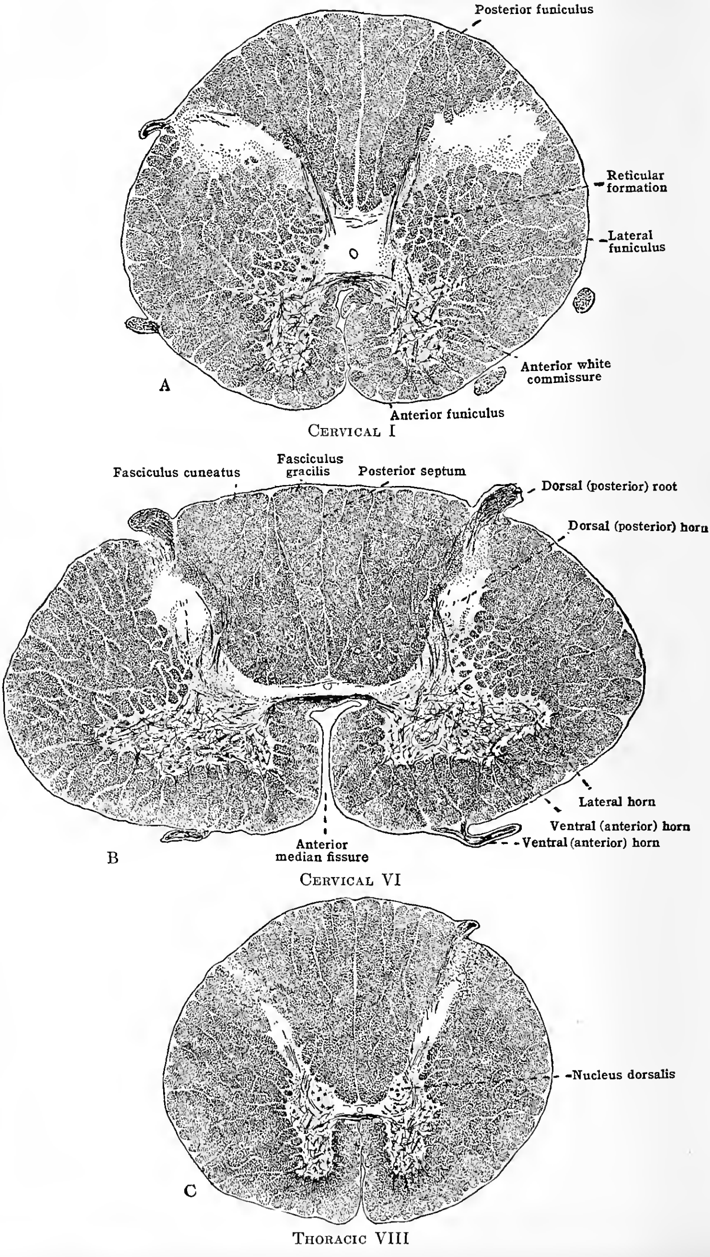
The white substance of the spinal cord.—The great mass of the axones of the spinal cord course longitudinally and form the thick mantle surrounding the column of grey substance. This mantle is divided into right and left homolateral halves by the anterior median fissure along its ventral aspect, and along its dorsal aspect by the posterior median septum, which is for the most part a connective-tissue partition derived from the pia mater along the line of the posterior median sulcus. The mantle is supported internally by interwoven neuroglia and white fibrous connective tissue, the latter, derived chiefly from the pia mater, closely investing it without.

The axones of the white substance belong to three general neurone systems:—(1) The *spino-cerebral and cerebro-spinal system*, which consists of axones of long course, one set ascending and another descending, forming links in the neurone chains between the cerebrum and the peripheral organs. The ascending axones of this system collect the general bodily sensations which are conveyed to the cerebrum, the cells of which in response contribute axones which descend the cord, conveying efferent or motor impulses. (2) The *spino-cerebellar and cerebello-spinal* system consists of conduction paths, one set ascending and another descending, which are connections between cerebellar structures and the grey substance of the spinal cord. (3) The *spinal association* and *commissural system* of axones which serve to *associate* the different levels and the two sides of the spinal cord and which are proper to the spinal cord, i. e., they do not pass outside its confines.

Both the first and second systems increase in bulk as the cord is ascended. The ascending axones of each system are contributed to the white substance of the cord along its length, and therefore accumulate upward; the axones descending from the encephalon are distributed to the different levels of the cord along its length, and therefore diminish downward.

The mass of the third system of axones varies according to locality. Wherever there is a greater mass of neurones to be associated, as there is in the enlargements of the cord, a greater number of these axones is required. Their cells of origin, being in the grey substance of the cord, contribute to its bulk and thus both the cells and the axones of this system serve to make the enlargements more marked. In the lumbar and sacral regions the greater mass of the entire white substance consists of axones belonging to this system. It forms a dense felt-work about the grey column throughout the cord. Necessarily this system contains axones of various lengths. Some merely associate different levels within a single segment

Fig. 616.—Transverse Sections from Different Segments of the Spinal Cord, showing Shape and Relative Proportions of Grey and White Substance in the Various Regions.



of the cord; others associate the different segments with each other. Axones which associate the structures of the spinal cord with those of the medulla oblongata may be included in this system. Many of these axones cross the mid-line both in the grey and in the white substance to associate the neurones of the two sides of the grey column. For purposes of distinction, such as cross the mid-line are called **commissural fibres,** while those which course upward and down-

ward on the same side are **association fibres.** Coursing in longitudinal bundles about the grey figure, the latter compose the **fasciculi proprii** or 'ground bundles' of the spinal cord.

METHODS BY WHICH THE CONDUCTION PATHS HAVE BEEN DETERMINED

A purely anatomical examination of a normal adult cord, prepared by whatever means, gives no indication of the fact that the mass of longitudinally coursing fibres of the white substance is composed of more or less definite bundles or fasciculi, each having a definite course, and whose axones form links (conduction paths) in a definite system of neurone chains.

Present information as to the size, position, and connections of the various fasciculi is based upon evidence obtained by three different lines of investigation:—

(1) **Physiological investigation.**—(*a*) Direct stimulation of definite bundles or areas in section and carefully noting the resulting reactions which indicate the function and course of the axones stimulated. (*b*) 'Wallerian degeneration' and the application of such methods as that of Marchi. When an axone is severed, that portion of it which is separated from its parent cell-body degenerates. Likewise a bundle of axones severed from their cells of origin, whether by accident or design, will degenerate from the point of the lesion on to the locality of their termination in whichever direction this may be. This phenomenon was noted by Waller in 1852 and is known as **Wallerian degeneration.** By the application of a staining technique which is differential for degenerated or degenerating axones and a study of serial sections containing the axones in question, their course and distribution may be determined. The locality of their cells of origin, if unknown, may be determined by repeated experiment till a point of lesion is found not followed by degeneration of the axones under investigation. (*c*) The axonic reaction or 'reaction from a distance.' Cell-bodies whose axones have been severed undergo chemical change and stain differently from those whose axones are intact. Thus cell-bodies giving origin to a bundle of severed axones may be located in correctly stained sections of the region containing them.

(2) **Embryological evidence.**—In the first stages of their development axones of the cerebro-spinal nervous system are non-medullated. They acquire their sheaths of myelin later. Axone pathways forming different chains become medullated at different periods. Based upon this fact a method of investigation originated by Flechsig is employed, by which the position and course of various pathways may be determined. A staining method differential for medullated axones alone is applied to the nervous systems of fœtuses of different ages, and pathways medullated at given stages may be followed from the locality of their origin to their termination. In the later stages, when most of the pathways are medullated and therefore stain alike, the less precocious pathways may be followed by their absence of medullation.

(3) **Direct anatomical evidence.**—(*a*) Stains differential for axones alone are applied to a given locality to determine the fact that the axones of a given bundle actually arise from the cell-bodies there, or that axones traced to a given locality actually terminate about the cell-bodies of that locality. For example, it may be proved anatomically that the axones of a dorsal root arise from the cells of the corresponding spinal ganglion, and then these axones may be traced into the spinal cord and their terminations noted either by collateral or terminal twigs, or the fasciculus they join in their cephalic course may be determined. (*b*) The staining properties and the size and distribution of the tigroid masses in the cell-bodies of sensory neurones differ from those in the motor neurones, and recently Malone has claimed that, in the central system, the cell-bodies in the nuclei of sensory neurone chains, those ascending toward the cerebral cortex, may be distinguished from the cell-bodies of the motor or descending chains by the arrangement and size of their tigroid masses. He claims further that in the same way, the cell-bodies of the somatic efferent neurones may be distinguished from those of the visceral efferent neurones. In this way the locality of origin of certain physiologically known paths may be determined.

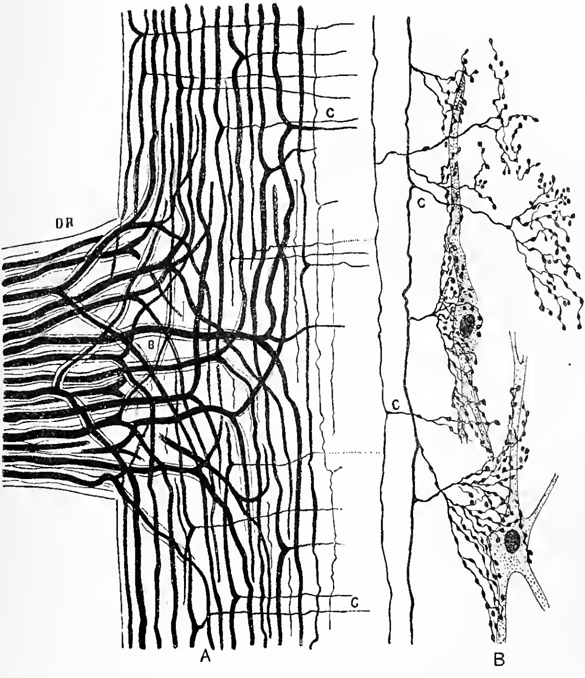
(4) The so-called *pathologico-anatomical method* is based upon the same general principles as is the physiological (or experimental) method. A pathological lesion, a local infection or a tumor for example, may destroy a nucleus of cell-bodies or sever a bundle of axones, and the resulting degeneration of the axones may be followed through serial sections suitably prepared. The locality of the lesion known, the path may be followed to determine the locality of its termination; its locality of termination known from the symptoms resulting, the path may be followed to its cells of origin, or to determine whatever be the locality of the lesion.

Funiculi.—In order that the various fasciculi may be referred to with greater ease, the white substance of the spinal cord in section is divided into three areas known as funiculi or columns and which correspond to the funiculi already mentioned as evident upon the surface of the cord when intact. The funiculi are outlined wholly upon the basis of their position in the cord and with reference to the median line and the contour of the column of grey substance; their component fasciculi are defined upon the basis of function. (1) The *posterior funiculus* or column is bounded by the posterior median septum and the line of the dorsal horn; (2) the *lateral funiculus* or column is bounded by the lateral concavity of the grey column and the lines of entrance and exit of the dorsal and ventral roots; (3) the *ventral funiculus* or column is bounded by the line of exit of the ventral roots, and by the anterior median fissure.

The posterior funiculus or column [funiculus posterior].—This funiculus is composed of two general varieties of axones arranged in five fasciculi. First, and constituting the predominant type in all the higher segments of the cord, are the afferent or general sensory axones, which arise in the spinal ganglia, enter the cord by the dorsal roots, assume their distribution to the neurones of the cord, and then take their ascending course toward the encephalon. The axone of the spinal ganglion neurone undergoes a T-shaped division a short distance from the cell-body, one limb of this division terminating in the peripheral organs and the other going to form the dorsal root. Upon entering the cord the dorsal root axones undergo a **Y**-shaped bifurcation in the neighbourhood of the dorsal horn, one branch ascending and the other descending. Their ascending branches form the **fasciculus gracilis** (Goll's column) and the **fasciculus cuneatus** (Burdach's column). These fasciculi are the chief ascending or sensory spino-cerebral connections, the direct sensory path to the brain. The neurones represented in them constitute the first link in the neurone chain between the periphery of the body and the cerebral cortex.

Fig. 617.—Showing Disposition of the Dorsal Root Fibres Upon Entering the Spinal Cord. (From Edinger, after Cajal.)

A, shows dorsal root axones DR, entering the spinal cord, bifurcating at B, and giving off collaterals C to the neurones of the cord. B shows the telodendria of these axones or of their collaterals displayed upon cell-bodies of the grey substance of the cord.



In threading their way toward the brain, these sensory axones tend to work toward the mid-line. Therefore those of longer course are to be found nearer the posterior septum, in the upper segments of the cord, than those axones which enter the cord by the dorsal roots of the upper segments. Thus it is that the fasciculus gracilis, the medial of the two fasciculi, contains the axones which arise in the spinal ganglia of the sacral and lumbar segments. In other words, it is the fasciculus bearing sensory impulses from the lower limbs to the brain, while the fasciculus cuneatus, the lateral of the two, is the corresponding pathway for the higher levels. Naturally, there is no fasciculus cuneatus as such in the lower segments of the spinal cord. The axones being much blended at first, it is only in the upper thoracic and cervical region that there is any anatomical demarcation between the two fasciculi. In this region the two become so distinct that there is in some cases an apparent connective-tissue septum between them, continuing inward from the postero-intermediate sulcus—the surface indication of the line of their junction (fig. 616).

Upon reaching the medulla oblongata the fibres of the fasciculus gracilis and the fasciculus cuneatus terminate about cells grouped to form the nuclei of these fasciculi. The nucleus of the fasciculus gracilis is situated medially and begins just below the point at which the central canal opens into the fourth ventricle; the nucleus of the fasciculus cuneatus is placed laterally and extends somewhat higher than the other nucleus. The neurones whose cell-bodies compose these nuclei constitute the second links in the neurone chains conveying sensory impulses from the periphery to the cerebral cortex.

The descending or *caudal branches* of the dorsal root axones are concerned wholly with the neurones of the spinal cord. They descend varying distances, some of them as much as four segments of the cord, and give off numerous collaterals on their way to the cells of the grey column. Those terminating about cell-bodies of the ventral horn which give rise to the ventral or motor root-fibres, are responsible for certain of the so-called *'reflex activities'* and thus contribute to the simplest of the **reflex arcs.** In descending they serve to associate different levels of the grey substance of the cord with impulses entering by way of a single dorsal root. Some of their collaterals cross the mid-line in the posterior white commissure, and thus become connected with neurones of the opposite side. The caudal branches of longer course are scattered throughout the ventral portion of the fasciculus cuneatus (*middle root zone*), and the longest show a tendency to collect along the border-line between the fasciculus cuneatus and the fasciculus gracilis, and thus contribute largely to the **comma-shaped fasciculus.** Also some of the longest of them in the lower levels course in the *oval bundle* or septo-marginal root zone.

The ascending branches of the dorsal root axones also give off collaterals to the grey substance of the cord, thus extending the area of distribution of a given dorsal nerve-root to levels of the cord above the region at which the root enters.

The greater number of the terminations of dorsal root axones within the spinal cord are concerned first with neurones other than those contributing ventral root-fibres. The greater mass of the neurones concerned are those of the Golgi type II and those contributing the **fasciculi proprii** or **ground bundles** of the spinal cord, or the second variety of axones composing the posterior funiculus. The latter fasciculi arise from the smaller cells of the grey column.

These axones pass from the grey substance to enter the surrounding white substance, bifurcate into ascending and descending branches, which in their turn give off numerous collaterals to the cells of the grey substance of the levels through which they pass. The cell-bodies giving origin to such axones are so numerous that the entire column of grey substance is surrounded by a continuous felt-work of axones of this variety.

The **dorsal fasciculus proprius** (anterior root zone of posterior column) arises chiefly from cells situated in the dorsal horn (*stratum zonale*). Coincident with the ingrowth and arrangement of the fasciculi gracilis and cuneatus many fibres of the dorsal fasciculus proprius go to form both the oval bundle and the comma-shaped fasciculus. Thus these two bundles are mixed, being fasciculi proprii which contain caudal branches of dorsal root axones. The association fibres in the oval bundle are the longest of any belonging to the dorsal fasciculus proprius. The cephalic and caudal branches combined of some are said to extend more than half the length of the cord and it has been claimed that some even associate the cervical region with the conus medullaris. Based upon this claim, Obersteiner has called the oval bundle, the "dorso-medial sacral field" and Edinger has referred to the most dorsal part of it as the "*tractus cervico-lumbalis dorsalis.*" The *'median triangle'* is formed by the continuation of the dorsal fasciculi proprii with the oval or septo-marginal fasciculus. Some of the axones of the dorsal fasciculus proprius cross the midline to distribute impulses to the neurones of the opposite side. These commissural axones, together with certain collaterals of the dorsal root axones, which cross the mid-line outside the dorsal white commissure, compose the so-called **cornu-commissural tract** at the base of the posterior septum.

The lateral funiculus or column [funiculus lateralis].—Not all the axones of the posterior or dorsal nerve-roots extend to the encephalon. Estimation shows that the sum of all the dorsal roots is greatly in excess of the sum contained in the fasciculi cuneatus and gracilis just before these enter their nuclei of termination. Therefore many of the ascending dorsal root axones are concerned with spinal-cord relations wholly.

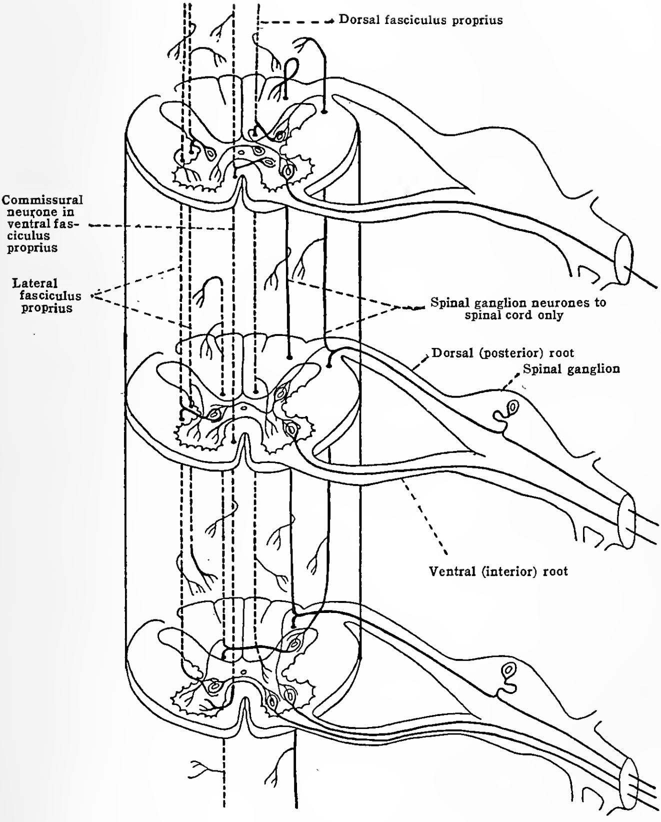
The **marginal zone of Lissauer,** situated along the lateral margin of the postero-lateral sulcus. is composed largely of dorsal root axones. Many of these finally work across the line of the sulcus into the posterior funiculus. Many of the dorsal root-fibres which do not reach the brain occur in Lissauer's zone. Many others of course occur throughout the posterior column. Lissauer's zone also contains some fibres arising from the small cells of the dorsal horn, and to this extent corresponds to a fasciculus proprius. Ranson has found that large numbers of the non-medullated dorsal root axones which enter the cord are contributed to Lissauer's zone.

The **lateral fasciculus proprius** (lateral ground bundle, lateral limiting layer) is situated in the lateral concavity of the grey column and is continuous with the other fasciculi proprii both dorsal and ventral. Beyond that it probably contains fewer commissural axones, it is of the same general significance as the others. It is frequently divided into small bundles by the reticular formation (see fig. 616).

The lateral cerebro-spinal fasciculus (crossed pyramidal tract). In contrast to the sensory fibres passing through the spinal cord conveying impulses destined to reach the cerebral cortex, axones are given off from the pyramidal cells of the

Fig. 618.—Diagram Illustrating the Formation of the Fasciculi Proprii (association fasciculi) and the Commissural Fibres of the Spinal Cord, and the General Architecture of the Cord as a Mechanism for Reflex Activities.

The ventral fasciculus proprius is omitted and the lateral is shown on one side only. The lower spinal ganglion neurone shown illustrates the type whose ascending branch is of much longer extent than that of the upper one.



cortex, which descend to terminate about the cells of the grey substance of the spinal cord, chiefly the cells which give origin to the ventral root-fibers.

Upon reaching the medulla oblongata in their descent, these axones are accumulated into two well-defined, ventrally placed bundles, the **pyramids,** one from each cerebral hemisphere. In passing through the brain stem the pyramids contribute many fibres which cross the mid-line to terminate in the motor nuclei of the cranial nerves of the opposite side, and thus decrease appreciably in bulk. According to the estimate of Thompson, only about 160,000 of the pyramidal fibres are destined to enter the spinal cord.

Upon reaching the lower part of the medulla, the greater mass of the fibres of each pyramid, which are destined to enter the cord, suddenly cross the mid-line in the 'decussation of the pyramids.' The remainder retain their ventral position in their descent decussating gradually in the cord itself. The pyramidal fibres which cross in the medulla course in the lateral column ventral to Lissauer's zone, and lateral to the lateral fasciculus proprius, and form the *lateral cerebro-spinal fasciculus* (crossed pyramidal tract). It is a large fasciculus, oval shaped in transection, and since its axones terminate in the grey column of the cord all along its length, it decreases in bulk as the cord is descended.

In addition to the three dispositions of the dorsal root axones given above, certain of them, either by collaterals or terminal twigs, form telodendria about the cells of the dorsal nucleus (Clarke's column), which nucleus extends from about the seventh cervical to the third lumbar segment of the cord. The axones given off by these cells pass to the dorso-lateral periphery of the lateral funiculus, and there collect to form the **dorsal spino-cerebellar fasciculus** (direct cerebellar tract of Flechsig). As such they ascend without interruption, and in the upper level of the medulla oblongata pass into the cerebellum by way of the inferior cerebellar peduncle or restiform body. Necessarily, this fasciculus is not evident in levels below the extent of the nucleus dorsalis.

Also situated superficially in the lateral funiculus is another ascending conduction path, and, like the dorsal spino-cerebellar fasciculus, to which it is adjacent, it is also in part at least a cerebellar connection. Its position suggests its name, **superficial ventro-lateral spino-cerebellar fasciculus (Gowers' tract).**

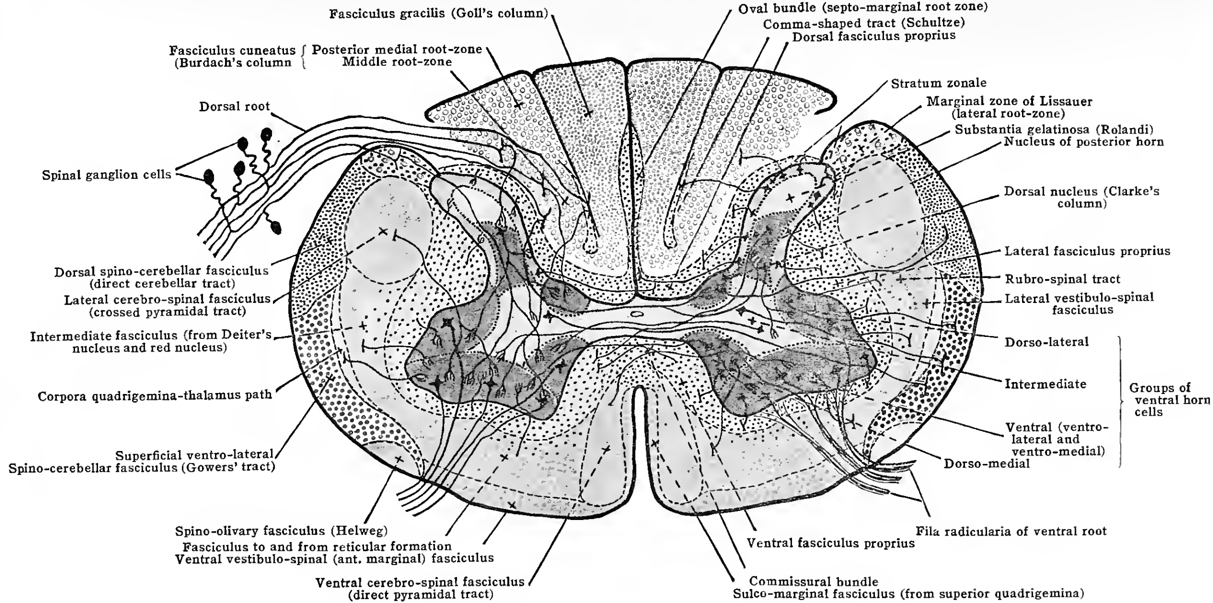
This tract at present does not include as great an area in transverse section as when originally described. The more internal portion of the original Gowers' tract is now given a separate significance, and will be considered separately. While the exact location in the grey column of all the cell-bodies giving origin to the superficial ventro-lateral spino-cerebellar fasciculus is uncertain, it is known that certain ventral horn cells contribute their axones to it. Many of its cells of origin are scattered in the area immediately ventral to the nucleus dorsalis, others in the intermediate and mesial portion of the lateral group of ventral horn cells. In the lumbar region these cells are quite numerous, and, therefore, the fasciculus begins at a lower level in the spinal cord than does the direct cerebellar tract. In degenerations it becomes visible in the upper segments of the lumbar region, and has been proved to increase notably in volume as the cord is ascended. Its axones arise for the most part directly from cell-bodies of the same side of the cord, though it has been shown by several investigators that many of its axones come from the grey substance of the opposite side by way of the ventral white commissure. Terminal twigs and collaterals of the dorsal root-fibres, mostly of the same side, but occasionally from the opposite side, terminate about its cells of origin. At one time Gowers' tract was considered an entity, but now, even in the more limited area it occupies, it must be considered a mixture of axones of several terminal destinations or distinct neurone systems. The destination of some of its axones has not been determined with certainty. A portion, the spino-cerebellar fasciculus proper, go to the cerebellum, and there have been traced to the cortex of the superior vermis. Most of these reach the cerebellum not by way of the restiform body, as does the dorsal spino-cerebellar tract, but pass on in the brain-stem to the level of the inferior corpora quadrigemina, and there turn back to join the brachium conjunctivum or superior cerebellar peduncle. (Auerbach, Mott, Hoche.) Only a few of its axones leave the fasciculus lower down in the medulla, to enter the cerebellum by way of the restiform body, in company with the dorsal spino-cerebellar tract. (Rossolimo, Tschermak.) Another portion of its axones are thought to reach the cerebrum, probably the nucleus lentiformis, though it has not been positively traced further than the superior corpora quadrigemina. Many axones in Gowers' tract of the cord correspond to those of the fasciculi proprii, and merely run varying distances in the cord, to turn again into its grey substance. Schaeffer followed some of these from the lumbar region up to the level of the second cervical nerve.

In the ventro-mesial border of Gowers' tract and immediately upon the periphery, near the antero-lateral sulcus (exit of ventral nerve-roots), there is found in the higher segments of the cord a small oval bundle, the **spino-olivary fasciculus** or **Helweg's** (Bechterew's) **bundle.** The functional direction of its fibres has not been settled.

It is asserted to arise from cell-bodies of the olive in the medulla oblongata, and in the cord is believed to be associated with the cells of the ventral column of grey substance, probably those of the lateral horn. More recent claims assert that it arises fron cell bodies in the cord and thus is spino-olivary. By some observers it has been traced as far down as the mid-thoracic region; by others, however, only as far as the third cervical segment. The olives being nuclei largely concerned with cerebellar connections, Helweg's fasciculus is probably an indirect cerebellar association with the spinal cord neurones. It is composed of axones of relatively very small diameter, and it is one of the last fasciculi of the spinal cord to become medullated.

Situated between the superficial ventro-lateral spino-cerebellar fasciculus and the lateral fasciculus proprius is an area which, in transverse sections, may be, by position, referred to collectively as the **intermediate fasciculus.** So intermingled are the axones comprising it that it has been called the **mixed lateral zone.** It contains fibres of at least five functional varieties:

Fig. 619.—Schematic Representation of the Shape and Position of the Various Fasciculi or Conduction Paths of the Spinal Cord and the Grouping and Significance of the Cell-bodies of the Grey Substance. (Compiled from the schemes of von Lenhossèk and Held.)



(1) Fibres belonging to the lateral fasciculus proprius which are of longer extent gradually course farther away from the grey substance of the cord and such mix into the intermediate fasciculus.

(2) It is said to contain fibres descending from the cerebellum to associate with the neurones of spinal cord, probably directly with the ventral root or motor neurones.

(3) **The rubro-spinal fasciculus.**—This arises from cell-bodies in the red nucleus of the tegmentum (in the mesencephalon) and is a crossed fasciculus. Axones arising from the red nucleus of one side cross the mid-line while yet in the mesencephalon and descend in the lateral funiculus of the cord to terminate gradually about cell-bodies of the ventral horn, both those which give rise of ventral root fibres and those which contribute to the fasciculi proprii. Its fibres are more thickly bundled in a crescentic area fitting onto the ventral side of the lateral cerebro-spinal fasciculus, and some are said to mix into the area of this latter.

(4) **The vestibulo-spinal fasciculus.**—This is sometimes called the lateral vestibulo-spinal fasciculus from the fact that there is a tract of similar significance in the ventral funiculus of the cord. It arises from some of the cell-bodies comprising Deiter's nucleus, the lateral nucleus of termination of the vestibular nerve, and from some of those of the spinal nucleus (nucleus of the descending root) of this nerve, all of which is in the medulla. It descends the cord, uncrossed, to terminate gradually about ventral horn cells, thus comprising a part of the apparatus for the equilibration of the body. Its fibres are thought to be more closely collected in the area immediately ventral to the rubro-spinal fasciculus, but of course commingle with the latter.

(5) The *corpora-quadrigemina-thalamus path.* The most lateral portion of the intermediate fasciculus, a small area once included in Gower's tract, contains fibres both ascending and descending, connecting the spinal cord with the thalamus (diencephalon) and the quadrigeminate bodies of the mesencephalon. These are crossed paths. The ascending fibres arise from cell-bodies in the ventral horn of one side, cross in the ventral white commissure (commissural neurones) and course upward in the intermediate fasciculus to their termination in the opposite side. Those terminating about cell-bodies in the thalamus form what is known as the **spino-thalamic tract,** while those terminating in the nuclei of the quadrigeminate bodies are called the **spino-mesencephalic** or **spino-tectal tract** (*tractus spino-tectalis*). It is not known in which region of the cord most of these fibres arise but it is quite probably the cervical region. The fibres which arise from cell-bodies of the thalamus and nuclei of the quadrigeminate bodies cross the mid-line *in the mesencephalon* and descend the cord to terminate gradually about cell-bodies in the ventral horn of the opposite side. Those from the thalamus are known as the **thalamo-spinal tract** and those from the quadrigemina, as the **mesencephalo- or tecto-spinal tract.** The latter is thought to be the larger.

By the fibres of the above tracts general sensory impulses from the body (skin, etc.) are carried to the central portion of the optic apparatus, and the descending fibres give a simple anatomical possibility for the movements of the body in response to visual and auditory impulses. The descending fibres are thought to terminate chiefly in contact with association neurones of the fasciculi proprii, these transferring the impulses to the neurones giving origin to the ventral or motor root fibres, but some are thought to terminate directly about the cell-bodies of ventral-root neurones. A portion of the intermediate fasciculus, most adjacent to Gower's tract, has been designated as *Loewenthal's tract.*

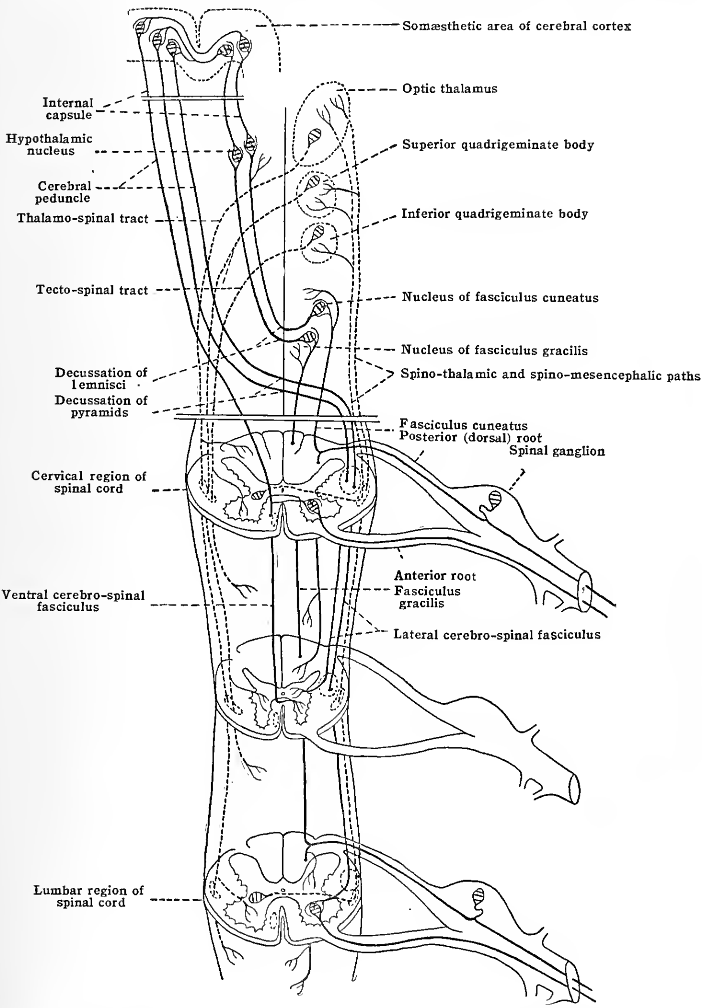
The anterior funiculus or column [funiculus anterior].—The *intermediate fasciculus* is continued ventrally and mesially across the line of exit of the ventral root axones, and thus into the anterior funiculus. This portion is also mixed, but its axones of long course associate somewhat different portions of the nerve axis from those connected by the more lateral portion.

According to the studies of Flechsig, von Bechterew, and Held, this mesial portion contains fibres, both ascending and descending, which associate the various levels of the grey substance of the spinal cord with the neurones in the reticular formation of the medulla oblongata. The levels to which they have been traced comprise the olivary nuclei, which are largely concerned in cerebellar connections, and the nuclei of the vagus, glosso-pharyngeal, auditory, facial and the spinal tract of the trigeminus. Also some of the ascending fibres are probably associated with the nuclei of the eye-moving nerves. This portion of the intermediate fasciculus also grades into and is mixed with the axones of the **ventral fasciculus proprius,** as is its lateral portion with the lateral fasciculus proprius. In other words, the fasciculi proprii proper, the axones nearest the grey substance, serve for the intersegmental association of the different levels of the grey substance of the cord, while the intermediate fasciculus contains axones of longer course which serve to associate more distant levels of the grey substance of the nerve axis—that of the spinal cord with its upward continuation into the medulla oblongata, pons and mesencephalon.

The **anterior marginal fasciculus, ventral vestibulo-spinal tract** (Loewenthal's tract) forms the superficial boundary of the mesial portion of the intermediate fasciculus. It is a narrow band, parallel with the surface of the cord, and extends mesially from the mesial extremity of Gowers' tract (from Helweg's bundle) to the beginning of the anterior median fissure.

The axones belonging to it proper are descending from the recipient nuclei of the vestibular nerve. Of these nuclei it has been held by some investigators that only Deiters' nucleus (the lateral nucleus of termination in the upper extremity of the medulla oblongata) gives origin to the axones of the anterior marginal fasciculus. Others agree with Tschermak that the superior and more laterally situated Bechterew's nucleus of the vestibular nerve also contributes axones to it, and quite probably the nucleus of the spinal root of the vestibular adds further axones. Still other investigations have shown that a part at least of the fasciculus comes from the nucleus fastigius (roof nucleus) of the cerebellum. Since many axones from both Deiters' and Bechterew's nucleus terminate in the nucleus fastigius, the ventral vestibulo-spinal fasciculus

Fig. 620.—Diagram of Spinal Cord Illustrating the Two Chief Varieties of Spino-cerebral and Cerebro-spinal Neurone Chains. The ventral tecto-spinal (sulco-marginal) fasciculus, fibres descending from the superior quadrigeminate bodies, is not filled in.



is, in any case, a conduction path from the nerve connections for equilibration to the grey substance of the spinal cord. The fasciculus is said to extend as far as the sacral region of the cord, its axones terminating about the cells of the ventral horns. The term "ventral" is added to its name to distinguish it from the vestibulo-spinal tract described above as coursing in the lateral funiculus. It is considered an uncrossed pathway.

The **ventral cerebro-spinal fasciculus** (anterior or direct pyramidal tract), as stated above, is the uncrossed portion of the descending cerebro-spinal system of neurones. It is a small, oblong bundle, situated mesially in the anterior funiculus, parallel with the anterior median fissure. Like the lateral cerebro-spinal fasciculus (crossed pyramidal tract), its axones arise from the large pyramidal cells of the motor area of the cerebral cortex, and transmit their impulses to the neurones of the ventral horns of the grey substance of the spinal cord, and almost entirely to those neurones which give origin to the ventral or motor root fibres.

It represents merely a delayed decussation of the pyramidal fibres, for instead of crossing to the opposite side in the lower portion of the medulla oblongata, as do the fibres of the lateral fasciculus, its fibres decussate all along its course, crossing in the ventral white commissure and in the *commissural bundle* of the cord to terminate about the ventral horn cells of the opposite side. Hoche, employing Marchi's method, found that a few of its fibres terminate in the ventral horn of the same side. This conforms to the pathological and experimental evidence that there are homolateral or uncrossed fibres in the crossed pyramidal tracts also. Like the crossed tract, the ventral pyramidal tract diminishes rapidly in volume as it descends the cord. Its loss is greatest in the cervical enlargement, and it is entirely exhausted in the thoracic cord. With the exception of the anthropoid apes and certain monkeys, none of the mammalia below man, which have been investigated, possess this ventral pyramidal tract

Lying between the ventral cerebro-spinal fasciculus and the pia mater of the anterior median fissure is a thin tract of descending axones continuous ventrally with the anterior marginal fasciculus. From its position it is known as the **sulco-marginal fasciculus**; functionally it is the ventral mesencephalo-spinal (tecto-spinal) tract.

The extent of its course in the spinal cord is uncertain. It arises from the cells of the grey substance of the superior pair of the quadrigeminate bodies, and there, in largest part at least, it crosses the mid-line, and in the so-called 'optic acoustic reflex path' descends through the medulla oblongata into the spinal cord of the opposite side. The superior quadrigeminate bodies having to do with sight, this tract forms a second path conveying visual impulses to the neurones of the spinal cord.

The **commissural bundle** is situated about the floor of the anterior median fissure, and is the most dorsal tract of the anterior funiculus. It contains decussating or commissural axones of three varieties.

(1) It contains the decussating axones of the ventral cerebro-spinal fasciculus throughout the extent of that fasciculus; (2) it is chiefly composed of the axones of the ventral fasciculus proprius which arise in the grey substance (ventral horn) of one side, cross the mid-line as commissural fibres, and course both upward and downward to be distributed to the neurones of different levels of the grey substance of the opposite side; (3) it contains decussating axones which arise from cell-bodies in the grey substance of one side and cross the mid-line to terminate about cell-bodies in practically the same level of the opposite side. The latter are merely axones belonging to the ventral white commissure which course without the confines of the grey figure. The commissural bundle is present throughout the length of the spinal cord, and is largest in the enlargements, i. e., where the association and commissural neurones occur in greater number generally. In its two last-mentioned varieties of axones it corresponds to the commissural portion of the dorsal fasciculus proprius (the cornu-commissural bundle).

The **ventral fasciculus proprius** is but a continuation of the lateral fasciculus proprius, and is composed of ascending and descending association fibres of the same general significance.

SUMMARY OF THE SPINAL CORD

The spinal cord contains two general classes of axones arranged into three general systems. It contains axones which—(a) enter it from cell-bodies situated outside its boundaries, i. e., in the spinal ganglia and in the encephalon, and (b) axones which arise from cell-bodies situated within its own grey substance, some of which axones pass outside its boundaries both to the periphery and into the encephalon; some of which remain wholly within it. Its axones comprise—(1) a system for the intersegmental association of its grey substance, both ascending and descending, association proper and commissural; (2) a spino-cerebral and cerebro-spinal system, ascending and descending; and (3) a spino-cerebellar and cerebello-spinal system, ascending and descending.

For these relations the grey substance of the cord contains three general classes of nerve-cells:—those which give rise to the peripheral efferent or motor axones of the ventral roots; those which give rise to central axones of long course, going to the encephalon; and those which supply its central axones of shorter course, the association and commissural systems.

The three systems: (1) **Association and commissural.**—Axones of spinal ganglion (afferent) neurones bifurcate within the cord into cephalic and caudal branches which extend varying distances upward and downward and terminate, (*a*) about cell-bodies whose axones are short and terminate within the grey substance of the same side and in the same level as their cell-bodies (*Golgi neurones of type II*); (*b*) about cell-bodies whose axones pass without the grey substance, bifurcate into cephalic and caudal branches to terminate in the grey substance of the same side but in various levels above and below (association fibres in the *dorsal*, *lateral* and *ventral fasciculi proprii*); (*c*) about cell-bodies whose axones cross the mid-line to terminate either in the same level of the grey substance of the opposite side, or bifurcate and the cephalic and caudal branches pass in the fasciculi proprii to terminate in various levels of the grey substance of the opposite side. The longer cephalic branches of (*b*) and (*c*) may terminate in the medulla oblongata. All, associated with ventral root (efferent) neurones, belong to the neurone chains for the so-called *reflex activities*.

(2) **The cerebral system.**—(a) The cephalic branches of certain spinal ganglion neurones *ascend* beyond the bounds of the spinal cord to terminate within the medulla. Those ascending from the spinal ganglia of lower thoracic and lumbo-sacral segments accumulate mesially to form the *fasciculus gracilis* which terminates in the nucleus of this fasciculus; those arising from the upper thoracic and cervical segments accumulate more laterally in the posterior funiculus to form the *fasciculus cuneatus* which terminates in the nucleus of the fasciculus cuneatus. (*b*) The impulses transferred to the neurones of these nuclei are borne across the mid-line and finally reach the sensory-motor area of the cerebral cortex, and cell-bodies here give rise to axones which *descend*, some decussating in the medulla to form the *lateral cerebro-spinal fasciculus*, others form the uncrossed *ventral cerebro-spinal fasciculus* which crosses the mid-line as it descends the cord. Both of these fasciculi transfer their impulses either directly to efferent ventral horn neurones, or to association neurones and these to the efferent neurones. (*c*) The cephalic and caudal branches of spinal ganglion neurones terminate about cell-bodies in the grey substance of the cord whose axones cross the mid-line and *ascend* laterally to terminate either in the quadrigeminate bodies (*spino-mesencephalic tract*), or in the thalamus (*spino-thalamic tract*). (*d*) Cell-bodies in thalamus and superior quadrigeminate bodies (receiving optic impulses) and in the inferior quadrigeminate bodies (probably mediating auditory impulses), give axones which cross the mid-line in the mesencephalon and *descend*, forming the *thalamo-spinal* and *mesencephalo-spinal tracts*, to terminate in contact with the efferent neurones of the cord. Axones from both sources descend in the lateral funiculus, while from the superior quadrigeminate body, a separate bundle descends in the ventral funiculus as the *sulco-marginal* (*ventral mesencephalo-spinal*) *fasciculus*. (*e*) The *rubro-spinal tract* arises from cell-bodies in the red nucleus (in the mesencephalon), crosses the mid-line and descends in the lateral funiculus to transfer (probably cerebellar) impulses to the efferent neurones of the spinal cord.

(3) **The cerebellar system.**—(*a*) The cephalic and caudal branches of spinal ganglion neurones give telodendria about the cell-bodies forming the *dorsal nucleus* of the cord (Clarke's column) and about cell-bodies situated in grey substances ventral to the dorsal nucleus ("Stilling's nucleus") and in the lateral horn. Axones arising from the cells of the dorsal nucleus pass laterally to form the *dorsal spino-cerebellar fasciculus* which *ascends* into the cerebellum by way of its inferior peduncle of the same side and terminates about cell-bodies of its cortex. Axones arising from Stilling's nucleus and the lateral horn cells, of both the *same* and *opposite sides* of the cord, accumulate to form the *superficial ventro-lateral spino-cerebellar fasciculus*, which *ascends* to enter the cerebellum by way of its superior peduncle and terminate about the cells of the cerebellar cortex. (*b*) A few axones arising in the roof nucleus of the cerebellum probably *descend* in the *anterior marginal fasciculus* in company with the *ventral vestibulo-spinal tract* to terminate upon the efferent neurones of the cord. (c) The inferior olivary nucleus, in the medulla, is a cerebellar relay and its cell-bodies are associated with the neurones of the upper portion of the same side of the spinal cord. Whether the axones arise in the olivary nucleus or in the grey substance of the cord is uncertain, but the more usual supposition favours the cord and thus the name, *spino-olivary fasciculus* is given them. (*d*) Among its other functions, the cerebellum is concerned with equilibration. The vestibular nerve is the afferent nerve of equilibration and a large mass of the axones arising from its nuclei of termination terminate in the cerebellum, in the roof nuclei especially. Axones arising from cell-bodies in Deiters' nucleus (its lateral nucleus of termination) and in the nucleus of its descending root *descend* the cord in the lateral funiculus to form the (lateral) *vestibulo-spinal tract*, and also in the *anterior marginal fasciculus* to form *ventral vestibulo-spinal tract*. Impulses borne by these axones reach the efferent or motor root neurones. The rubro-spinal fasciculus, mentioned above also may be possibly considered as belonging to the cerebellar system.

Sympathetic relations.—The cell-bodies of the efferent neurones in the ventral horns are of two general varieties: (*a*) those whose axones terminate upon skeletal muscle (somatic efferent), and (*b*) those whose axones terminate in contact with cell-bodies of sympathetic neurones, the *splanchnic* or *visceral efferent neurones*. The axones of the sympathetic neurones, in their turn, terminate upon cardiac and smooth muscle (motor) and in glands (secretory). Like the somatic, the visceral efferent neurones receive impulses within the ventral horns (*a*) from the cephalic and caudal branches of spinal ganglion neurones, (*b*) the descending cerebro-spinal fasciculi, and (*c*) from either, by way of the fasciculi proprii and Golgi neurones of type II. Their cell-bodies are situated for the most part in the dorsal portion of the lateral horn (dorso-lateral group of cells), which is the only portion of the lateral horn present in the thoracic region of the cord. Many of the visceral efferent fibres leave the spinal nerves distal to the spinal ganglia and make the white communicating rami, thus going to the nearest sympathetic ganglia; others pass on in the spinal nerve and its branches to terminate in more distal sympathetic ganglia. Dogiel has described axones which arise in sympathetic ganglia and terminate upon the cell-bodies of the spinal ganglia. Such convey sensory impulses which, however, enter the spinal cord by way of the dorsal root branch of the spinal ganglion neurone. Such afferent sympathetic neurones are relatively rare, the peripheral distribution of the ordinary

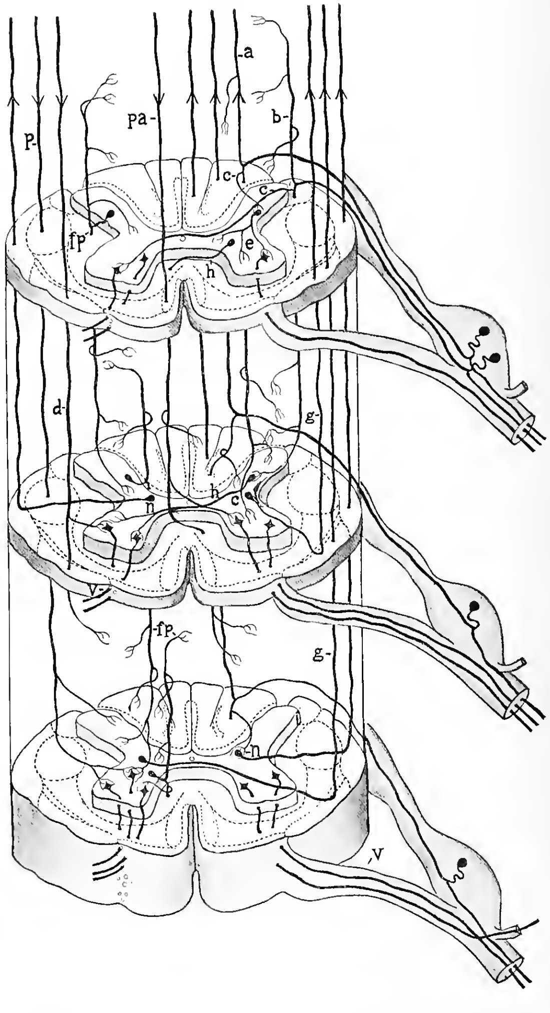
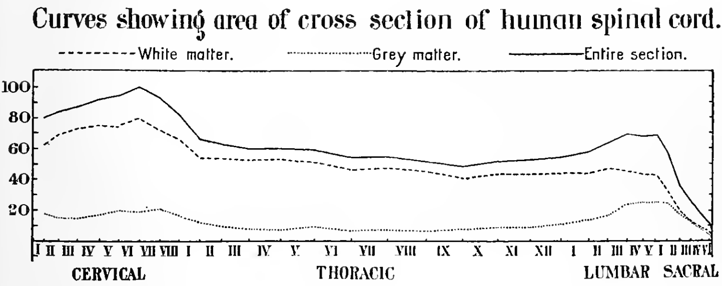
a, afferent (spinal ganglion) axone of spino-cerebral chain with bifurcation and caudal branch; b, afferent axone coursing in Lissauer's zone and distributed wholly within the cord; c, collaterals of a and b disposed in three ways; p, pyramidal axone in lateral (crossed) cerebro-spinal fasciculus distributed to levels of grey substance; pa, axone in ventral cerebro-spinal fasciculus decussating before termination; v, ventral root or motor neurones; n, nucleus dorsalis giving axone to dorsal spino-cerebellar fasciculus; g, ascending neurones of Gowers' tract; d, descending axone from cerebellum (probable); fp, neurones of fasciculi proprii, association proper; h, commissural neurones; e, Golgi cell of type II.



spinal ganglion neurone in the domain of the sympathetic supplying the needs for sensory axones.

In transverse sections of the spinal cord, the relative area of white substance as compared with that of grey increases as the cord is ascended. The absolute area of each varies with the locality, both being greatest in the enlargements. The grey substance predominates in the conus medullaris and lower lumbar segments. The white substance begins to predominate in the upper lumbar segments, not because of the increased presence of ascending and descending cerebral and cerebellar axones, but because of the increased volume of the fasciculi proprii coincident with the greater mass of grey substance to be intersegmentally associated in this region. In the thoracic region the greatly predominating white substance

Fig. 622.—Graphic Representation of the Varying Amounts of Grey and White Substance and of the Variations in Area of Entire Sections of the Different Segments of the Spinal Cord. (From Donaldson and Davis.)
(Based upon measurements from several adult human spinal cords.)



is composed mostly of the axones of long course. The greatly increased absolute amount of white substance in the cervical region is due both to the greater accumulation of cerebral and cerebellar axones in this region and to the increased volume of the fasciculi proprii of the cervical enlargement.

ORDER OF MEDULLATION OF THE FASCICULI OF THE CORD

The axones of the spinal cord begin to acquire their myelin sheaths during the fifth month of intra-uterine life and myelinization is not fully completed till between the fifteenth and twentieth years. In general, axones which have the same origin and the same locality of termination—the same function—acquire their sheaths at the same time. While it has been proved that the medullary sheath does not necessarily precede the functioning of an axone, it may be said that those fasciculi which first attain complete and definite functional ability are the first to become medullated. At birth all the fasciculi of the spinal cord are medullated except Helweg's fasciculus, and occasionally the lateral and ventral cerebro-spinal tracts. The latter tracts vary considerably and in general may be said to become medullated between the ninth month (before birth) and the second year. As indicated by their medullation, those axones by which the cord is enabled to function as an organ *per se*, that is, the axones making possible the simpler reflex activities, complete their development before those axones which involve the brain with the activities of the cord.

According to Flechsig and van Gehuchten, and investigators succeeding them, the following is the order in which the axones of the cord become medullated:—

(1) The afferent and efferent nerve-roots and commissural fibres of the grey substance.

(2) The fasciculi proprii, first the ventral, then the lateral, and last the dorsal, fasciculus proprius.

(3) The fasciculus cuneatus (Burdach's column) and Lissauer's zone—the area of those ascending spino-cerebral fibres which run the shorter course and which convey impulses from the upper limbs, thorax and neck.

(4) Fasciculus gracilis (Goll's column).

(5) The dorsal spino-cerebellar fasciculus (direct cerebellar tract).

(6) The superficial antero-lateral spino-cerebellar fasciculus (Gowers' tract).

(7) The lateral cerebro-spinal fasciculus (crossed pyramidal) and the ventral cerebro-spinal fasciculus (direct pyramidal tract).

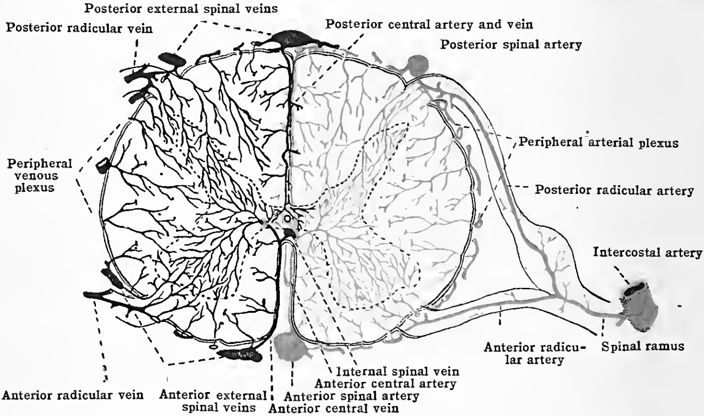
(8) The spino-olivary or Helweg's (Bechterew's) fasciculus.

The axones descending from the cerebellum and the brain-stem are so mixed with other axones that it is difficult to determine the sequence of their medullation. The fasciculi containing them also contain axones of the variety in the fasciculi proprii and so show medullation early. It is probable that the ascending, spino-cerebellar, fibres acquire their myelin earlier than the descending, if descending exist.

Blood Supply of the Spinal Cord

The spinal rami of the sacral, lumbar, intercostal, or vertebral arteries, as the case may be, accompany the spinal nerves through the intervertebral foramina, traverse the dura mater and arachnoid, and each divides into a dorsal and a ventral radicular artery. These accompany the nerve-roots to the surface of the cord, and there break up into an anastomosing plexus in the pia mater. From this plexus are derived three tortuously coursing longitudinal arteries and numerous independent central branches, which latter penetrate the cord direct. Of the longitudinal arteries, the **anterior spinal artery** zigzags along the anterior median fissure and gives off the anterior central branches, which pass into the fissure and penetrate the cord. These branches give off a few twigs to the white substance in passing, but their most partial distribution is to the ventral portion of the grey substance. The two **posterior spinal arteries**, one on each side, course near the lines of entrance of the dorsal root-fibres. They each branch and anastomose, so that often two or more posterior arteries may appear in section upon either side

Fig. 623.—Semi-diagrammatic Representation of the Blood Supply of the Spinal Cord.



of the dorsal root. These give off transverse or central twigs to the white substance, but especially to the grey substance of the dorsal horns. Of the remaining central branches many enter the cord along the efferent fibres of the ventral roots, and are distributed chiefly to the grey substance; others from the peripheral plexus throughout penetrate the cord and break up into capillaries within the white substance. Some of the terminal twigs of these also enter the grey substance. The blood supply of the grey substance is so much more abundant than that of the white substance that in injected preparations the outline of the grey figure may be easily distinguished by its abundance of capillaries alone. The central branches are of the terminal variety. In the white substance the capillaries run for the most part longitudinally, or parallel with the axones.

The *venous system* is quite similar to the arterial. The blood of the central arteries is collected into corresponding central venous branches which converge into a superficial venous plexus in which are six main longitudinal channels, one along the posterior median sulcus, one along the anterior median fissure, and one along each of the four lines of the nerve-roots. These comprise the **posterior** and **anterior external spinal veins** (fig. 623).

The **internal spinal veins** course along the ventral surface of the grey commissure, and arise from the convergence of certain of the twigs of the *anterior central vein*. The *posterior central vein* courses along the posterior median septum in company with the posterior central artery, and empties into the *median dorsal vein*. The venous system communicates with the coarser extra-dural or internal vertebral plexus chiefly by way of the **radicular veins.**

II. THE BRAIN OR ENCEPHALON

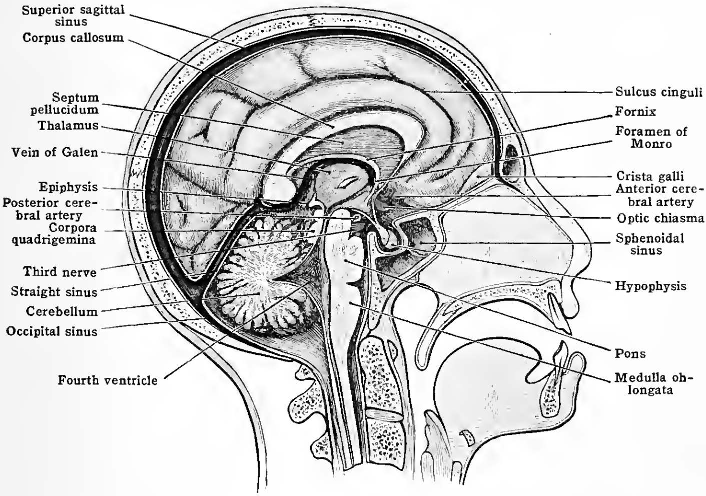
The brain is that greatly modified and enlarged portion of the central nervous system which is enclosed within the cranial cavity. It is surrounded and supported by the same three membranes (meninges) that envelop the spinal cord.

While there is a considerable subarachnoid space, the brain more nearly fills its cavity than does the spinal cord.

The average length of the brain is about 165 mm. and its greatest transverse diameter about 140 mm. It averages longer in the male than in the female. Exclusive of its dura mater, the normal brain weighs from 1100 to 1700 gm. (40–60 oz.), varying in weight with the stature of the individual or with the bulk of the tissues to be innervated. Its average weight is 1360 gm. (48 oz.) in males and 1250 gm. (44 oz.) in females. It averages about fifty times heavier than the spinal cord, or about 98 per cent. of the entire cerebro-spinal axis. In its precocious growth it is at birth relatively much larger than at maturity. At birth it comprises about 13 per cent. of the total body-weight, while at maturity it averages only about 2 per cent of the weight of the body. Its specific gravity averages 1.036. In proportion to the body-weight the brain-weight averages somewhat higher in smaller men and women. Some very small dogs and monkeys and some mice have brains heavier in proportion to body-weight than man.

The minimal weight of the adult brain compatible with human intelligence may be placed at from 950 to 1000 grams. Above the minimal, there is only a general relation between the degree of intelligence and the weight of the brain, owing to the fact that several factors may be coincident with large brains. It may be said in general, however, that the average brain weight of eminent men is above the general average. Some men judged eminent have had brains weighing less than the general average. Of the records generally accepted, the greatest brain weight

Fig. 624.—Mesial Section of the Head of a Female Thirty-five Years Old.



for eminent men is 2012 grams, recorded for the poet and novelist, Ivan Tourgenieff. The trustworthiness of this weighing is doubted by some authorities. From the undisputed records the following may be taken: Cuvier, 1830 grams; John Abercrombie, 1786 grams; Thackery, 1658 grams; Kant, 1600 grams; Spurzheim, 1559 grams; Daniel Webster, 1518 grams; Louis Agassiz, 1495 grams; Dante, 1420 grams; Helmholtz, 1440 grams; Goltz, 1395 grams; Liebig, 1352 grams; Walt Whitman, 1282 grams; Gall, 1198 grams. In the average brain weights for the races that for the Caucasian stands highest, the Chinese standing next, then the Malay, followed by the Negro, with the Australian lowest.

The differences between the meninges of the brain and those of the spinal cord occur chiefly in the dura mater. (1) The *dura mater* is about double the thickness of that of the spinal cord, and consists of two closely adhering layers, the outermost of which serves as the internal periosteum of the cranial bones, while that of the cord is entirely separate from the periosteum lining the vertebral canal. (2) The inner layer is duplicated in places into strong partitions which extend between the great natural divisions of the encephalon. Of these, the sickle-shaped *falx cerebri* extends between the hemispheres of the cerebrum, the crescentic *tentorium cerebelli* extends between the cerebellum and the overlapping posterior portion of the cerebrum, and the smaller *falx cerebelli* occupies the notch between the hemispheres of the cerebellum. Contained within these partitions of the dura mater are the great collecting venous sinuses of the brain. These will be considered in the more detailed description of the cranial meninges.

General topography.—In its superior aspect or **convex surface** the encephalon is oval in contour, with its **frontal pole** usually narrower than its **occipital pole.**

Viewed from above, the **cerebrum** comprises almost the entire dorsal aspect, the occipital lobes overlapping the **cerebellum** to such an extent that only the lateral and lower margins of the cerebellar hemispheres are visible. The **great longitudinal fissure** of the cerebrum separates the cerebral hemispheres.

Laterally the **temporal lobes,** with their rounded anterior extremities, the **temporal poles,** are each separated from the frontal and **parietal lobes** above by the **lateral cerebral fissure** (fissure of Sylvius). In the depths of this fissure and overlapped by the temporal lobe is situated the **insula,** or **island of Reil** (central lobe).

The surface of each cerebral hemisphere is thrown into numerous folds or curved elevations, the **gyri cerebri** or convolutions, which are separated from each other by slit-like fissures, the **sulci cerebri.** The gyri (and sulci) vary greatly in length, in depth, and in their degrees of curvature. The larger and deeper of them are similar in the two hemispheres; most of them are individually variable, but each gyrus of one hemisphere is homologous with that of the like region of the other hemisphere. By gently pressing open the great longitudinal fissure, the **corpus callosum,** the chief commissural pathway between the cerebral hemispheres, may be seen. The occipital margin of this large transverse band of white substance is rounded and thickened into the **splenium** of the corpus callosum, while its frontal margin is curved ventrally into its **genu** and rostrum.

The **base of the encephalon** (fig. 625) is more irregular than the convex surface, and consists of a greater variety of structures. In the mid-line between the frontal lobes appears the anterior and inferior extension of the great longitudinal fissure. When the margins of this are separated, the outer aspect of the **rostrum** of the *corpus callosum,* the downward continuation of the curve of the genu, is exposed.

The inferior surface of each frontal lobe is concave, due to its compression upon the superior wall of the orbit. The *orbital gyri* with their respective *orbital sulci* occupy this concave area.

The cranial nerves [nervi cerebrales].—Along the mesial border of each orbital area, and parallel with the great longitudinal fissure, lie the **olfactory bulbs** continued into the **olfactory tracts.** Each olfactory bulb is the first central connection or the 'nucleus of reception' of the **olfactory nerve,** the first of the cranial nerves. A few fine filaments of this nerve may often be discerned penetrating the ventral surface of the bulb. The olfactory bulb and tract lies in the *olfactory sulcus,* which forms the lateral boundary of the *gyrus rectus,* the most mesial gyrus of the inferior surface of the frontal lobe. Upon reaching the area of Broca (area parolfactoria), or the region about the medial extremity of the gyrus rectus, each olfactory tract undergoes a slight expansion, the **olfactory tubercle,** and then divides into three roots or **olfactory striæ**—a medial, an intermediate, and a lateral, which comprise the **olfactory trigone.** The striæ begin their respective courses upon the **anterior perforated substance,** an area which contains numerous small foramina through which the antero-lateral group of central cerebral arteries enters the brain. This region forms the anterior boundary of that area of the base of the encephalon in which the substance of the brain becomes continuous across the mid-line.

At the medial boundary of the anterior perforated substance the **optic nerves** come together and fuse to form the **optic chiasma.** Thence the **optic tracts** disappear under the poles of the temporal lobes in their backward course to the *thalami* and the geniculate bodies or metathalami.

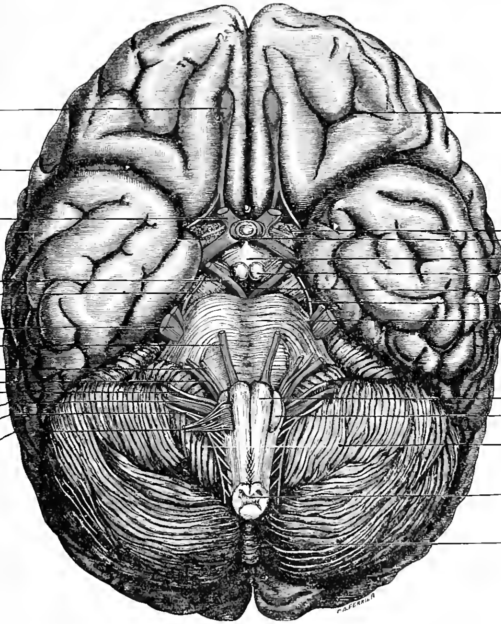
Immediately behind the optic chiasma occurs that diverticulum from the floor of the third ventricle known as the **tuber cinereum.** It is connected by its tubular stalk, the **infundibulum,** with the **hypophysis** or pituitary body, which occupies its special depression (sella turcica) in the floor of the cranium and is usually torn from the encephalon in the process of its removal. Behind the tuber cinereum are the two **mammillary bodies** (corpora albicantia), each of which is connected with the fornix, one of the larger association fasciculi of the cerebrum. The **peduncles of the cerebrum** (crura cerebri) are the two great funiculi which associate the cerebral hemispheres with all the structures below them. They diverge from the anterior border of the **pons** (Varoli) and, one for each hemisphere, disappear under the poles of the temporal lobes. The pons (brachium pontis or middle cerebellar peduncle) is chiefly a bridge of white substance or a commissure between the cerebellar hemispheres.

The **oculomotor** or third pair of cranial nerves make their exit from the **posterior perforated substance** in the **interpeduncular fossa** just behind the corpora mammillaria.

The **trochlear nerves** emerge around the lateral aspects of the pedunculi cerebri along the anterior border of the pons. The trochlear is the smallest of the cranial nerves, and the only pair arising from the dorsal aspect of the brain.

The **trigeminus,** or fifth cranial nerve, is the largest. It penetrates the pons to find its recipient nuclei in the depths of the brain-stem. It is a purely sensory nerve, but it is accompanied by the much smaller **masticator nerve** which is motor and is usually referred to as the motor root of the trigeminus.

FIG. 625.—VIEW OF THE BASE OF THE BRAIN. (After Beaunis.)



Five pairs of cranial nerves are attached to the brain-stem along the inferior border of the pons:—the **abducens** nerve, which is motor, emerges near the mid-line; the **facial,** motor, emerges from the more lateral aspect of the brain-stem; the **glosso-palatine** or the intermediate nerve of Wrisberg, largely sensory, is attached in company with the facial; and, entering the extreme lateral aspect of the stem are the **cochlear** and **vestibular** nerves. These latter two, when taken together as one, are known as the **acoustic** (auditory) or eighth cranial nerve. They are both purely sensory. The cochlear courses for the most part laterally and dorsally around the *inferior cerebellar peduncle,* giving it the appearance from which it derives its name, **'restiform body.'**

The remaining four pairs of the cranial nerves are attached directly to the **medulla oblongata.** This comprises that portion of the brain-stem beginning at the inferior border of the pons above, and continuous with the first segment of the spinal cord below. On its ventral surface the **pyramids** and the **olives** (olivary bodies) are the two most prominent structures. The pyramids, which are continuous below into the pyramidal (cerebro-spinal) tracts of the spinal cord, form the two tapering prominences along either side of the anterior median fissure; the olives are the oblong oval elevations situated between the pyramids and the restiform bodies, and each is the superficial indication of the inferior olivary nucleus.

The **glosso-pharyngeal,** the **vagus** (pneumogastric), and the **spinal accessory** cranial nerves are attached along the lateral aspect of the medulla oblongata in line with the facial nerve and between the olive and the restiform body. The spinal accessory, purely motor, is assembled from a series of rootlets which emerge from the lateral aspect of the first three or four cervical segments of the spinal cord, as well as from the medulla. It becomes fully formed before reaching the level of the olive, and passes lateralward in company with the vagus and further on joins the latter in part. The root filaments of the vagus and glosso-pharyngeal are arranged in a continuous series, and, if severed near the surface of the medulla, those belonging to the one nerve are difficult to distinguish from those belonging to the other. Both of these are mixed motor and sensory.

The **hypoglossal,** purely motor, emerges as a series of rootlets between the pyramid and the olive. Thus it arises nearer the mid-line, and in line with the abducens, trochlear, and oculomotor.

If the occipital lobes be lifted from the superior surface of the cerebellum and the tentorium cerebelli removed, the **quadrigeminate bodies** of the mid-brain or mesencephalon may be observed. These are situated above the cerebral peduncles, in the region of the ventral appearance of the oculomotor and trochlear nerves. Resting upon the superior pair of the quadrigeminate bodies [colliculi superiores] is the **epiphysis** or pineal body, and just anterior to this is the cavity of the third ventricle, bounded laterally by the thalami and roofed over by the **tela chorioidea of the third ventricle** (velum interpositum).

By separating the inferior margin of the cerebellum from the dorsal surface of the medulla oblongata the lower portion of the **fourth ventricle** (rhomboid fossa) may be seen. The **cisterna cerebello-medullaris,** the subarachnoid space in this region, is occupied in part by a thickening of the arachnoid. This is continuous with the tela chorioidea (ligula) and chorioid plexus of the fourth ventricle. The former roofs over the lower portion of the fourth ventricle, and, passing through it in the medial line, is the lymph passage, the **foramen of Magendie,** by which the cavity of the fourth ventricle communicates with the subarachnoid space. The fourth ventricle, as it becomes continuous with the central canal of the spinal cord, terminates in a point, the **calamus scriptorius.** From the inferior surface, the cerebellar hemispheres are more definitely demarcated, and between them is the **vermis** or central lobe of the cerebellum.

Divisions of the encephalon.—The encephalon as a whole is developed from a series of expansions, flexures, and thickenings of the wall of the cephalic portion of the primitive neural tube, the three primary brain vesicles. Being continuous with the spinal cord, it is arbitrarily considered as beginning just below the level of the decussation of the pyramids, or at a line drawn transversely between the decussation of the pyramids and the level of the first pair of cervical nerves.

In its general conformation four natural divisions of the brain are apparent: the two most enlarged portions—(1) the cerebral hemispheres and (2) the cerebellum; (3) the mid-brain (mesencephalon) between the cerebral hemispheres and the cerebellum, and (4) the medulla oblongata, the portion below the pons and above the spinal cord (fig. 602). However, the most logical and advantageous arrangement of the divisions and subdivisions of the encephalon is on the basis of their development from the walls of the embryonic brain vesicles. (See fig. 598.) On this basis, for example, both the medulla oblongata and the cerebellum with its pons are derived from the posterior of the primary vesicles, and are, therefore, included in a single gross division of the encephalon, viz., the *rhombencephalon.* In the following outline the anatomical components of the encephalon are arranged with reference to the three primary vesicles from the walls of which they are derived, and the primary flexures and thickenings of the walls of which they are elaborations.

During the early growth of the neural tube its basal or ventral portion and the lateral portions acquire a greater thickness than the roof of the tube, and thus the tube is longitudinally divided into a basal or **ventral zone** and an alar or **dorsal zone.** This is especially marked in the brain vesicles. Structures arising from the dorsal zone begin as localised thickenings of the roof. For example, in the rhombencephalon the greater part of the medulla oblongata and of the pons region is derived from the ventral zone, while the cerebellum is derived from the dorsal zone. The first of the flexures occurs in the region of the future mesencephalon, and is known as the **cephalic flexure;** next occurs the **cervical flexure,** at the junction with the spinal cord;

OUTLINE OF THE DIVISIONS OF THE ENCEPHALON

- Encephalon (Brain)
  - Rhombencephalon
    - Medulla oblongata—myelencephalon, I. (After-brain)
    - Metencephalon (Hind-brain)
      - Cerebellum, II_2,
      - Pons (Varolii), II_1,
      - *Middle part of fourth ventricle.*
    - Isthmus rhombencephali. — III.
      - Superior cerebellar peduncles,
      - Anterior medullary velum,
      - *Superior part of fourth ventricle.*
    - (Medulla oblongata, Metencephalon, Isthmus rhombencephali:) Posterior primary vesicle.
  - Cerebrum.
    - Mesencephalon (Mid-brain) — Middle primary vesicle.
      - Quadrigeminate bodies (colliculi), IV_2,
      - Cerebral peduncles (crura), IV_1,
      - Posterior perforated substance, IV,
      - *Aquæductus cerebri* (*Sylvii*).
    - Prosencephalon (Fore-brain) — Anterior primary vesicle.
      - Diencephalon (Inter-brain)
        - Thalamencephalon
          - Thalamus, V_2,
          - Metathalamus, V_3 (Geniculate bodies),

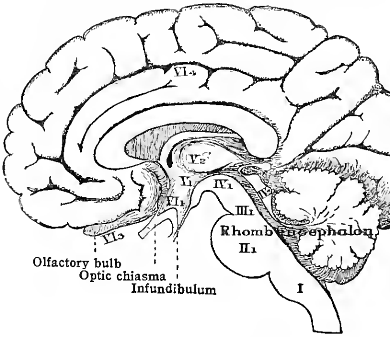
third, the **pontine flexure**, in the region of the future fourth ventricle. Both the cervical and pontine flexures, while having a significance in the growth processes, are almost entirely obliterated in the later growth of the encephalon.

The location of the development of the various parts of the encephalon may be determined, and their elaboration and changes in shape and position may be traced by comparing the accompanying figs. 626, 627, 628. The reference numbers in

Fig. 628.—Median Sagittal Section of Adult Human Brain. (Drawing of model by His.) (Reference numerals same as in figs. 626 and 627.)



the last three figures correspond with the like numerals after the names of the parts on p. 797 in the outline of the divisions of the encephalon. The more detailed subdivisions of the parts will be met with in their individual descriptions.

THE RHOMBENCEPHALON

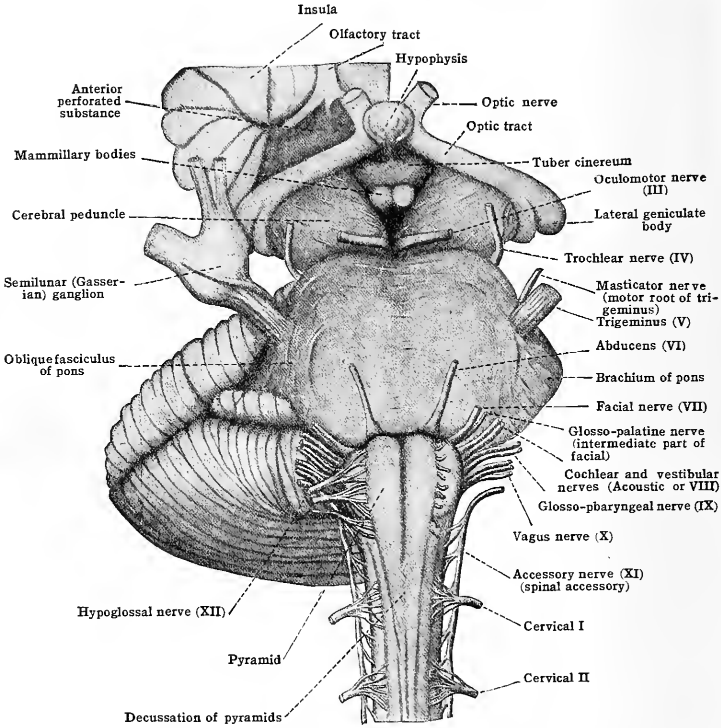
1. THE MEDULLA OBLONGATA

The **medulla oblongata** [myelencephalon] is the upward continuation of the spinal cord. It is only about 25 mm. long, extending from just above the first cervical nerve (beginning of the first cervical segment of the spinal cord) to the inferior border of the pons. It lies almost wholly within the cranial cavity, resting upon the superior surface of the basal portion of the occipital bone, with its lower extremity in the foramen magnum. Its weight is from 6 to 7 gm. or about one-half of one per cent of the whole cerebro-spinal axis. It is a continuation of the spinal cord, and more. It contains structures continuous with and homologous to the structures of the spinal cord, and in addition it contains structures which have no homologues in the spinal cord. Due in part to these additional structures, the medulla, as it approaches the pons, rapidly expands in both its dorso-ventral and especially in its lateral diameters. With it are associated nine of the pairs of cranial nerves.

On its anterior or **ventral aspect** the anterior median fissure of the spinal cord becomes broader and deeper because of the great height attained by the **pyramids.** At the level at which the pyramids emerge from the pons, the region in which they are largest, the fissure terminates in a triangular recess so deep as to merit the name **foramen cæcum.** The pyramids are the great descending cerebral or motor funiculi. In the medulla oblongata they decrease in bulk in passing toward the spinal cord, for the reason that many of the pyramidal axones are contributed to structures of the medulla, chiefly after crossing the mid-line. At the lower end of the medulla occurs the **decussation of the pyramids,** by which the anterior median fissure is almost obliterated for about 6 mm., and which, upon removal of the pia mater, may be easily observed as bundles of fibres interdigitating obliquely across the mid-line.

Not all the pyramidal fibres cross to the opposite side at this level in man, but a portion of those coursing in the lateral portion of the pyramid maintain their ventro-mesial position and continue directly into the spinal cord, to form there the ventral cerebro-spinal fasciculus or direct pyramidal tract. However, most of such fibres finally cross the mid-line during their course in the spinal cord. The exact proportion of the direct fibres is variable, but always the greater mass of each pyramid crosses to the opposite side at the level of the decussation of the pyramids, and descends the cord as the lateral cerebro-spinal fasciculus or crossed pyramidal tract. Both of these pyramidal tracts are described in the discussion of the fasciculi of the cord.

FIG. 629.—SEMI-DIAGRAMMATIC REPRESENTATION OF THE VENTRAL ASPECT OF THE RHOMBENCEPHALON AND ADJACENT PORTIONS OF THE CEREBRUM. (Modified from Quain.)

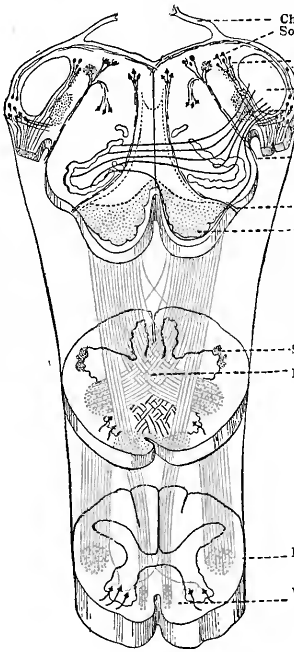


Each pyramid is bounded laterally by the **antero-lateral sulcus,** also continuous with that of the same name in the spinal cord. Toward the pons this sulcus separates the pyramid from the **olive** [oliva] (inferior olivary nucleus), and in the region of the olive there emerge along this sulcus the root filaments of the hypoglossal nerve. These are in line with the filaments of the ventral roots of the spinal nerves. The olives, as their name implies, are oblong oval eminences about 1.2 cm. in length. They extend to the border of the pons, and are somewhat thicker at their upper ends. Their surfaces are usually smooth, except at their lower ends, where they frequently appear ribbed, owing to bundles of the **external arcuate fibres** passing across them to and from the *restiform* body, which occupies the extreme lateral portion of the medulla. Along the line between the restiform body and the olive are attached the root filaments of the *vagus, glosso-pharyngeal,* and *spinal accessory nerves.* Both the *abducens* and the *facial* nerve emerge along the inferior border of the pons, the facial in line with the glosso-pharyngeal, but the abducens in line with the hypoglossus.

Dorsal aspect.—The increased lateral diameter of the medulla oblongata is contributed to a great extent by the **restiform bodies.** These are the inferior cerebellar peduncles (crura cerebelli ad medullam oblongatam) and contain the majority of the ascending fibres, which associate the cerebellum with the structures below it.

In toto, the restiform bodies are much larger than could be formed by the combined cerebellar fasciculi of the spinal cord, their great size being due to their receiving numerous axones coursing in both directions, which connect the cerebellum with structures contained in the medulla oblongata alone, so that in the medulla they increase as they approach the cerebellum. Their mesial borders form the lateral boundaries of the fourth ventricle. Their name (*restiform*, meaning rope-like) was suggested from the appearance frequently given them by the fibres of the cochlear (acoustic division of the eighth) nerve, which course around their lateral periphery to become the *striæ medullares* in the floor of the fourth ventricle.

FIG. 630.—DIAGRAM SHOWING THE DECUSSATION OF THE PYRAMIDS. The uppermost level represented is near the inferior border of the pons.

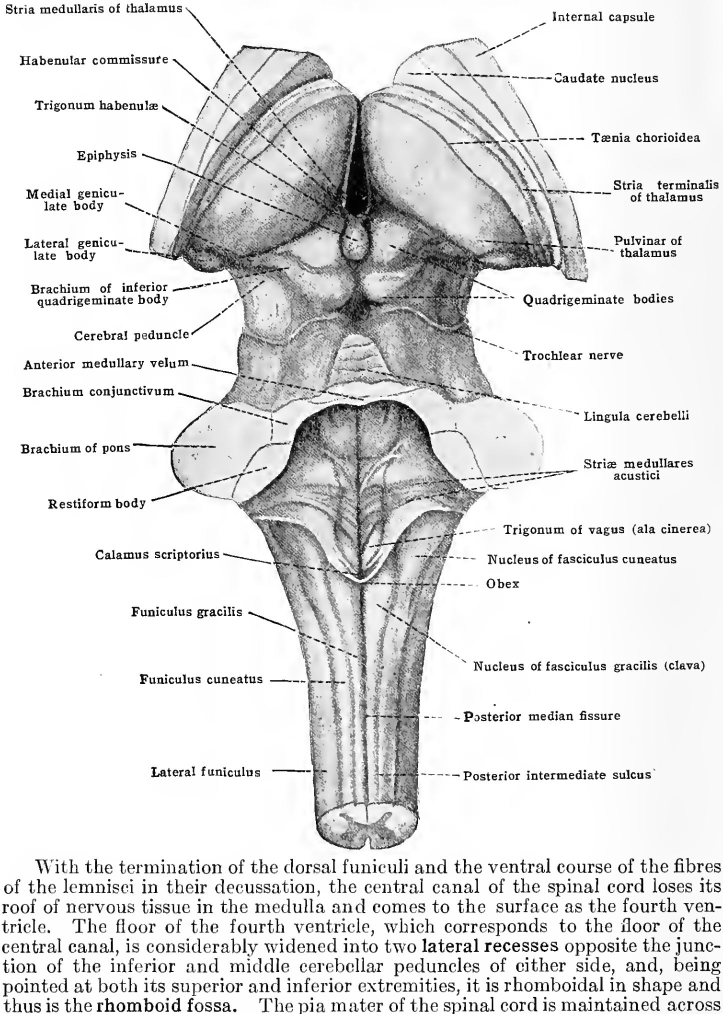


Upon removal of the cerebellum it may be seen that below the *calamus scriptorius* (inferior terminus of the fourth ventricle) the structures manifest in the dorsal surface of the medulla are directly continuous with those of the spinal cord. The fasciculus gracilis (Goll's column) of the spinal cord acquires a greater height and volume and becomes the **funiculus gracilis** of the medulla, and because of this increased height the posterior median sulcus of the cord becomes deepened into the **posterior median fissure.** The posterior intermediate sulcus is also accentuated by the fasciculus cuneatus (Burdach's column) likewise now enlarged into the **funiculus cuneatus** of the medulla. The lateral funiculus of the medulla, of course, does not contain the lateral or crossed pyramidal tract present in the spinal cord.

At the border of the calamus scriptorius the funiculus gracilis terminates in a slight elevation, the **clava**, which is the superficial indication of the **nucleus of the fasciculus gracilis.** Beginning somewhat more anteriorly, and having a somewhat greater length, is a similar enlargement of the funiculus cuneatus, the **tuberculum cuneatum** or **nucleus of the fasciculus cuneatus.**

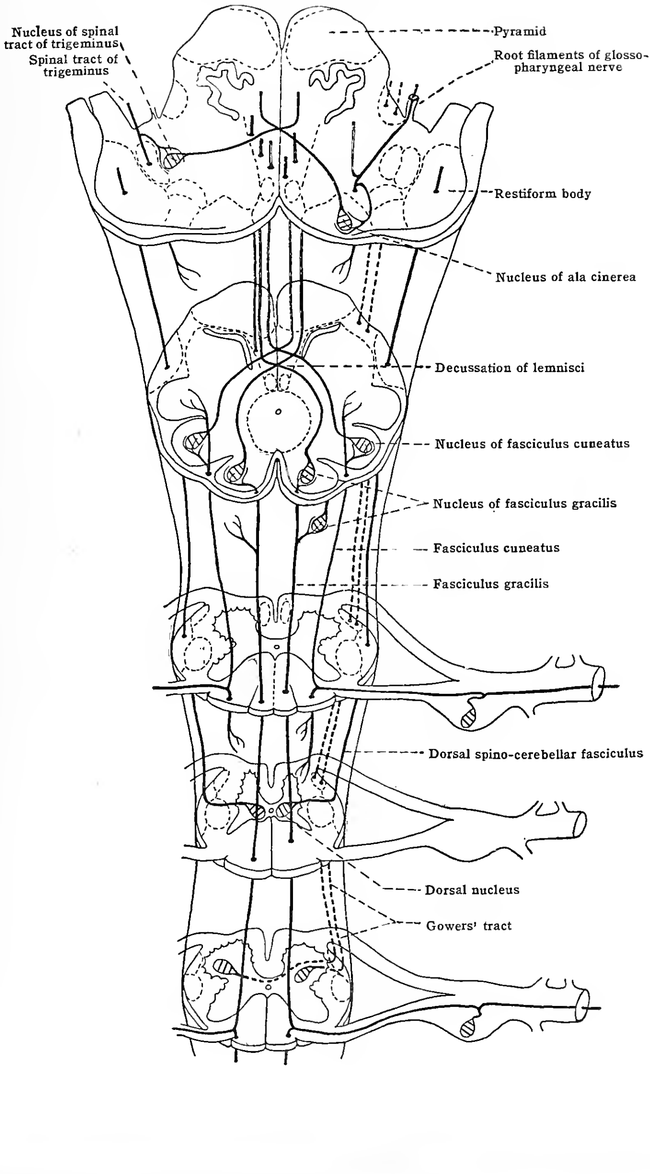
These nuclei are the groups of nerve cell-bodies about which the ascending or sensory axones of the respective fasciculi terminate or where the sensory impulses are transferred to a second neurone in their course to the structures of the encephalon. These cell-bodies in their turn give off axones which immediately cross the mid-line and assume a more ventral position, contributing largely to the *lemniscus* or fillet of the opposite side, and thus such axones are the encephalic continuation of the central sensory pathway conveying impulses from the periphery of one side of the body to the opposite side of the cerebrum. The crossing of these axones is known as the *decussation of the lemnisci.*

Fig. 631.—Dorsal Aspect of Medulla Oblongata and Mesencephalon, Showing the Floor of the Fourth Ventricle (Rhomboid Fossa). (Modified from Spalteholz.)



With the termination of the dorsal funiculi and the ventral course of the fibres of the lemnisci in their decussation, the central canal of the spinal cord loses its roof of nervous tissue in the medulla and comes to the surface as the fourth ventricle. The floor of the fourth ventricle, which corresponds to the floor of the central canal, is considerably widened into two **lateral recesses** opposite the junction of the inferior and middle cerebellar peduncles of either side, and, being pointed at both its superior and inferior extremities, it is rhomboidal in shape and thus is the **rhomboid fossa.** The pia mater of the spinal cord is maintained across the tip of the calamus scriptorius to form the **obex,** a small, semilunar lamina roofing over the immediate opening of the central canal. The obex carries a few medullated commissural fibres.

FIG. 632.—DIAGRAM OF THE SPINO-CEREBELLAR FASCICULI AND THE ORIGIN AND DECUSSATION OF THE LEMNISCI.



2. THE PONS

The **pons** (**Varoli**) is, for the most part, a great commissure or 'bridge' of white substance coursing about the ventral aspect of the brain-stem, and connecting the cerebellar hemisphere of one side with that of the other. In addition it contains fibres passing both to and from the structures of the brain-stem and the grey substance of the cerebellum, and fibres descending from the cerebral cortex. Each of its lateral halves forms the middle of the three cerebellar peduncles, the *brachium pontis* of either side.

In size it naturally varies directly with the development of the cerebellum, both in a given animal and relatively throughout the animal series. In man it attains its greatest relative size, and possesses a median or **basilar sulcus** in which lies the basilar artery. Its sagittal dimension varies from 25 to 30 mm., while its transverse dimension (longitudinal with the course of its fibres) is somewhat greater. It is a rounded white prominence interposed between the visible portion of the cerebral peduncles (crura) above and the medulla oblongata below. Its *inferior margin* is rounded to form the **inferior pontine sulcus,** which, between the points of the emergence of the pyramids, is continuous with and transverse to the foramen cæcum. Its *superior margin* is thicker and is rounded to form the **superior pontine sulcus,** which, between the cerebral peduncles, is continuous with and transverse to the interpeduncular fossa. (See fig. 629.) It is bilaterally symmetrical. The ventro-lateral bulgings of its sides (and, therefore, the basilar sulcus) are produced by the passage through it of the fibres of the cerebral peduncles from above, to reappear as the pyramids below. Its ventral surface rests upon the basilar process of the occipital bone and the dorsum sellæ of the sphenoid, while its lateral surfaces are adjacent to the posterior parts of the petrous portions of the temporal bones.

The fibres of the thicker superior portion of the pons (*fasciculus superior pontis*) course obliquely downward to their entrance into the brachium of the pons and the cerebellar hemisphere; those of the lower and mid-portions (*fasciculus medius pontis*) course more transversely, naturally converging upon approaching the cerebellum. Certain fibres of the upper mid-portion course at first transversely and then turn abruptly downward across the fibres above them, to join the inferior portion of the brachium pontis. This bundle is termed the **oblique fasciculus** (fig. 629). The *trigeminus* or fifth cranial nerve penetrates the superior lateral portion of each brachium pontis near the point of the downward turn of the oblique fasciculus; its large afferent root and the masticator nerve (its small efferent root) accompany each other quite closely. On either side of the basal surface of the pons usually may be seen a small bundle of fibres which begins in the interpeduncular fossa, near or in the sulcus of the oculomotor nerve. It passes laterally along or under the superior border of the pons, loses some of its fibres in the lateral sulcus of the mesencephalon, then runs inferiorly between the superior cerebellar peduncle and the brachium of the pons to disappear in the junction of these. Being sometimes double, it is known as the **lateral filaments of the pons** (*fila lateralia pontis* or *tænia pontis*). The location of the cell-bodies giving origin to it is uncertain.

That portion of the rhombencephalon overlying the pons and forming the floor of the fourth ventricle is not really a part of the pons at all. It is merely a continuation of the brain-stem from the medulla below to the structures above. Therefore on the *dorsal surface* there is no line of demarcation between the pons and medulla below or between the pons and isthmus above. The fibres of the trigeminus and masticator nerve pass through the pontine fibres to and from their nuclei in the brain-stem.

3. THE CEREBELLUM

The **cerebellum** or *hind brain* is the largest portion of the rhombencephalon. It lies in the posterior or cerebellar fossa of the cranium, and dorsal to the pons and medulla oblongata, overhanging the latter. It fits under the occipital lobes of the cerebral hemispheres, from which it is separated by a strong duplication of the inner layer of the dura mater, the *tentorium cerebelli.*

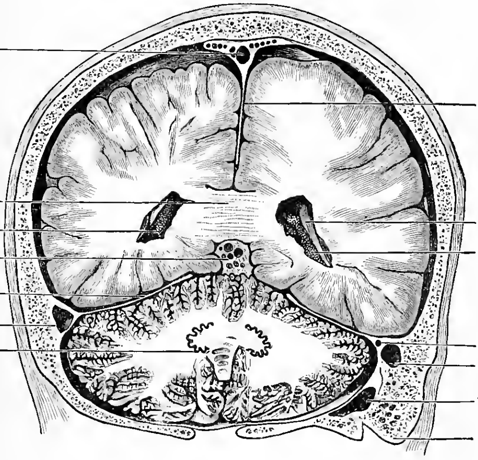
Its greatest diameter lies transversely, and its average weight, exclusive of the dura mater, is about 140 gm., or about 10 per cent. of the entire encephalon. It varies in development with the cerebrum, and, like it, averages larger in the male. It is relatively larger in adults than in children. Its development begins as a thickening of the anterior portion of the roof (dorsal zone) of the posterior of the three primary brain vesicles. Resting upon the brain-stem, it roofs over the fourth ventricle and is connected with the structures anterior, below, and posterior to it by its three pairs of peduncles.

The surface of the cerebellum is thrown into numerous narrow folia or **gyri,** which in the given localities run more or less parallel with each other. They are separated by narrow but relatively deep **sulci.** Unlike the spinal cord and medulla, in which the grey substance is centrally placed and surrounded by a mantle of white substance, the surface of the cerebellum is itself a cortex of grey substance, the *cortical substance* [substantia corticalis], enclosing a core of white substance, the *medullary* body [corpus medullare]. However, within this central core of white substance are situated definite grey masses, the *nuclei* of the cre bellum.

The **gross divisions** of the cerebellum are three: the two larger lateral portions, the **hemispheres,** and between these the smaller central portion, the **vermis.** The demarcation between these gross divisions is not very evident from the dorsal surface, because the hemispheres in their extraordinary development in man encroach upon the vermis, and, being pressed under the overlapping occipital ends of the cerebral hemispheres, they become partially fused upon the vermis

Fig. 633.—Section of Head Passing Through the Mastoid Processes of the Temporal Bones and Behind the Medulla Oblongata. Showing the Position of the Cerebellum.

(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



along the dorsal mid-line. Though differentiated simultaneously with the cerebellar hemispheres in the human fœtus, in most of the mammalia the vermis is the largest and most evident of the parts, and it is practically the only part which exists in the fishes, reptiles, and birds. In man, owing to the fact that the vermis does not keep pace in development with the hemispheres, there results a very decided notch between the two hemispheres along the line of the entire ventral and inferior aspect of the cerebellum, the floor of this notch being the surface of the vermis. The inferior portion of the notch is the **posterior cerebellar notch** (incisura marsupialis); its prolongation above is wider than below, and is termed the **superior cerebellar notch.** It is occupied by a fold of the dura mater, the falx cerebelli. With the variations in contour of the cerebellum, certain of its sulci are broader and deeper, and merit the name **fissures.** These are more or less definitely placed, and subdivide the hemispheres into **lobes** and the vermis (the median lobe) into **lobules.**

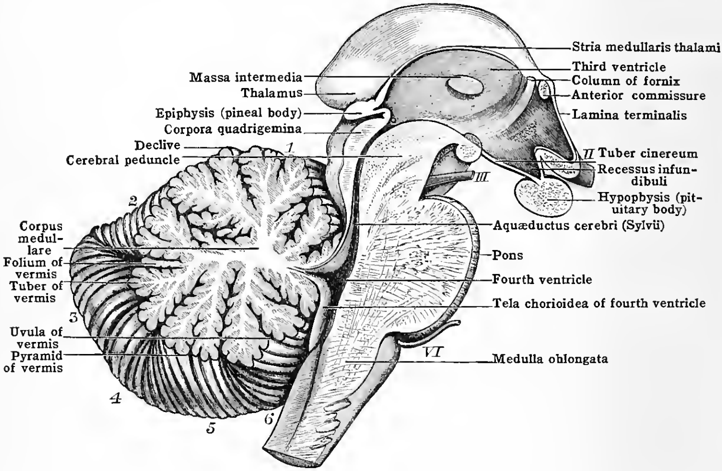
Superior surface.—The superior surface is bounded from the inferior surface by the **horizontal fissure** (fig. 635) which extends ventrolaterally, to the entrance of the brachium of the pons. Between this and the extreme anterior border of the dorsal surface are two other fissures, the **posterior** and **anterior semilunar fissures.** These, like the horizontal fissure, may be traced, with slight interruptions, across the mid-line, and consequently mark off not only the two hemispheres but also the vermis into corresponding divisions.

The **superior semilunar lobe** [lobulus semilunaris superior] (postero-superior lobe) of each hemisphere lies between the horizontal and the posterior semilunar fissures. It largely composes the outer border of the cerebellum, and, therefore, is the longest of the lobes.

The adjacent surface of the hemispheres, because of the frequently less complete development of the anterior semilunar fissure, is sometimes referred to as the **quadrangular lobe,** with its *posterior* and its *anterior portions.* On the other hand, especially when the anterior semilunar fissure is well marked, this area may be divided into—(1) the *posterior semilunar lobe,* between the posterior and anterior semilunar fissures, and (2) the *anterior semilunar lobe,* anterior to the anterior semilunar fissure (fig. 635).

Anterior to the quadrangular lobe on each hemisphere is the **ala of the central lobule,** bounded by the postcentral and the precentral sulcus. Anterior to this, on the anterior margin of the hemisphere, is the **vinculum lingulae,** a slender process continuous with the lingula of the vermis (fig. 658).

Fig. 634.—Median Section Through Cerebellum and Brain-stem. (Allen Thompson, after Reichert.)
1. culmen monticuli; 2, superior semilunar lobe; 3, inferior semilunar lobe; 4, slender lobe; 5, biventral lobe; 6, tonsil.



The superior aspect of the vermis, the **superior vermis,** because of the fusion of the hemispheres, is, for the most part, a slight ridge, the **monticulus** (fig. 635), instead of a depression. However, in the posterior portion of the dorsal surface the depression of the posterior notch begins, and here the horizontal and the posterior semilunar fissures approach each other so closely that the corresponding subdivision of the vermis is seldom more than a single folium, the **folium vermis** (*cacuminis*).

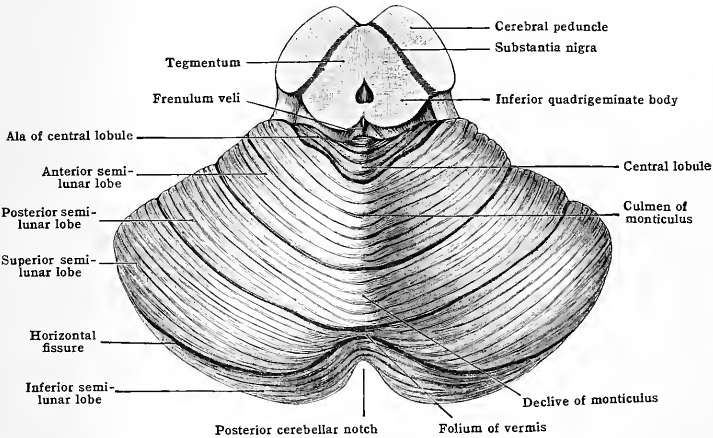
The monticulus proper is divided into an inferior lobule, the **declive,** and a superior lobule, the **culmen.** These appear as continuations across the midline of the posterior and anterior semilunar lobes of the hemispheres, and are separated by the corresponding fissures (fig. 635).

At the extreme anterior part of the superior surface and in the bottom of the anterior cerebellar notch lies a more definitely defined portion of the vermis. This is the **central lobule** (fig. 635). It is broadened laterally into two pointed wings, the *alæ* of the central lobule, the folia of which, if present, are parallel with those of the anterior semilunar lobes and separated from them by the **postcentral sulcus.**

If the anterior margin of the central lobule be lifted, the **lingula cerebelli** (*lingula vermis*) will appear separated from the central lobule by the **pre-central sulcus.** It is a thin, tongue-like anterior projection of the cortical substance comprising four to eight folia adhering upon the *anterior medullary velum,* the roof of the superior portion of the fourth ventricle.

Inferior surface.—The three cerebellar peduncles of each side join to form a single mass of white substance, and enter the ventral aspect of each hemisphere at the medial and ventral extremity of the horizontal fissure. The inferior surface of the cerebellum is less convex than the superior surface. The hemispheres are decidedly separated by a continuation of the posterior cerebellar notch, which becomes broader, the **vallecula of the cerebellum,** which contains the inferior portion of the vermis, **vermis inferior,** and whose margins embrace the medulla oblongata. The inferior surfaces of the hemispheres are each divided by the intervening fissures into four lobes (fig. 636).

Fig. 635.—Diagram of the Superior Surface of the Cerebellum.



Below, the **inferior semilunar lobe** (postero-inferior lobe) is separated from the superior semilunar lobe of the superior surface by the horizontal fissure. It is the largest of the inferior lobes, and is broader at its medial extremity. Frequently two and sometimes three of its curved sulci appear deeper than others, and separate it into two or three **slender lobules** [lobuli graciles]. More commonly there are two of these, the *lobulus gracilis posterior* and *lobulus gracilis anterior,* separated by the *postero-inferior sulcus.*

The **biventral lobe** is smaller and more curved than the inferior semilunar lobe, from the anterior margin of which it is separated by the curved **antero-inferior sulcus.** Its medial extremity is pointed and does not extend to the vermis; its lateral extremity is broader and curves anteriorly to the ventral extremity of the horizontal fissure—the line of outer termination of the inferior semilunar lobe.

The **tonsil** [tonsilla cerebelli] (*amygdala*) is a rounded, triangular mass, placed mesially within the inner curvature of the biventral lobe, and separated from it by the **retrotonsillar fissure.** Its inferior mesial border slightly overlaps the vermis.

The smallest of the lobes is the **flocculus.** It lies adjacent to the inferior and lateral surface of the mass of white substance produced by the confluence of the three cerebellar peduncles, and extends into the mesial extremity of the horizontal fissure. It is so flattened that its short folia give it the appearance suggesting its name. Occasionally there is added a second, less perfectly formed portion, the *secondary flocculus.* From each floccular lobe there passes toward the midline a thin band of white substance, the **peduncle of the flocculus;** these extend to meet each other at the most anterior portion of the inferior vermis, and thus form the narrow **posterior medullary velum.**

The **inferior vermis** (figs. 634, 636) is more definitely demarcated than the superior. Lying in the floor of the vallecula cerebelli, it is separated on each side from the adjacent lobes of the hemispheres by a well-marked sulcus about it, the *nidus avis.* By contour and by deeper transverse fissures (sulci) occurring at intervals across it, four divisions or lobules of the inferior vermis are recognised. These lobules, like those of the superior vermis, are each in intimate relation with the pair of lobes of the hemispheres adjacent to it on either side.

1. The **tuber vermis** is adjacent to the folium vermis of the superior aspect, and thus is the most inferior lobule of the inferior vermis. It is a short, somewhat pyramidal-shaped division, whose four or five transversely arranged folia are continuous with the folia of the inferior semilunar lobes on either side.

2. The **pyramid** is separated from the tuber vermis by the *post-pyramidal sulcus.* Its several folia cross the vallecula cerebelli and curve to connect with the biventral lobes on either side.

3. The **uvulva** is separated from the pyramid by the *prepyramidal sulcus.* It is triangular in shape. Its base or broader inferior portion appears as two laterally projecting ridges of grey substance, the **furrowed bands** or *alæ uvulæ,* which extend across the floor of the nidus avis and under the mesial margins of the tonsils on either side. In these bands its folia curve and become continuous with the tonsils. The uvula and the two tonsils are sometimes referred to collectively as the *uvular lobe.*

4. The **nodule** is the smallest and most anterior division of the inferior vermis. It is separated from the uvula by the **post-nodular sulcus,** and is closely associated anteriorly with the posterior medullary velum, the transverse continuation of the peduncles of the floccular lobes.

Summary of External Features of Cerebellum

Superior Surface.

Hemisphere		Vermis	
	Anterior border—Anterior medullary velum—Anterior border		
Vinculum of Lingula		*Lingula*

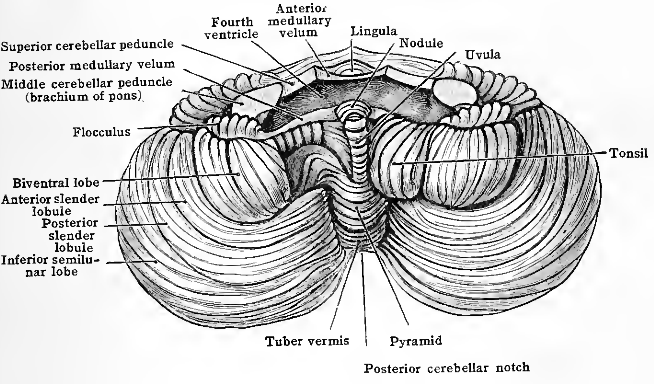
Internal structure of the cerebellum (fig. 637).—The white substance of the cerebellum is continuous with its peduncles and forms a compact central mass. Over the surface of this the grey substance or cortex is spread in a thin but uniform and much folded layer. Upon section of the cerebellum certain of the sulci as well as the fissures are shown to be much deeper than is apparent from the surface. The deeper sulci separate the lobes into divisions, the **medullary laminæ,** each of which is composed of a number of folia and each of which has its own core of white substance. The folia of the laminæ line the sulci (and fissures), and also comprise their surface aspect, and are separated by the shallow, *secondary sulci.* The larger laminæ are subdivided into from two to four secondary laminæ of varying size. Such subdivision is especially marked in the vermis. Here each lamina comprises a lobule and is, therefore, separated by a fissure, and each lobule is usually subdivided with the exception of the nodule, the folium, and the lingula. In sagittal sections, or sections transverse to the general direction of the sulci, this arrangement of the laminæ gives a foliate appearance, which, especially in sagittal sections of the vermis, is termed the **arbor vitæ** (see fig. 634).

The **cerebellar cortex** consists of three layers and contains four general types of cell-bodies of neurones, all of which possess features peculiar to the cerebellum.

The outermost or **molecular** layer contains small **stellate cells**, "basket cells," with relatively long dendrites. These serve to associate the different portions of a given folium. The axones of the largest of them give off branches which form pericellular baskets about the bodies of the *cells of Purkinje*, each axone contributing to several baskets. The layer of **Purkinje cells**, or the middle layer, is quite thin. The bodies of the cells of Purkinje are arranged in a single layer, and their elaborate systems of dendrites extend throughout and largely compose the molecular layer. The dendrites of these, the most essential cells of the cortex, are displayed in the form of arborescent fans (see fig. 604), arranged parallel with each other and transverse

FIG. 636.—DIAGRAM OF THE INFERIOR SURFACE OF THE CEREBELLUM AFTER THE REMOVAL OF THE MEDULLA OBLONGATA, PONS, AND MESENCEPHALON.

The tonsil of the right side is omitted in order to display the connection of the pyramid with the biventral lobe, the furrowed band of the uvula, and more fully the posterior medullary velum. The anterior notch is less evident than in the actual specimen.



to the long axis of the folium containing them. Their axones are given off from the base of the cell-body and acquire their medullary sheaths quite close to the cell-body, and, after giving off several collaterals in the inner layer, pass into the general white substance and thence to other laminæ or lobes. Certain of them go to structures outside the cerebellum. The inner layer is the **granular layer**. It contains numerous small nerve-cells or "granule-cells" which possess from two to five radiating dendrites, unbranched except at their termination, which occurs suddenly in the form of three to six claw-like twigs. Their axones are given off either from the cell-body direct or more often from the base of one of the dendrites, and pass outward into the molecular layer, where they bifurcate and course in both directions parallel to the long axis of the folium, to become associated with the dendrites of the cells of Purkinje. In the layer of the cells of Purkinje there is situated at intervals a neurone of the Golgi type II (see fig. 604). The short, elaborately branched axone of this neurone is distributed among the cells of the granular layer. Axones conveying impulses to the cerebellar cortex terminate in the granular layer as '*moss fibres*,' or directly upon the cells of Purkinje as '*climbing fibres*,' and probably upon the cells of the Golgi type II.

Thus the neurones which receive impulses coming to the cortex are the cells of Purkinje, probably the Golgi cells of type II, and the granule-cells; those which distribute these impulses to other neurones of the folium are the Golgi cells of type II, the granule-cells, and the basket-cells (association neurones), and the collaterals of the cells of Purkinje. Impulses are conveyed from the cortex of a folium to that of other folia, lamina, lobules or lobes, or to the nuclei of the cerebellum, or to structures outside the cerebellum by the axones of the cells of Purkinje.

The **nuclei of the cerebellum** (fig. 637) are in its central core of white substance. They are four in number, and all are paired, those of each pair being situated opposite each other on either side of the mid-line.

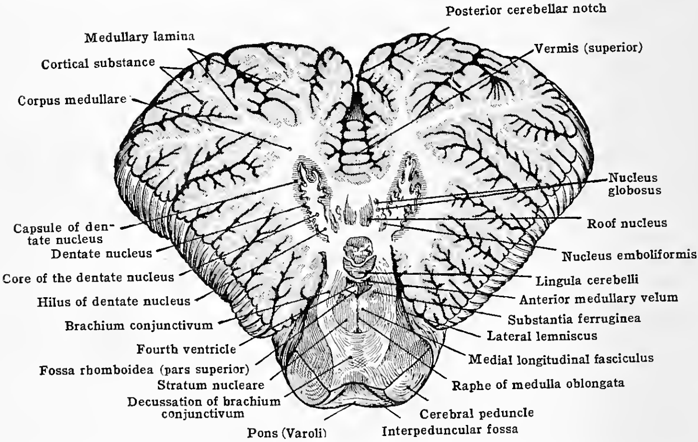
1. The largest of them is the **dentate nucleus.** This is an isolated mass of grey substance situated in the core of white substance of each hemisphere. It is in the form of a folded or corrugated cup-shaped lamina, with the opening of the cup (*hilus*) directed anteriorly and obliquely toward the mid-line. It contains a mass of white substance and possesses a capsule. Its cell-bodies give rise to most of the fibres forming the superior cerebellar peduncles.

2. The **nucleus emboliformis** is an oblong and much smaller mass of grey substance, which lies immediately medial to the hilus of the dentate nucleus. It is probably of the same significance as the dentate nucleus, being merely a portion separated from it.

3. The **nucleus globosus,** the smallest of the cerebellar nuclei, is an irregular horizontal mass of grey substance with its larger end placed in front. It lies close to the medial side of the nucleus emboliformis, and often appears separated into two or more rounded or globular masses.

4. The **roof nucleus** [nucleus fastigii] is the second largest of the cerebellar nuclei, and is the most mesially placed. The pair is situated in the roof of the

Fig. 637.—Section of Cerebellum and Brain-stem Passing Obliquely Through Inferior Portion of Cerebellum to Superior Margin of Pons. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



fourth ventricle, and so near the mid-line that both nuclei are in the white substance of the vermis. They are ovoid in shape, and the nucleus of one side receives axones from the nucleus of the vestibular nerve chiefly of the opposite side, the decussation of these axones taking place in the vermis. Its cells are larger than those of the two first-mentioned nuclei.

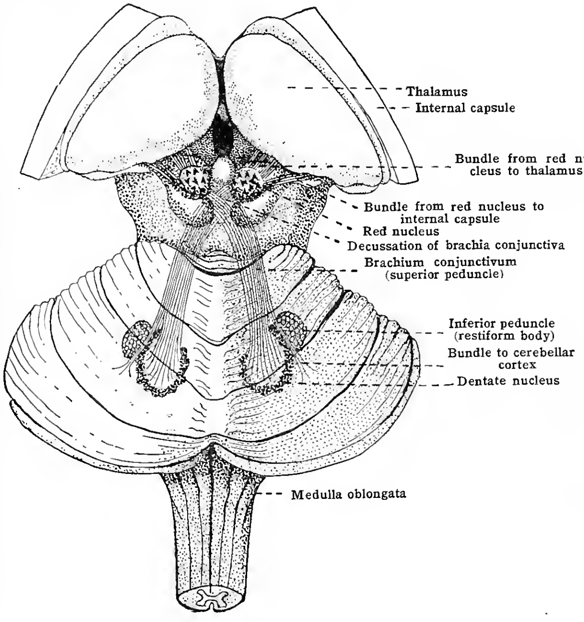
The peduncles of the cerebellum.—The peduncles consist of three pairs—the inferior, middle, and superior. The three peduncles of each side come together at the level of the lower border of the pons, and the entering and emerging fibres of which they are composed become continuous with the central core of white substance of the cerebellar hemispheres. (Fig. 631, 638, 639.)

The **restiform body** of the medulla oblongata is the inferior peduncle. It forms the lateral boundary of the inferior portion of the fourth ventricle, and upon reaching the level of the pons turns sharply backward into the cerebellum. In the region of the turn it is encircled externally by fibres of the cochlear nerve. It contains fibres, both ascending and descending, between the cerebellar cortex and the structures below the cerebellum.

Its fibres include: (1) fibres from the spinal cord including the dorsal spino-cerebellar fasciculus (direct cerebellar tract) and probably a small proportion of the ascending fibres of the superficial ventro-lateral spino-cerebellar fasciculus (Gowers' tract); (2) fibres from the olive of the same and opposite side of the medulla oblongata; (3) fibres from the nuclei of the funiculus gracilis and cuneatus of the same and opposite sides; (4) fibres to and from the olive of the opposite side; (5) fibres to the nuclei of the motor cranial nerves; (6) fibres descending to the ventral horn cells of the spinal cord. The ascending or afferent fibres of the spino-cerebellar and cerebello-olivary fasciculi are the principal components of the inferior peduncle; the existence of fibres (5) and (6) is not well established. Of these, the fibres of the direct cerebellar tract terminate in the cortex of the superior vermis of both sides of the mid-line, but, for the most part, in that of the same side. The olivary fibres end in the cortex of both the superior vermis and the adjacent cortex of the hemispheres, and some of them terminate in the nucleus dentatus.

The **brachium pontis** or the middle peduncle is the largest of the three cerebellar peduncles. In it the pons fibres pass slightly downward and into the cerebellar hemisphere, between the lips of the anterior part of the horizontal fissure, entering lateral to the inferior peduncle.

Fig. 638.—Transparency Drawing Showing the Origin, Course, and Connections of the Superior Cerebellar Peduncles (Brachia Conjunctiva) in the Formation of 'Stilling's Scissors.'



It consists of the transverse fibres of the pons, and within the cerebellum its fibres are distributed in two main groups—the upper transverse fibres of the pons apparently pass downward to radiate in the lower portion of the hemisphere, while the lower transverse fibres pass upward and medialward to radiate in the superior part of the hemisphere and vermis. For the most part the fibres of the middle peduncle may be considered as commissural fibres, passing from one side of the cerebellum to the other. Each peduncle contains fibres coursing in opposite directions. Many of these fibres are interrupted in their course to the opposite side by cells scattered throughout the pons, *nuclei of the pons*, and, therefore, in each brachium pontis some of the fibres are processes of the cells of the cerebellum and course toward the opposite side, while others are processes of the cells of the pontine nuclei and course to the cerebellar hemisphere of the same side. Many cell-bodies of the nuclei of the pons whose axones terminate in the cerebellum receive impulses from fibres descending from the *cerebral* cortex of the opposite side—*cortico-pontine fibres*. Furthermore, there are evidences after degeneration that the brachium pontis also contains a few fibres from the cerebellum to the structures of the brain-stem and spinal cord.

The **brachium conjunctivum** or superior cerebellar peduncle emerges from the cerebellum on the medial side of the brachium pontis and also on the superior and medial side of the course of the restiform body. It forms the lateral boundary of the superior portion of the fourth ventricle and is the cerebello-cerebral peduncle. Its transverse section appears semilunar in shape, with the concave side next to the cavity of the ventricle. The medial border, which inclines toward the mid-line, is connected with that of the corresponding peduncle of the opposite side by the *anterior medullary velum,* which thus roofs over the superior part of the fourth ventricle. The lateral border is distinguished from the pons by an open furrow or lateral sulcus.

The superior cerebellar peduncles are almost entirely efferent pathways as to the cerebellum and form the chief connections between the cerebellum and the cerebrum. They arise almost wholly from the dentate nuclei. As they course forward they slightly converge and disappear under the inferior quadrigeminate bodies. Here, in the tegmentum of the mesencephalon, they undergo an almost total decussation, and then the majority of the fibres of each peduncle, having thus crossed the mid-line, terminate in the *red nucleus* of the opposite side. The red, nucleus lies in the tegmentum of the mesencephalon, below the superior quadrigeminate bodies, and therefore quite close to the decussation. The cells of the red nucleus, about which the fibres of the peduncle terminate, in their turn send processes (axones) into (1) the rubro-spinal tract of the spinal cord and (2) into the prosencephalon, most of which latter terminate in the thalamus whose cell-bodies give fibres to the cerebral cortex by way of the internal capsule; but some pass from the red nucleus under the thalamus to join the internal capsule.

In addition to the fibres having the origin and course described above, and which constitute the greater mass of the superior cerebellar peduncle, each peduncle is said to contain fibres which—(1) arise in the cerebellar cortex of the same and opposite sides of the mid-line, instead of from the dentate nucleus, and which join the peduncle at the side of the dentate nucleus, between it and the restiform body; (2) fibres which do not cross the mid-line in the decussation, but terminate in the red nucleus of the same side; (3) some fibres are not interrupted in the red nucleus, but pass directly into the thalamus; (4) a small proportion of fibres afferent as to the cerebellum, which arise in the structures of the cerebrum and pass in to the cerebellum; and (5) the greater part, if not all, of the ascending fibres of the superficial ventro-lateral spino-cerebellar fasciculus (Gowers' tract) of the spinal cord. The latter, instead of entering the cerebellum by way of the restiform body, are deflected in the upper medulla and pass in the lateral tegmentum of the pons to the anterior medullary velum, where they turn backward to enter the cerebellum in its superior peduncle and pass to its cortex, probably from the lateral side of the dentate nucleus (see fig. 656).

The anatomy of the fourth ventricle.—The fourth ventricle is rhomboidal in shape, being considerably widened at the level of the brachia pontis and pointed at each end. Its floor consists of a slight depression in the brain-stem, the *fossa rhomboidea,* and corresponds to the floor of the central canal. Its pointed inferior end, the **calamus scriptorius,** is directly continuous with the central canal, and its narrowed superior end is continued into the aquæductus cerebri (Sylvii) of the mesencephalon, which is nothing more than a resumption of the tubular form of the canal.

The entire cavity of the ventricle is lined with an epithelium which is continuous with the epithelium, or ependyma, of the central canal below and the aqueduct above. The entire ventricle involves the *isthmus of the rhombencephalon,* the *metencephalon* and a portion of the *medulla oblongata.* It is divided for study into an inferior, an intermediate and a superior part.

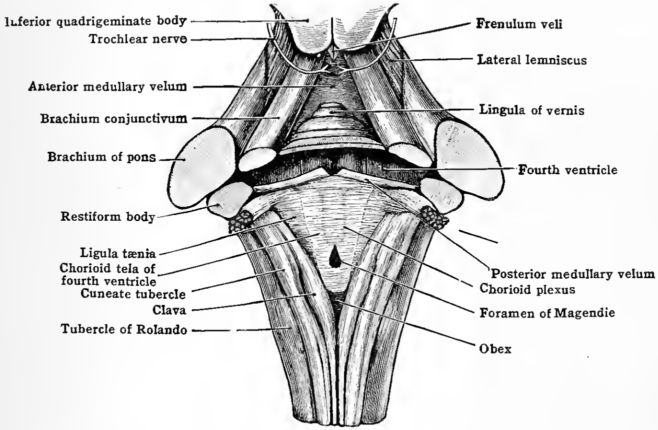
The *roof of the superior portion* of the fourth ventricle is nervous, consisting of a thin lamina of white substance, the *anterior* (superior) *medullary velum,* thickened at the sides by the brachia conjunctiva. At its extreme mesencephalic end (in the isthmus of the rhombencephalon) the anterior medullary velum is slightly thickened by a continuation of the white substance of the inferior quadrigeminate bodies, forming the **frenulum veli.** The inferior portion of the velum is continuous with the white substance of the cerebellum, and is covered by the lingula cerebelli, an extension of the cortical substance of the superior vermis (fig. 631).

The *roof of the intermediate portion* of the fourth ventricle is formed by the cerebellum proper, the vermis and the mesial portions of the hemispheres. The nervous portion of the roof terminates with the *posterior* (inferior) *medullary velum,* a thin, narrow band of white substance which is the continuation of the peduncles of the floccular lobes, and which connects them at the mid-line with the nodule of the inferior vermis.

The *roof of the inferior portion* of the fourth ventricle is non-nervous. It is the **chorioid tela** of the fourth ventricle, a semilunar lamina consisting of the epithelial lining of the ventricle, reinforced by a continuation of the connective tissue of the pia mater and the adjacent portion of the arachnoid. Along the line of its attachment to the surface of the medulla it is thickened, and in sections this portion bears the name **ligula** (*tænia ventriculi quarti*). The thickest portion spans the tip of the calamus scriptorius and is termed the **obex.** The width of the ventricular cavity is extended laterally from its widest part into the *lateral recesses*, narrow pockets on each side and around the upper parts of the restiform bodies. In the mid-line of the lower part of the chorioid tela there is a more or less well-marked opening, the *foramen of Magendie* (medial aperture of the fourth ventricle), which is a lymph-channel connecting the cavity of the ventricle with the subarachnoid space. There is a similar opening from each lateral recess (*lateral apertures of Key and Retzius*).

The *chorioid plexuses* of the fourth ventricle consist of highly vascular, lobular, villus-like processes of the ventricular lining (and pia-mater) of the chorioid tela. They are reddish in the fresh specimen, and the epithelial lining of the ventricle is closely adapted to the unevennesses of their surfaces. From below they run as

Fig. 639.—Diagram of the Roof and Lateral Boundaries of the Fourth Ventricle. The trochlear nerve should be shown emerging from the lateral boundary of the frenulum veli.



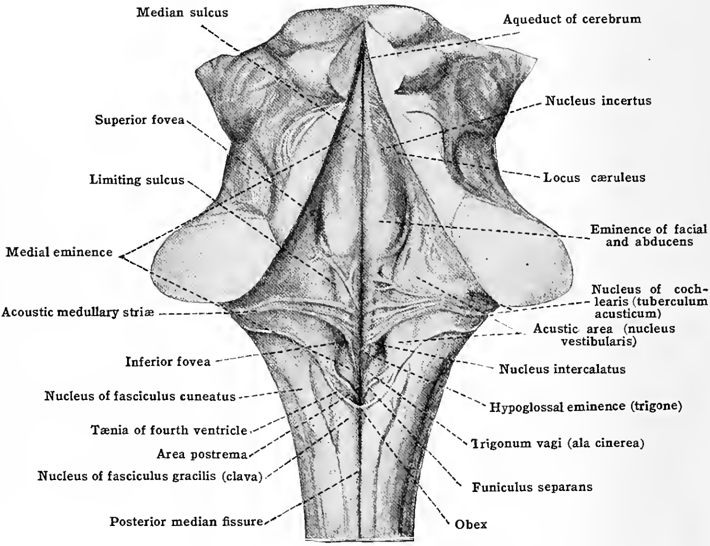
two parallel masses on either side of the mid-line, which become united above, and then are separated again into two lateral processes which bend at right angles and project into the lateral recesses. Portions frequently protrude through the three openings of the ventricle into the subarachnoid space.

The floor of the fourth ventricle [fossa rhomboidea] (fig. 640).—This is thrown into eminences and depressions indicative of the internal structures of the brain-stem subjacent to it. Its *inferior portion* is the dorsal surface of the upper portion of the medulla oblongata; its *intermediate portion* is the dorsal surface of the pons region, while its *superior portion* belongs to the isthmus of the rhombencephalon. Its triangular lower extremity terminates as the opening of the central canal of the spinal cord. This portion is deepened at the obex and shows furrows which point downward and converge medialward, giving the appearance known as the **calamus scriptorius.** The mid-line of the floor is sharply distinguished by the well-marked **median sulcus,** which becomes shallower above than below. In the tip of the calamus scriptorius, immediately anterior to the obex, the median sulcus deepens to become continuous into the central canal. This terminal depression is known as the **ventricle of Arantius.** Throughout the length of the floor on either side of the median sulcus is a continuous ridge, the **medial eminence,** which is bounded laterally by the **limiting sulcus.** Underlying the floor of the ventricle is a layer of grey substance of varying thickness, which is continuous with that surrounding the central canal of the cord. The medial eminence is subdivided into portions of unequal width and elevation, and the limiting sulcus accordingly shows foveæ of different depths.

Beginning at the calamus scriptorius, the following areas of the floor of the fourth ventricle are usually distinguished (fig. 640):—

The **area postrema** of Retzius is a superficial vascular structure bounded inferiorly by the tænia and overlying the terminal portion of the nucleus of the fasciculus gracilis (clava) and a portion of the nucleus of termination of the vagus nerve. The **funiculus separans**, a short oblique fold of the floor, composed chiefly of neuroglia, separates the area postrema from the **ala cinerea** (*trigonum vagi*), which is an oblique, grey-coloured, wing-shaped eminence indicating the middle third of the nucleus of termination (recipient nucleus) of the vagus and glossopharyngeal nerves. At the superior extremity of the ala cinerea is a well-marked triangular depression of the limiting sulcus known as the **inferior fovea**. Mesial to and extending above the ala cinerea is a narrow triangular eminence lying close to the median sulcus, which represents the nucleus of origin of the hypoglossal nerve, the **hypoglossal eminence** [trigonum n. hypoglossi]. The lateral field of this eminence shows small oblique rugæ, giving it a "feathery" appearance, the **area plumiformis** of Retzius. The **nucleus intercalatus** of Van Gehuchten is a wedge-shaped portion very slightly demarcated from the hypoglossal eminence, and intercalated between it and the inferior fovea. This nucleus is considered by some observers as an inferior

Fig. 640.—Dorsal Surface of the Brain-stem Showing the Anatomy of the Floor of the Fourth Ventricle. (Modified from Spalteholz.)



medial extension of the nucleus of termination of the vestibular nerve (area acustica), but Streeter, who has made a detailed study of the floor of the fourth ventricle by means of serial sections, doubts that it is a part of this nucleus. It is much more probable that it supplies visceral efferent fibres to the vagus and is thus a continuation of the dorsal efferent nucleus of the vagus.

Superior to the inferior fovea, and crossing each half of the floor of the fourth ventricle, are the **acoustic striæ**. These are bundles of axones arising in the dorsal nuclei of termination of the cochlear or auditory nerve, which are situated in the lateral periphery of each restiform body. The bundles course around the dorsal periphery of the upper portion of the restiform body, then across each half of the floor of the ventricle to the median sulcus, in which they suddenly turn ventrally into the substance of the medulla oblongata, and in doing so they cross the mid-line to enter the substance of the opposite side. The striæ vary greatly in different individuals, both in the degree of their prominence and their direction. Sometimes no striæ are visible from the surface. Frequently a bundle may be discerned which courses obliquely upward and lateralward from the median sulcus to disappear in the floor further away from the mid-line and again, a bundle may depart from the transverse course before reaching the median sulcus. Such a bundle ascending is sometimes called *conductor sonorus*. The acoustic striæ cross the **acoustic area**. This is the flattened elevation which occupies the whole lateral portion of the intermediate portion of the floor of the ventricle, lateral to the limiting sulcus, and extends into the inferior portion lateral to the inferior fovea. It represents the subjacent nucleus of termination of the vestibular nerve. The dorsal and ventral nuclei of the cochlear nerve (*tuberculum acusticum*) are indicated by the ventro-lateral fullness in the contour of the restiform body. In many of the mammals they produce a well-marked protuberance.

In its superior portion the medial eminence occupies the greater part of the floor of the fourth ventricle, and in the upper part of the intermediate portion of the floor it presents a broader, well-marked, elongated elevation, the eminence of the facial and abducens or the **colliculus facialis.** This represents the mesially placed nucleus of origin of the abducens and the genu of the root of the facial nerve, which root courses around and above the nucleus of the abducens. The nucleus of the facial is too deeply situated to produce an eminence. Lateral to this eminence is a depression of the limiting sulcus, which overlies the mesial part of the region of the larger portion of the nucleus of termination of the trigeminus, and is the *fovea trigemini* or **superior fovea.** The strip of the floor above the superior fovea and lateral to the medial eminence often appears greyish blue or dark brown, owing to pigmented cells subjacent to it, and is known as the **locus cæruleus.** It also represents a portion of the nucleus of the trigeminus. The most superior portion of the medial eminence becomes narrow and lies close to the mid-line. The function of the underlying grey substance producing it is uncertain, and for this reason Streeter has named the elevation **nucleus incertus,** noting that by position it is closely related to the upper portion of the nucleus of the trigeminus.

Internal Structure of the Medulla Oblongata and Pons

The finer detail of the internal structure lies within the scope of microscopic rather than of gross anatomy. However, the significance and relations of certain of the more important and larger of the internal structures of the medulla and pons as observed in sections may be considered.

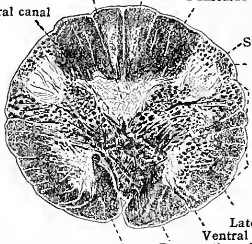
The entire brain-stem may be regarded as an upward continuation of the spinal cord, to which structures are added giving each part its peculiar character and conformation, and in which the structures characteristic of the spinal cord are modified in varying degrees.

The **pyramids,** the great descending or motor cerebro-spinal fasciculi, are directly continuous into the pyramidal fasciculi of the spinal cord. They form the extreme ventro-medial portion of the medulla, and from the fact that they contribute numerous fibres to the efferent nuclei (nuclei of origin) of the cranial nerves and to other portions of the grey substance of the brain-stem, they decrease appreciably in bulk in descending toward the spinal cord. Most of the fibres contributed to the medulla, as well as to other divisions of the brain-stem, decussate as they leave the pyramids, and terminate in the grey substance of the opposite side. However, the chief **decussation of the pyramids** occurs in the lower end of the medulla. Here usually about three-fourths of the fibres then comprising the pyramids cross the mid-line to form the lateral cerebro-spinal fasciculus (crossed pyramidal tract) of the spinal cord immediately below. The remaining fourth, comprising the more lateral fibres or those furthest away from the mid-line, continues uncrossed into the spinal cord as the ventral cerebro-spinal fasciculus or direct pyramidal tract. The majority of the latter fibres decussate gradually in the commissural bundle and in the ventral white commissure of the cord as they approach the levels of their termination. In practically all vertebrates except man and the apes there are no ventral pyramidal fasciculi, the decussation in the medulla being a total one. In man, the proportion of fibres crossing in the chief decussation varies. Cases have been noted in which apparently the entire pyramids decussate at this level. In other cases the direct or ventral pyramidal tract may be much larger than usual, at the expense of the lateral. The decussation usually appears to be symmetrical and it occurs so suddenly that the fibres, in coursing from the ventral to the lateral positions, detach the tips of the ventral horns of the spinal cord from the remainder of the grey figure, and these appear as isolated, irregularly shaped masses of grey substance in transverse sections of the medulla. From this level upward the outline of the grey figure of the cord is lost, and the cell-columns of the ventral horns occur in more or less detached groups as the motor nuclei of the cranial nerves.

The **origin and decussation of the lemnisci** (fillet) begins immediately above the decussation of the pyramids, and here the arrangements characteristic of the spinal cord are further modified. The dorsal portion of the grey figure of the cord is manifest up to this level, but here, after a considerable increase in its thickness, the grey commissure gives rise to two thick dorsal outgrowths on each side of the mid-line. These dorsal projections of grey substance comprise the nuclei of termination (relays) of the chief ascending or sensory spino-cerebral fasciculi of the spinal cord. The **nucleus of the fasciculus gracilis** (nucleus of Goll's column) arises a little before the **nucleus of the fasciculus cuneatus** (nucleus of Burdach's column). The former extends slightly downward from its point of origin, so that its inferior extremity is included in sections through the decussation of the pyramids (fig. 641). It produces a slight bulbous enlargement (the *clava*) of the end of the funiculus gracilis, while the nucleus of the fasciculus cuneatus corresponds to the *cuneate tubercle* of the external contour of the medulla (figs. 632, 640). From the cells of these nuclei arise the lemniscus—the cephalic continuation of the spino-cerebral pathway which conveys the general bodily sensations to the cerebrum. In passing out of the nuclei the fibres of the lemniscus course in a ventro-medial direction. Curving around the region of the central canal, they contribute largely to the **internal arcuate fibres,** then, sweeping across the mid-line, they convert it into the **raphe,** and immediately after crossing (decussating) they turn cephalad and collect to form the bundle known as the **lemniscus.**

In the medulla, the lemnisci are two thin bands of fibres spread vertically on each side of the raphe, with their lower or ventral edges thicker than their dorsal edges. In their course toward the cerebrum they increase in bulk, owing chiefly to fibres being added to them from the nuclei of termination of the afferent roots of the cranial nerves, which fibres likewise cross the mid-line as internal arcuate fibres to join the lemniscus of the opposite side. In passing through the pons, the lemnisci gradually become spread horizontally, and beyond the pons their then more lateral portions are further displaced and come to course in the lateral borders of the isthmus rhombencephali and mesencephalon, while the medial portions remain nearer the mid-line. This lateral spreading of each lemniscus produces the **lateral lemniscus** and the **medial lemniscus**, distinguished in transverse sections of the superior pons and mesencephalic

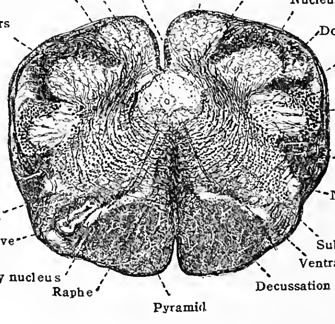
Fig. 641.—Transverse Section of Medulla Oblongata at the Level of the Decussation of the Pyramids.



regions of the brain stem (fig. 660). The lateral lemniscus is contributed very largely by the cell-bodies of the nuclei of termination of the cochlear nerve of the opposite side.

The **reticular formation** of the medulla and pons region is considerably more abundant than in the spinal cord. As in the spinal cord, it consists of grey substance through which nerve-fibres, singly and in small bundles, course in all directions, and more sparsely than in other regions. In the medulla it is traversed by the internal arcuate fibres. It may be con-

Fig. 642.—Transverse Section of Medulla Oblongata at Level of the Decussation of the Lemnisci.

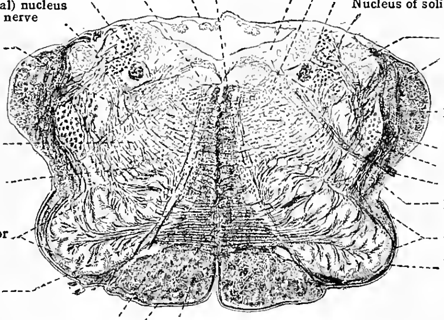


sidered an enlarged continuation of the middle portion of the grey column of the cord, dispersed by numerous fibres, giving it the reticulated appearance which suggests its name. Its numerous nerve-cells belong, for the most part, to the association and commissural systems of the brain stem, and, therefore, the fibres arising in it correspond largely to the fasciculi proprii of the spinal cord. As in the cord, most of the fibres are of short course, serving to associate different portions of the same level and adjacent levels with each other. Those of long course show a tendency to collect into a small, well-marked bundle which courses one on each side close to the mid-line, ventral to the central canal in the closed part of the medulla, and near the median sulcus of the floor of the fourth ventricle, in the open part. In the mesencephalon this bundle is again situated closely ventral to the aquæductus cerebri.

This bundle is known as the **medial longitudinal fasciculus** (posterior longitudinal bundle). It corresponds more nearly to the ventral fasciculus proprius of the spinal cord than to others of the fasciculi proprii. In the medulla it appears as the dorsal edge of the lemniscus, but in the shifting of the position of the lemniscus in the pons region, it retains its medial position and thus becomes isolated. By position it is especially adapted for the association of the nuclei of the cranial nerves. Evidence has been found that those fibres which arise in the corpora quadrigemina and descend the spinal cord in its sulco-marginal or ventral mesencephalo-spinal fasciculus, pass through the medulla in the medial longitudinal fasciculus. The nuclei of termination of the vestibular nerve are said also to contribute many fibres to it.

The **inferior olivary nucleus** is an added structure in the medulla oblongata, i. e., it has no homologue in the spinal cord. The two of them occupy the olivary prominences, *the olives* of the exterior, and constitute the most conspicuous and striking isolated masses of grey substance in sections of the medulla. They appear as crenated laminæ of grey substance folded so as to encup a dense mass of white substance, and in actual shape the entire nucleus has the form of an irregular corrugated cup with the opening or **hilus** on the side toward the midline. The mass is so crumpled that the diameter of the hilus is appreciably less than the length of the nucleus, and thus transverse sections of either extremity of it appear as closed capsules.

FIG. 643.—TRANSVERSE SECTION OF MEDULLA OBLONGATA THROUGH NUCLEI OF VAGUS AND HYPOGLOSSUS AND THROUGH THE MIDDLE OF THE OLIVES.



There are several small detached portions of the olivary nucleus known as the **accessory olivary nuclei.** These are named according to their position with reference to the chief portion or olive proper. They are plates less corrugated than the chief nucleus, and appear rod-like in sections. The largest is the *dorsal accessory olivary nucleus.* The *medial accessory olivary nucleus* is widest at its inferior end, which extends a little below the inferior extremity of the chief nucleus. The *lateral accessory olivary nucleus* is the smallest. In serial sections the accessory nuclei are found to be plates of grey substance usually continuous with one another.

The olivary nuclei are mainly cerebellar connections. By both ascending and descending fibres each cerebellar hemisphere is connected with the olivary nucleus of the same and opposite sides. Serial sections of a human brain with congenital absence of one cerebellar hemisphere, described by Strong, show that the chief connection of a hemisphere is with the olive of the opposite side. These fibres necessarily pass between the cerebellum and the olives by way of the restiform body, and, in so doing, form an obliquely coursing bundle in the lateral border of the medulla known as the **cerebello-olivary fibres** (fig. 643). The olivary nuclei also comprise a secondary relay between the spinal cord and the cerebellum by way of the spino-olivary fasciculus of the cervical cord, and it will be noted that they receive fibres from the thalami. The latter fibres, the **thalamo-olivary tract,** approach the olive at its lateral periphery, while upward through the brain-stem the tract courses in a more medial position. This tract comprises one of the cerebro-cerebellar paths. Arising in the thalamus and terminating in the olive, its impulses reach the opposite cerebellar hemisphere by way of the cerebello-olivary fibres.

The **arcuate fibres** are referred to as internal and external, according as they course dorsal or ventral to the inferior olivary nucleus.

The **internal arcuate fibres** comprise fibres destined for both the cerebellum and cerebrum, and also for the association of the tegmental grey substance of the two sides in which they course. Certain of the fibres passing between one restiform body (cerebellar hemisphere) and the olive of the opposite side course internal to the olive of the same side, and thus form the ventral portion of the internal arcuate fibres. As noted above, the internal arcuate fibres consist in greatest part of fibres being contributed to the lemnisci, arising from the cells of the nucleus of the fasciculus gracilis and fasciculus cuneatus and sweeping downward and decussating to form the lemniscus of the opposite side. However, all the fibres arising in these nuclei do not enter the lemniscus. A few of them cross the mid-line with the internal arcuates, but pass on to enter the restiform body (cerebellar hemisphere) of the opposite side. Some of these course ventrally and, upon approaching the olive of the opposite side, are deflected around the ventral side of both the olive and the pyramid, and thus pass to the restiform body as external arcuate fibres also. Certain of the internal arcuate fibres arise from the cells of the nuclei of termination of the cranial nerves and from small cells situated in the grey substance of the reticular formation. These, in crossing the mid-line, correspond to the white commissures of the spinal cord. Some of them terminate in the medulla; others, especially those from the nuclei of termination of the cranial nerves, join the lemniscus and pass toward the cerebrum; others reach the cerebellar hemisphere of the opposite side.

The **external arcuate fibres**, in addition to those mentioned above, comprise certain fibres which arise in the nuclei of the fasciculus gracilis and cuneatus and pursue a dorso-lateral course to enter the restiform body (cerebellar hemisphere) of the same side. These form the dorsal segment of the external arcuates. The greater mass of the external arcuates are cerebello-olivary fibres. Certain of those passing from one olive to the restiform body of the opposite side are deflected at the raphe, and course on the ventral side of both the other olive and the pyramid in order to reach the opposite cerebello-olivary bundle. Likewise, those passing from the restiform body to the opposite olive are deflected by the olive of the same side and pursue a similar course to the raphe. While out of the hilus of each olive streams a dense mass of white substance, yet many of the fibres concerned with the olive pierce its walls from all sides.

Many of the external arcuate fibres are said to be interrupted in the **nucleus arcuatus.** This is a thin sheet of grey substance, variable in amount, which lies on the ventral aspect of

Fig. 644.—Reconstruction of the Inferior Olivary Nucleus, Dorso-lateral Surface. (After Sabin.)

each pyramid, and, though it decreases inferiorly, it may be evident down to the decussation of the pyramids. The nucleus receives its name from the fact that its larger portion is interpolated in the course of the external arcuates. It is continuous anteriorly with the grey substance or nuclei of the pons.

The external arcuate fibres of longer course, like the olives with which they are largely concerned, have no homologues in the spinal cord.

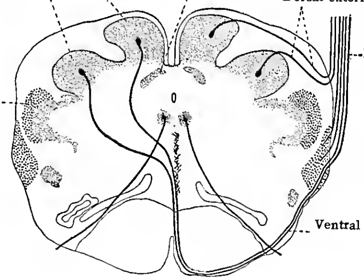
The *central canal* of the closed portion of the medulla is surrounded by a greater amount of **central grey substance, substantia grisea centralis,** than is the canal in the spinal cord. This is largely gelatinous substance, *the central gelatinous substance*, and the nerve-fibres in coursing through the grey substance are partially deflected by it, leaving it as a cylindrical, more evident area of grey substance than in other regions. In the open portion of the medulla the central grey substance naturally forms a more transparent lamina just under the floor of the fourth ventricle. In the mesencephalon it again surrounds the reformed canal or aqueduct of the cerebrum.

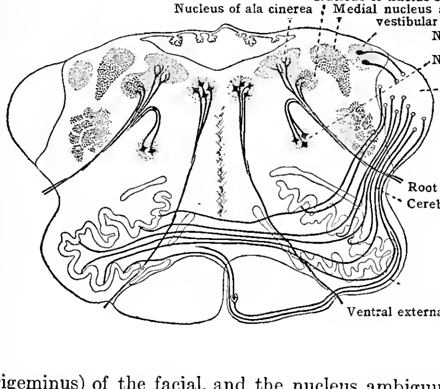
The **central connections of the cranial nerves** are most easily homologised with spinal-cord structures. Functionally the cranial nerves are of three varieties:—(1) the motor or efferent nerves, comprising the oculomotor, the trochlear, masticator, the abducens, the facial, the spinal accessory, and the hypoglossus; (2) the sensory or afferent, comprising the olfactory, the optic, the trigeminus, the vestibular, and the cochlear and (3) the mixed, motor and sensory nerves, comprising the glosso-palatine, the glosso-pharyngeal, and the vagus. The **nuclei of origin** of the motor or efferent cranial nerves and the efferent portions of the mixed nerves are directly continuous with the cell columns of the ventral horns of the spinal cord, while the emerging root filaments and roots of these nerves correspond to the ventral roots of the spinal nerves. The **nuclei of ter-**

mination of the afferent or sensory cranial nerves and of the sensory portions of the mixed nerves correspond directly to the nuclei of the fasciculus gracilis and fasciculus cuneatus, and to the cell-bodies of association and commissural neurones of the medulla and cord and, functionally, are merely anterior continuations of these.

The nuclei of the efferent or motor cranial nerves lie in two parallel lines, one near the mid-line and the other more laterally placed. The nuclei giving origin to the oculomotor, the trochlear, the abducens, and the hypoglossus are near the mid-line, and correspond to the ventro-medial and dorso-medial cell groups of the ventral horns of the spinal cord; the nuclei of origin of the masticator (motor

FIGS. 645 AND 646.—DIAGRAMS SHOWING THE COMPOSITION OF THE CEREBELLAR PORTIONS OF THE INTERNAL AND EXTERNAL ARCUATE FIBRES.





root of the trigeminus) of the facial, and the nucleus ambiguus giving origin to the motor portions of the glosso-pharyngeal and vagus nerves, together with the nucleus of the spinal accessory, correspond to the ventro-lateral and dorso-lateral cell-groups of the ventral horns of the spinal cord. The nerve-roots having medial nuclei of origin are those which make their exit from the brain-stem along the more medial superficial line, while those having the more lateral nuclei comprise the more lateral line of roots apparent on the surface of the stem. Some of the efferent fibres of the vagus, supposedly visceral efferent, arise from a small nucleus dorso-medial to the nucleus ambiguus, the *dorsal efferent nucleus of the vagus.* The first two pairs of cranial nerves, the olfactory and optic, are attached to the prosencephalon. These are purely sensory, and make their entrance near the mid-line of the brain, both having superficially placed nuclei of termination. Of the other nerves, all having sensory or afferent functions enter the brain along the lateral or more dorsal line, and the ganglia giving origin to their afferent axones correspond directly to the spinal ganglia of the dorsal or afferent roots of the spinal nerves.

Commissural and associational neurones are much more numerous in the brain-stem than in the spinal cord. Their axones serve to connect the structures on the two sides of the mid-line and to associate the different levels of the same side. Just as in the spinal cord, those of longer course correspond to the fasciculi proprii. Many of their axones descend into the spinal cord.

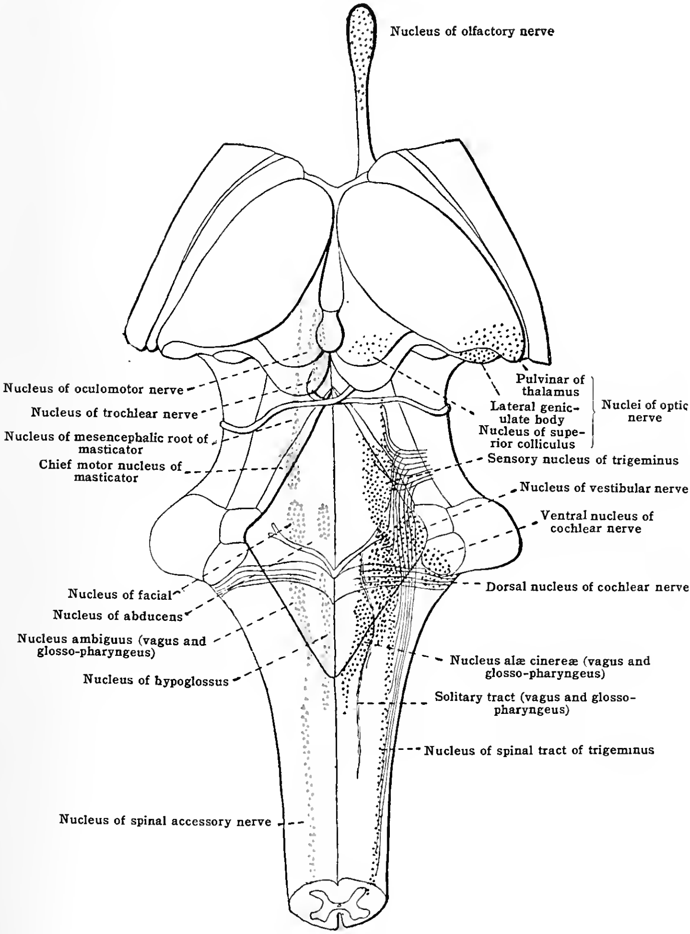
Of the fifteen pairs of cranial nerves, eleven pairs are attached to the medulla oblongata and pons, viz., the trigeminus, the masticator, abducens, facial, glosso-palatine, vestibular, cochlear, glosso-pharyngeal, vagus, spinal accessory, and hypoglossus.

The **hypoglossus,** the motor nerve of the tongue, has its nucleus of origin beginning in the lower portion of the floor of the fourth ventricle at the level of the acustic striæ. It is a long nucleus, lying close to the mid-line and just under the floor of the ventricle (hypoglossal eminence) and extending down to the region of the funiculus separans. Here it curves ventrally to a slight degree, and below the obex assumes a position ventro-lateral to the central canal, and thus extends a short distance below the level of the inferior tip of the olive. The nerve arises as a series of rootlets which traverse the entire thickness of the medulla (fig. 643), to emerge in line in the furrow between the olive and the pyramid and fuse to form the trunk of the nerve. The lowermost of the rootlets usually emerge below the olive. The nucleus receives impulses—(1) from the cerebrum by way of divergent fibres from the pyramid of the opposite side (voluntary); (2) impulses brought in by the sensory fibres of the cranial nerves (reflex); and (3) by axones from other levels of the medulla (associational). None of its axones are supposed to decussate, though numerous commissural fibres are known to pass between the nuclei of the two sides.

The **spinal accessory** is likewise a purely motor nerve, and has a laterally placed, long, and much attenuated nucleus of origin. Above, its nucleus is in line with and practically continuous with the nucleus giving motor fibres to the vagus and glosso-pharyngeus (nucleus ambiguus). Below, it consists of the lateral and dorso-lateral groups of cells of the ventral horn of the first five or six segments of the spinal cord. The nerve arises as a series of rootlets which emerge laterally and join a common trunk, which passes upward between the dorsal and ventral roots of the upper cervical nerves and parallel with the medulla to turn lateralward in company with the vagus. (See fig. 629). The upper rootlets arise from that part of the nucleus contiguous to the inferior end of the nucleus ambiguus, and are described as comprising the medullary or *accessory part* of the nerve; those which arise from the ventral horn cells below are described as the *spinal part*. The trunk of the spinal accessory fuses with the vagus in the region between its two ganglia, and, before separation, contributes fibres (the accessory part) to the trunk of the vagus. Some of the accessory fibres are distributed as motor fibres to the muscles of the larynx and some of them are visceral efferent fibres. The latter probably terminate chiefly in sympathetic ganglia which send axones to the heart. The spinal part is distributed to the sterno-mastoid and trapezius muscles. The nucleus of the spinal accessory receives terminal twigs of pyramidal fibres from the opposite side and is otherwise subjected to influences similar to those affecting the cells giving origin to the motor roots of the spinal nerves.

The **vagus** or pneumogastric and the **glosso-pharyngeus,** though they have widely different peripheral distributions, are so similar in origin and central connections that they may be described together. Both contain efferent fibres, though both are in greater part sensory. They are similar as to the origin of both their efferent and afferent components. The afferent fibres of the vagus arise in its jugular ganglion and its nodosal ganglion (ganglion of the trunk); the afferent fibres of the glosso-pharyngeus arise in its superior ganglion and its petrosal ganglion. In both nerves these fibres enter the lateral aspect of the medulla and bifurcate into ascending and descending branches, similar to those of the dorsal root-fibres in the spinal cord. Some of these branches terminate in practically the same level of the medulla about cell-bodies situated on the same and the opposite sides. Such branches end chiefly in the nuclei of the hypoglossal and spinal accessory, and about the cells giving origin to the efferent components of the vagus and glosso-pharyngeus themselves—short reflex arcs. However, most of the afferent fibres terminate in the nucleus of termination of the vagus and glosso-pharyngeus:—(1) the **nucleus of the ala cinerea,** the middle portion of which is indicated in the floor of the fourth ventricle by the ala cinerea; (2) in the closed portion of the medulla, the lower end of the nucleus of the ala cinerea comes to lie in the dorso-lateral proximity of the central canal, and this portion is known as the *commissural nucleus of the ala cinera* (figs. 642 and 645) from the fact that fibres may be seen which pass directly from it across the mid-line; (3) the longer of the descending branches of the bifurcated fibres collect to form the **solitary tract,** a compact bundle situated dorsally just ventro-lateral to the nucleus of the ala cinerea and quite conspicuous in sections of the medulla. The fibres of this bundle terminate in the *nucleus of the solitary tract*, which is but a ventro-lateral and downward continuation of the nucleus of the ala cinerea enclosing the bundles forming the tract. It is most probable that the fibres of the solitary tract are chiefly from the vagus (pneumogastric), though Bruce has found evidence that the glosso-pharyngeal contributes to it appreciably. It decreases rapidly in descending the medulla, owing to the rapid termination of its fibres about the cells of its nucleus. It, with the axones given by the cells of its nucleus, is believed to extend as far downward as the level of the fourth cervical segment of the spinal cord. This being in the level of origin of the phrenic nerve, the tract forms a link in the respiratory apparatus which aids in the coordinated respiratory movements. The axones given off by the cells of the nucleus of the ala cinerea (terminal nuclei of the vagus and glosso-pharyngeus) course on both sides of the

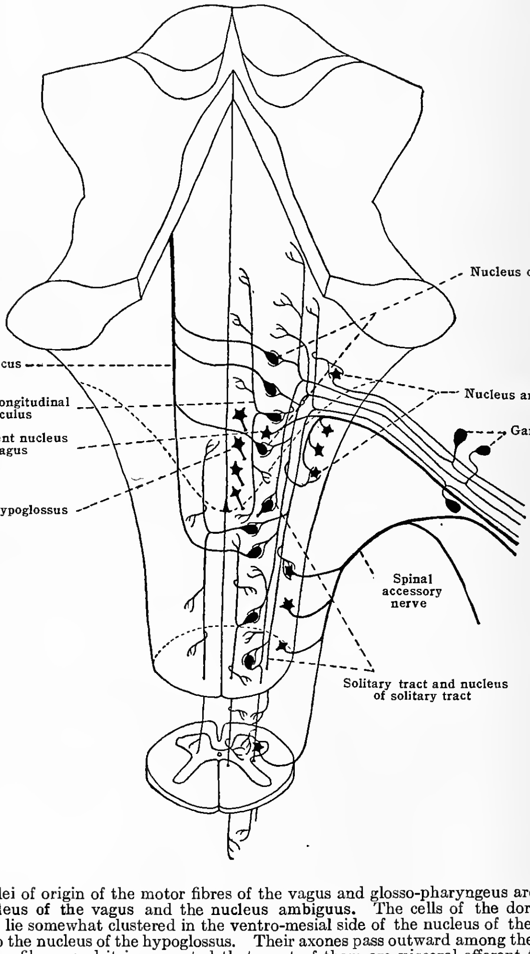
Fig. 647.—Scheme showing the Relative Size and Position of the Nuclei of Origin (Red) of the Motor and the Nuclei of Termination (Blue) of the Sensory Cranial Nerves.



mid-line, associating nuclei of other cranial nerves with vagus and glosso-pharyngeal impulses, many decussating to be distributed to the structures of the opposite side. Many join the lemniscus of the opposite side and pass into the cerebrum; others are distributed to the motor neurones of the cervical cord of the same and opposite sides (reflex axones), and no doubt others form central connections with the cells of the reticular formation of the medulla, though their precise relations have not been determined."

Cell-bodies in the nucleus of the ala cinerea, the nucleus of the solitary tract and in the commissural nucleus of the ala cinerea comprise the so-called respiratory and vaso-motor nuclei ("centres") of the medulla. Some of the caudal branches of the axones given off by the cells of these nuclei descend the spinal cord, not only to the segments giving origin to the phrenic nerve, but also to those supplying the intercostal and levatores costarum muscles. Some of these augment the solitary tract; most of them descend in the reticular formation of the medulla and cord. Further, axones given off by these cells convey vaso-motor impulses which are distributed to visceral efferent neurones throughout the cord.

Fig. 648.—Diagram illustrating Principal Central Relations of the Vagus Nerve, exclusive of Relations to Descending Cerebral or Pyramidal Fibres.

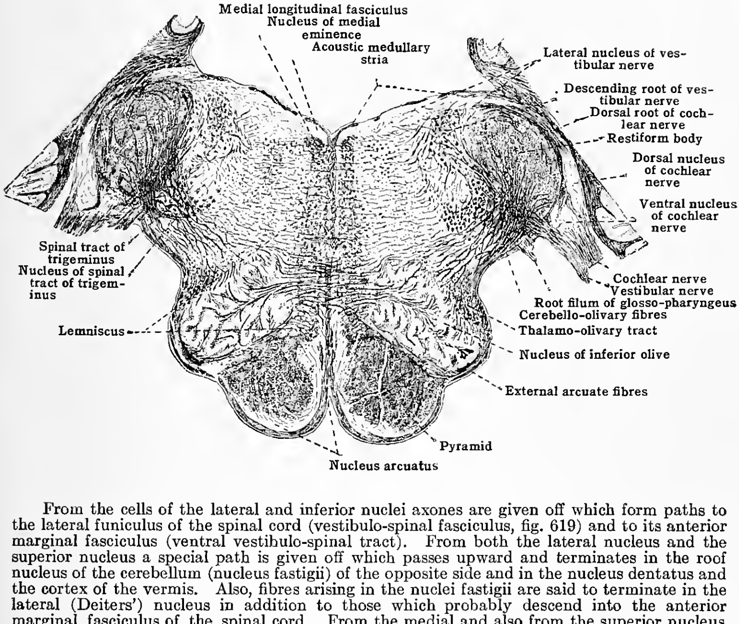


The nuclei of origin of the motor fibres of the vagus and glosso-pharyngeus are the dorsal efferent nucleus of the vagus and the nucleus ambiguus. The cells of the dorsal nucleus of the vagus lie somewhat clustered in the ventro-mesial side of the nucleus of the ala cinerea and lateral to the nucleus of the hypoglossus. Their axones pass outward among the entering or afferent vagus fibres, and it is suggested that most of them are visceral efferent fibres of the vagus, i. e., they terminate about sympathetic neurones. The *nucleus ambiguus* or ventral efferent nucleus of both nerves lies in the lateral half of the reticular formation, about mid-way between the olive and the line traversed by the rootlets of the two nerves. Its upper end is larger. Its cells are considerably dispersed by the fibres of the reticular formation. The axones arising from its cells course at first dorsalward and then turn abruptly outward to join the rootlets of the vagus or glosso-pharyngeus, as the case may be. The vagus is thought to receive more efferent fibres from the nucleus ambiguus than does the glosso-pharyngeus, and Cunningham notes that it may be questioned whether the latter nerve contains any motor fibres at all, there being paths by which the fibres of its motor branch (to the stylo-pharyngeus muscle) might enter it other than direct from motor nuclei.

The *vestibular* and *cochlear* nerves are usually considered as one nerve and together are designated as the acoustic or eighth cranial nerve. While both are purely sensory, are similar in development and course together, they are distinct as to function and their nuclei of termination differ. They are here described as separate cranial nerves. The two nerves approach the brain stem together and enter it at the lateral aspect of the junction of medulla oblongata and pons.

The **vestibular nerve** arises as the central processes of the bipolar cells of the *vestibular ganglion*, and passes into the brain-stem on the ventro-mesial side of the restiform body to find its nucleus of termination (nucleus vestibularis) in the floor of the fourth ventricle. This nucleus occupies a triangular area of considerable extent (area acustica, fig. 640), and is usually subdivided into a *lateral nucleus* (Deiters'), a *medial nucleus* (Schwalbe's), a *superior nucleus* (Bechterew's), and an *inferior nucleus* (nucleus spinalis). The latter is a downward prolongation of the general nucleus vestibularis which accompanies the *descending or spinal root* of the nerve.

Fig. 649.—Transverse Section of Medulla at Inferior Border of Pons.



From the cells of the lateral and inferior nuclei axones are given off which form paths to the lateral funiculus of the spinal cord (vestibulo-spinal fasciculus, fig. 619) and to its anterior marginal fasciculus (ventral vestibulo-spinal tract). From both the lateral nucleus and the superior nucleus a special path is given off which passes upward and terminates in the roof nucleus of the cerebellum (nucleus fastigii) of the opposite side and in the nucleus dentatus and the cortex of the vermis. Also, fibres arising in the nuclei fastigii are said to terminate in the lateral (Deiters') nucleus in addition to those which probably descend into the anterior marginal fasciculus of the spinal cord. From the medial and also from the superior nucleus fibres pass to the medial longitudinal fasciculus of both sides, and are distributed to the nucleus of the abducens of the same side and to the nuclei of the trochlear and oculomotor nerves of the opposite side and of the masticator nerve of the same and opposite sides. From the lateral and medial nuclei, and probably from all, fibres arise which cross the midline to enter the lemniscus and ascend to the cerebrum (lateral portion of the thalamus) on the opposite side. The lateral (Deiters') nucleus is said to contribute more fibres to the medial longitudinal fasciculus than does a nucleus of any other cranial nerve. If any of these fibres descend the cord, they must do so in its anterior marginal fasciculus.

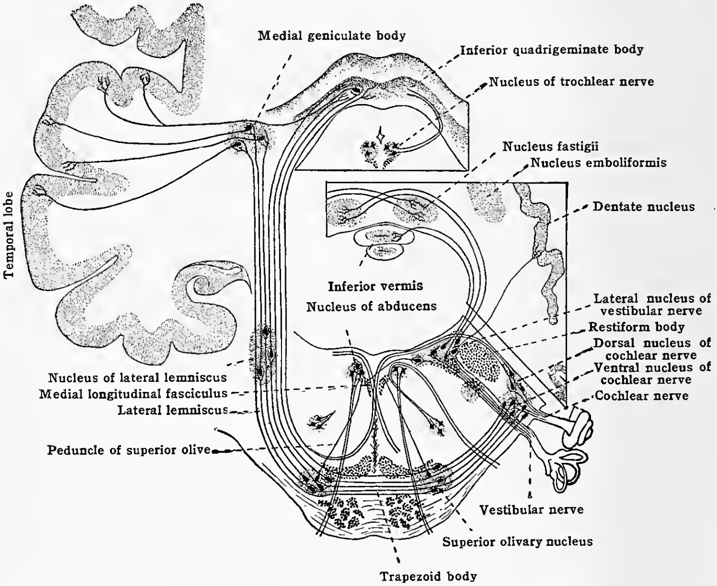
The *inferior nucleus* is accompanied by the *descending* or *spinal root* of the vestibular nerve, which begins to assemble in the nuclei above. This root is composed of both caudal branches of the entering fibres of the nerve and chiefly of fibres arising from the cells of its nuclei. Thus for the vestibular nerve it corresponds in every way to the solitary tract for the vagus, and to the spinal tract of the trigeminus. Such of its fibres as descend into the spinal cord most probably do so in the lateral vestibulo-spinal fasciculus.

Many of the anatomical details of the central connections of the vestibular nerve have not yet been determined with exactness. In addition to whatever other functions it may have, it is considered to be the nerve of equilibration, and the connections noted above may be considered the pathways by which it exercises this function. The fibres of the apparatus which are represented in the spinal cord are supposed to convey impulses to the ventral horn (motor) cells of the cord as far down as the lumbar region.

The **cochlear nerve**, the auditory nerve proper, arises as the central processes of the bipolar cells of the *spiral ganglion* of the cochlea. In the lateral periphery of the restiform body, just before the latter enters the cerebellum, the nerve finds its two nuclei of termination, the *ventral nucleus* and the *dorsal nucleus* (tuberculum acusticum, fig. 640).

From the **dorsal nucleus** arise the *acoustic medullary striæ*. These bundles pass around the dorsal aspect of the restiform body and course just under the ependyma of the floor of the fourth ventricle to the mid-line, where they suddenly turn downward into the substance of the medulla and in doing so, cross to the opposite side and join the lemniscus. As the lemniscus becomes separated higher up into a medial and lateral portion, these fibres course in the lateral lemniscul and are distributed chiefly to the grey substance of the inferior quadrigeminate and media,

Fig. 650.—Scheme showing Some of the Central Connections of the Acoustic Nerve. (In part after Edinger.)



geniculate body of that side. At the mid-line some of their fibres join the median longitudinal fasciculus and by way of it are distributed to the nuclei of origin of other cranial nerves. In frequent cases, the acoustic striæ course so deeply beneath the ependyma as not to be superficially visible in the floor of the fourth ventricle.

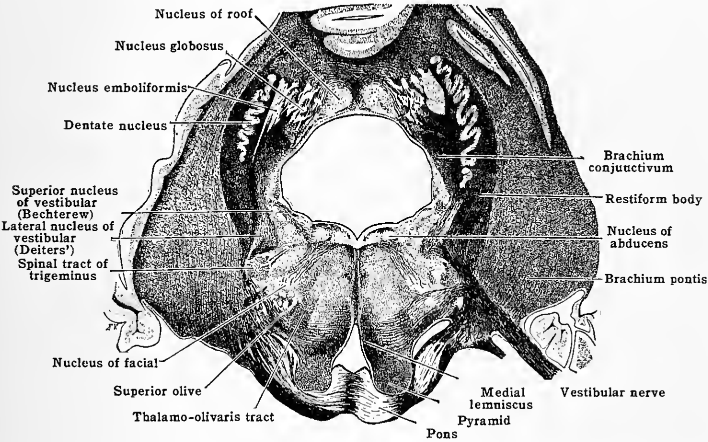
From the **ventral nucleus** of termination fibres arise which terminate about the cells of the **superior olivary nucleus** of the same and opposite sides. The superior olive is a small accumulation of grey substance which lies in the level of the inferior portion of the pons, and in line with the much larger inferior olivary nucleus of the medulla. However, it is not analogous to the latter in any sense. The two superior olives form links in the central acoustic chain. From cells of the superior olivary nucleus of the same and opposite sides, fibres arise which pass by way of the lateral lemniscus and terminate in the grey substance of the inferior quadrigeminate body and in the medial geniculate body, thus associating these bodies with the ventral nucleus of cochlear termination of the opposite side. From the medial geniculate body fibres arise which pass to the cortex of the superior temporal gyrus. This path is supplemented by fibres arising in the inferior quadrigeminate body, which likewise go to the temporal lobe. In the lateral lemniscus some of the acoustic fibres are interrupted by cells of the *nucleus of the lateral lemniscus*. In crossing the mid-line, between the superior olives, the fibres from the two sources form a more or less compact bundle, the **corpus trapezoideum** (trapezium). To this are added fibres crossing between the **nuclei trapeozidei,** smaller masses of grey substance just ventral to the superior olives and probably of the same significance.

Also, some fibres arising in the nuclei of termination of the cochlear nerve pass to the inferior quadrigeminate body of the same side. On the other hand, the connection with the medial geniculate body is thought to be wholly a crossed one. Further, some fibres are described as terminating in the *superior quadrigeminate body* of both the same and the opposite side. These, forming the *stratum lemnisci* of this body, are especially suggestive of associating auditory impulses with eye movements.

All the fibres arising in the superior olivary nucleus do not enter the corpus trapezoideum and the lateral lemniscus. A small bundle, the **peduncle of the superior olive,** arises in each nucleus and courses dorsally to the region of the nucleus of the abducens. Here certain of its fibres terminate about the cells of the nucleus of the abducens, while others enter the medial longitudinal fasciculus and pass to the nuclei of the trochlear and oculomotor nerves, thus further establishing connections between auditory impulses and eye movements.

The **facial nerve** is commonly described as consisting of the "facial proper" and its so-called sensory root or *pars intermedia,* the two together being designated as the seventh cranial nerve. However, the pars intermedia neither serves as a sensory root for the facial nor is it purely sensory. Many years ago Sapolini considered it a separate nerve and later it was called the *intermediate nerve of Wrisberg.* More recent investigations of its development and distribution, especially those of Streeter and Sheldon, further indicate that it merits a separate description

Fig. 651.—Transverse Section through Inferior Border of Pons and Portion of Overlying Cerebellum. (From Villiger.)



and a separate name, and, indicative of its distribution, it is here described as the *glosso-palatine nerve.* The facial, the glosso-palatine and the abducens all have their nuclei within the level of the pons though the roots of all appear from under its inferior border.

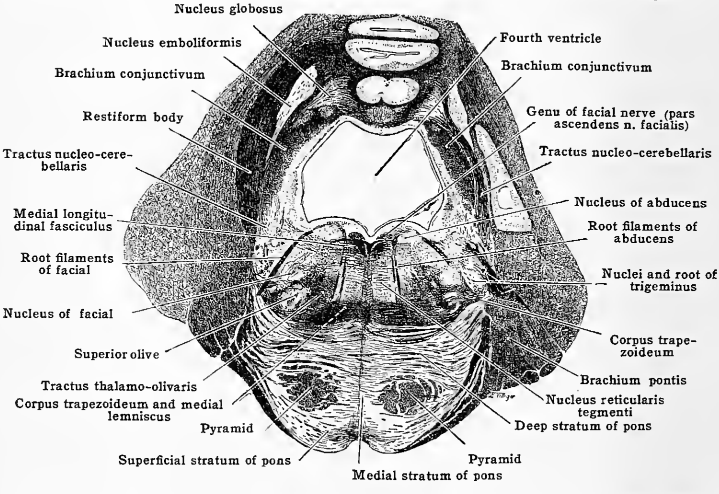
The **facial** [nervus facialis] has its nucleus (of origin) in the ventro-lateral region of the reticular formation, superior to and in line with the nucleus ambiguus. The axones given off by the cell-bodies of the nucleus collect into a bundle which, instead of passing ventrally and directly to the exterior of the pons, courses at first dorso-mesially to the mesial side of the nucleus of the abducens (ascending root of the facial); then it turns and courses superiorly for a few millimetres, parallel with the nucleus of the abducens and immediately beneath the floor of the fourth ventricle (*genu internum*); then it turns abruptly and pursues a ventro-lateral and inferior direction to its point of exit at the inferior border of the pons, just lateral to the olive and mesial to the entrance of the vestibular nerve. Its exit usually involves a few pons fibres. In transverse sections through the middle of the nucleus of the abducens the genu of the facial appears as a compact transversely cut bundle at the dorso-medial side of this nucleus.

The nucleus of the facial is described as consisting of two chief groups of cells, an anterior and a posterior group which give rise respectively to the axones of the superior and inferior branches of the facial nerve. It receives cortical impulses from the lower portion of the anterior central gyrus of the cerebral cortex, from the root fibres of the trigeminus of the same side, which serves as its sensory root, and (chiefly) fibres arising from the nuclei of termination of the trigeminus. The nuclei of termination of the optic and the auditory nerves of the same and opposite sides give rise to fibres which terminate about its cells. The fibres from the cerebral cortex descend in the pyramidal fasciculi and cross by way of the raphe and arcuate fibres to terminate in the nucleus of the opposite side. The anterior group of the cells of the facial nucleus must receive cortical fibres not only from the cerebral hemisphere of the opposite but also from that of the same side, evidenced by the fact that the superior branch of the nerve is but little affected in facial paralysis resulting from a lesion in the cerebral cortex of one side. A lesion destroying the root of the nerve or its nucleus of origin will of course give total facial paralysis in the side of the lesion.

The **glosso-palatine nerve** (*nervus intermedius*, sensory root of facial, etc.) is a mixed nerve but largely sensory. It accompanies the facial from a short distance beyond the geniculum (genu externum) of the facial to its attachment to the brain stem. Its *sensory fibres* arise as T-fibres of the cells of the *geniculate ganglion* (at the geniculum of the facial). The peripheral processes go as the *chorda tympani* to supply the epithelium of the anterior part of the tongue and that of the palate, especially of the palatine arches. The central processes enter the brain stem, bifurcate into caudal and cephalic branches, and find their nucleus of termination in a superior extension of the nucleus of the solitary tract (the ventral portion of the nucleus of the ala cinerea). The geniculate ganglion contains some cell-bodies of sympathetic neurones, left over in it during the period of migration form its homologue of the ganglion crest.

The *efferent fibres* of the glosso-palatine arise from cell-bodies lying dorso-medial to the nucleus of the facial and in the level between this and the nucleus of the masticator nerve superior to it. Its cells are usually scattered in the reticular formation in line with the dorsal efferent nucleus of the vagus. Since most of its fibres, at least, are concerned with sympathetic neurones (terminate in sympathetic ganglia) and convey secretory impulses destined for the salivary glands, it has been called the **nucleus salivatorius**.

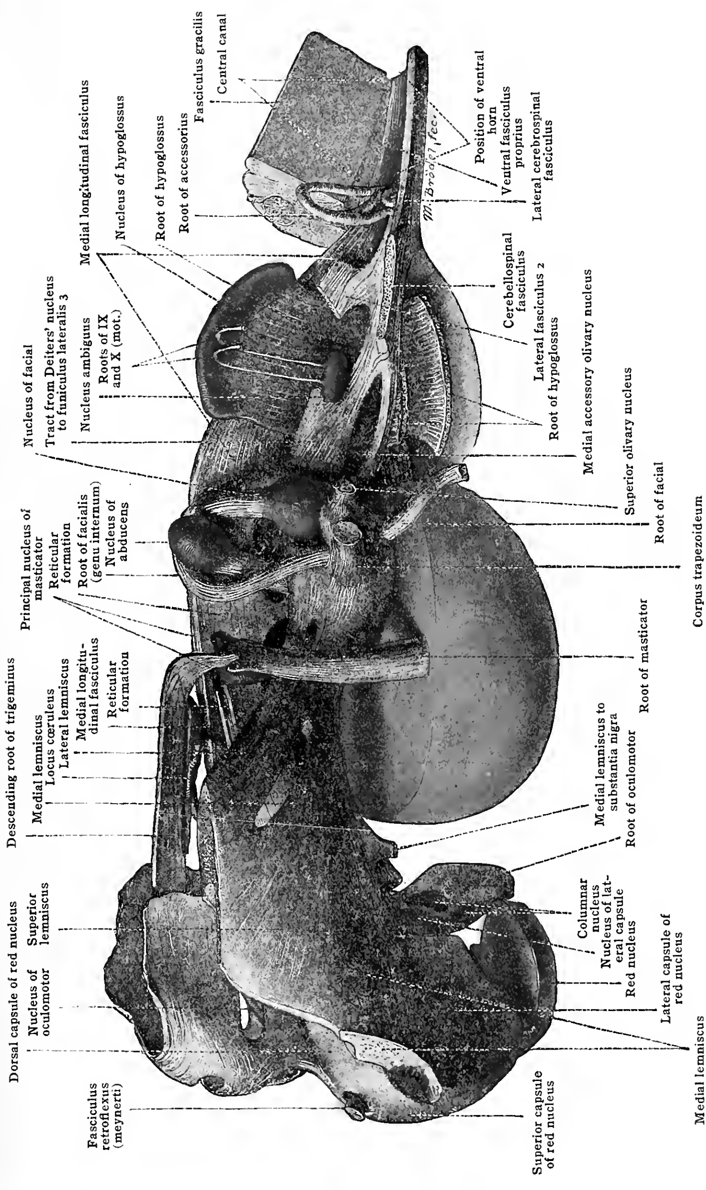
Fig. 652.—Transverse Section through Pons and Portion of Cerebellum at Level of Nuclei and Root Filaments of Abducens and Facial Nerves. (From Villiger.)



The **abducens** is a small, purely motor nerve, which supplies the lateral rectus muscle of the eye. Its *nucleus of origin* lies close to the mid-line in the medial eminence of the floor of the fourth ventricle, and in line with that of the hypoglossus. Its root-fibres, uncrossed, pursue a ventral course, inclining a little laterally and curving inferiorly to emerge from under the inferior border of the pons. They pass lateral to the pyramid, and often between some of its fasciculi. The nucleus receives cortical or voluntary impulses by way of the pyramidal fasciculi chiefly of the opposite side. Its connection with the auditory apparatus and the medial longitudinal fasciculus has already been noted. It probably receives afferent impulses through the fibres of the trigeminus as well as by fibres descending from the nuclei of termination of the optic nerve. It is also associated, by way of the medial longitudinal fasciculus, with the nucleus of the oculomotor nerve of the same and opposite sides.

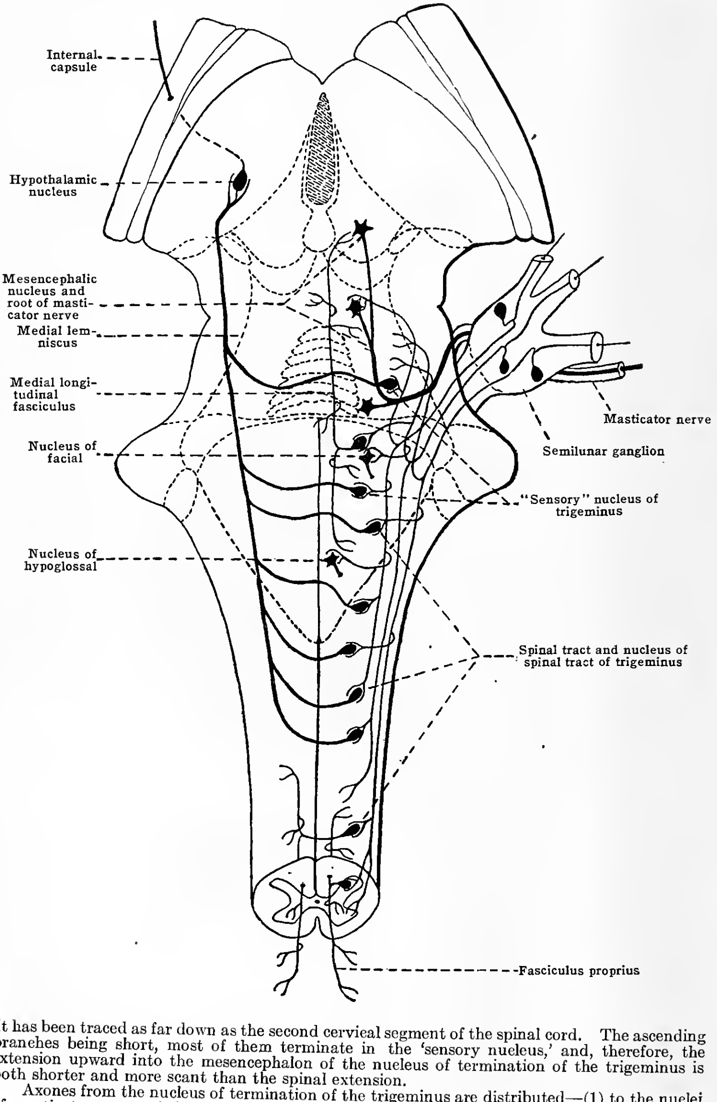
The **trigeminus** is considerably larger than any of the nerves inferior to it, and has the most extensive central connections of any of the cranial nerves. It is a purely sensory nerve which enters through the brachium pontis in line with the facial nerve. It serves as the nerve of general sensibility for the face from the vertex of the scalp downward, and thus it corresponds to the afferent fibres (dorsal root) for all the nerves giving motor supply to structures underlying its domain. Its fibres arise from its large, trilobed, **semilunar** (Gasserian) **ganglion,** situated outside the brain. This corresponds to the dorsal root ganglion of a spinal nerve, and its cells give off the characteristic T-fibres with peripheral and central branches. The central or afferent branches upon entering the brain-stem bifurcate into ascending and descending divisions, just as the entering dorsal root-fibres of the spinal nerves, and find their *nucleus of termination* in a dorso-lateral column of grey substance, lying deeply and extending longitudinally through the brain stem, and consisting of the upward continuation of the gelatinous substance of Rolando of the spinal cord. Opposite the entrance of the nerve is a considerably thickened portion of this column of grey substance, known as the *sensory nucleus* of the trigeminus, and the remainder below is called the *nucleus of the spinal tract* (fig. 647). Both parts are equally "sensory." After bifurcation the branches of the entering fibres of the trigeminus terminate about the cells of these nuclei. The descending branches are much longer than the ascending,

Fig. 653.—Drawing of Model of Brain-stem showing the Nuclei of Origin of the Motor Cranial Nerves. (After Sabin.)



and in passing downward form the **spinal tract of the trigeminus**, well marked in all transverse sections of the medulla oblongata (figs. 641, 642, 643, 649). The spinal tract decreases rapidly in descending the medulla, owing to the rapid termination of its fibres in the nucleus of the tract.

FIG. 654.—DIAGRAM ILLUSTRATING THE PRINCIPAL CENTRAL CONNECTIONS OF THE TRIGEMINUS AND MASTICATOR NERVES, EXCLUSIVE OF THEIR RELATIONS TO DESCENDING CEREBRAL OR PYRAMIDAL FIBRES.



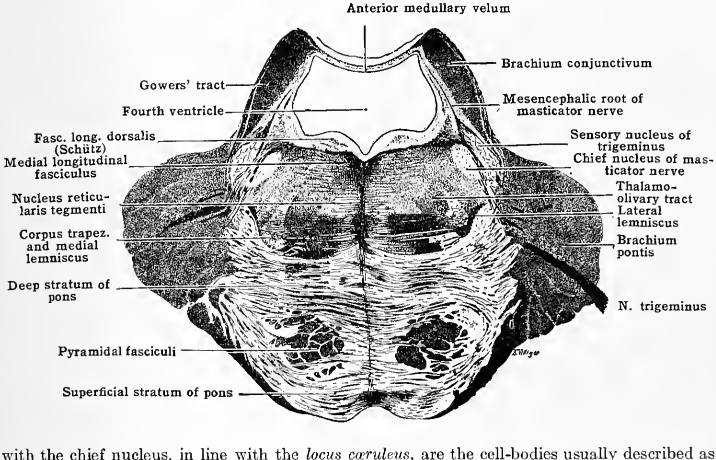
It has been traced as far down as the second cervical segment of the spinal cord. The ascending branches being short, most of them terminate in the 'sensory nucleus,' and, therefore, the extension upward into the mesencephalon of the nucleus of termination of the trigeminus is both shorter and more scant than the spinal extension.

Axones from the nucleus of termination of the trigeminus are distributed—(1) to the nuclei of masticator nerve of the same and opposite sides (short or simple reflex fibres); (2) to the nuclei of the other motor cranial nerves, especially of the facial; (3) to the thalamus of the same and chiefly the opposite side, and thus, through interpolation of thalamic neurones, their impulses reach the somæsthetic area of the cerebral cortex. These fibres ascend in the recticular formation of the opposite side, most of them finally coursing strictly within the medial lemniscus. In crossing the mid-line they contribute to the internal arcuates. (4) Some fibres of both the trigeminus direct and from its nucleus pass laterally into the cerebellum. The longer of the reflex or association axones arising in the nucleus of termination may contribute to the medial longitudinal fasciculus; many of them descend to terminate in the grey substance of the spinal cord below the levels in which the fibres of the spinal tract proper terminate. The nucleus of termination is directly homologous to the nuclei of the fasciculus gracilis and fasciculus cuneatus, and, like the nuclei of termination of all sensory cranial nerves, it contains cell-bodies homologous to those which give rise to the fasciculi proprii and commissural fibres of the spinal cord.

The **masticator nerve** [*portio minor n. trigemini*] is a purely motor nerve, usually called the motor root of the trigeminus from the fact only that it makes its exit from the pons by the side of the entering fibres of the trigeminus, passes outward over the ventro-mesial side of the semilunar ganglion and accompanies the inferior maxillary division (mandibular nerve) of the trigeminus till it divides totally into its branches for the motor supply of the muscles of mastication. It serves, therefore, as but a relatively small part of the "motor root" of the trigeminus.

The nucleus of origin of the masticator nerve is attenuated into two parts: (1) The *chief nucleus* (*nucleus princeps*) lies on the dorso-medial side of the larger portion (sensory nucleus) of the nucleus of termination of the trigeminus. It is the larger of the two parts and gives origin to much the greater part of the masticator. (2) Scattered anteriorly and continuous

Fig. 655.—Transverse Section Through Upper Part of Pons at the Level of the Entrance of the Trigeminus. (From Villiger.)



with the chief nucleus, in line with the *locus cœruleus*, are the cell-bodies usually described as the *nucleus of the mesencephalic* (descending) *root.* These cells lie in decreasing linear distribution, through the mesencephalon, as far anterior as the posterior commissure of the cerebrum, and the *mesencephalic root* of the nerve accumulates as it descends to join the exit of the fibres arising from the chief nucleus. The average diameter of its cells is somewhat less than for the chief nucleus.

It is not clearly settled that the fibres arising from the mesencephalic nucleus of the masticator nerve go to the muscles of mastication. As suggested by Kölliker, some of these may supply the tensor veli palatini and tensor tympani muscles. Recent investigations of lower animals by Johnston and Willems indicate that the mesencephalic root may contain no motor fibres at all, representing instead a portion of the sensory trigeminus fibres. It is claimed that some fibres in descending give off collaterals which terminate about cells in the chief nucleus, and thus an impulse descending by them is given a wider distribution and also reinforced by the interpolation of another neurone. Such fibres, however, may be the sensory fibres just mentioned terminating upon the cells of the nucleus to form simple reflex arcs.

It is claimed that each masticator nerve receives a few fibres arising from the cells of the nucleus of that of the opposite side.

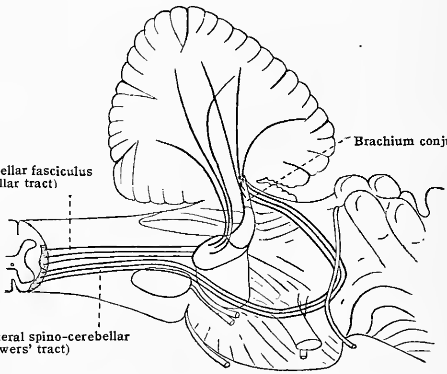
Both parts of the nucleus of the masticator receive afferent impulses brought in by the trigeminus of the same (chiefly) and of the opposite side, and both receive cortical impulses by fibres from the inferior portion of the precentral gyrus which descend in the cerebral peduncles and cross to terminate in the nucleus of the opposite side.

The internal structure of the pons.—The nuclei and roots of the trigeminus, masticator, abducens, facial, glosso-palatine, cochlear and vestibular nerves are extended within the level of the pons, and their position and course have been described above. The pons proper (the bridge) consists of a mass of transversely running fibres continuous on either side into the brachia pontis or middle cerebellar peduncles. In the animal series the relative amount of these fibres varies with the size of the cerebellum upon which they are dependent. They are relatively more abundant in man than in other animals.

In transverse sections the pons fibres are seen to course ventrally about the main axis of the brain-stem, making it possible to divide the section into a *basilar* or *ventral part* and a *dorsal part* (*tegmentum*). The fibres in their transverse and ventral course around the medulla oblongata involve the pyramids. At the inferior border of the pons the fibres little more than separate the pyramids as such from the main axis of the brain-stem, but more superiorly the pons fibres pass through the pyramids, splitting them into the **pyramidal fasciculi.** These pyramidal or chief *longitudinal fibres* of the pons are the continuation of the basal portion of the cerebral peduncles through the pons, to emerge as the pyramids proper at its inferior border. They occupy an intermediate or central area among the pons fibres of either side, leaving the periphery of the pons uninvaded. The *superficial pons fibres* form the solid bundle of its ventral and lateral periphery and the *deep pons fibres* form similar bundles dorsally enclosing the area of pyramidal fasciculi (fig. 655).

In transverse sections through the *inferior portion* of the pons, the *dorsal or tegmental part* consists of structures continuous with and analogous to the structures of the medulla oblongata immediately below, exclusive of the pyramids. In addition, this region contains the superior olivary nucleus and the corpus trapezoideum. The significance of these structures and their relation to the nucleus of termination of the cochlear nerve is shown in figs. 650, 651 and 652. In this region the *lemniscus* (fillet) changes from the sagittal to the coronal plane, and its

FIG. 656.—DIAGRAM SHOWING THE RHOMBENCEPHALIC COURSE OF GOWERS' TRACT AND THE DIRECT CEREBELLAR TRACT.



lateral edges are becoming drawn outward and carry the lateral lemniscus of the regions superior to this. The medial longitudinal fasciculus, left alone by the change in the arrangement of the leminscus, maintains its dorsal position throughout the pons and into the mesencephalon above. The **thalamo-olivary tract** appears loosely collected in the dorsal part of the pons, dorso-medial to the nucleus of the superior olive.

The **restiform body** acquires in this inferior region a more dorso-lateral position than in the medulla below. Its fibres are beginning to turn upward in their course to the cerebellum mesial to the brachium pontis. Here the restiform body is nearing completion, and the fibres now contained in it may be summarised as follows:—

(1) The fibres of the dorsal spino-cerebellar fasciculus (direct cerebellar tract) of the same side.

(2) Fibres from the nuclei of the fasciculus gracilis and fasciculus cuneatus of the same and opposite side (external arcuate fibres).

(3) Fibres to and from the inferior olives of the same and (chiefly) the opposite side (cerebello-olivary fibres).

(4) Sensory cerebellar fibres from the nuclei of termination of the vagus, glosso-pharyngeus, vestibular and trigeminus, vestibular especially, and from the cells of the reticular formation.

(5) Descending fibres to the motor nuclei of the vagus and glosso-pharyngeal, and fibres descending into the anterior marginal fasciculus of the spinal cord, the latter, however, being in large part interrupted by cells in the nuclei of the vestibular nerve.

(6) A few fibres arising from the arcuate nuclei. These nuclei are continuous superiorly with the nuclei of the pons and some of their fibres are described as entering the cerebellum by way of the restiform body instead of by way of the brachium of the pons as in the levels above.

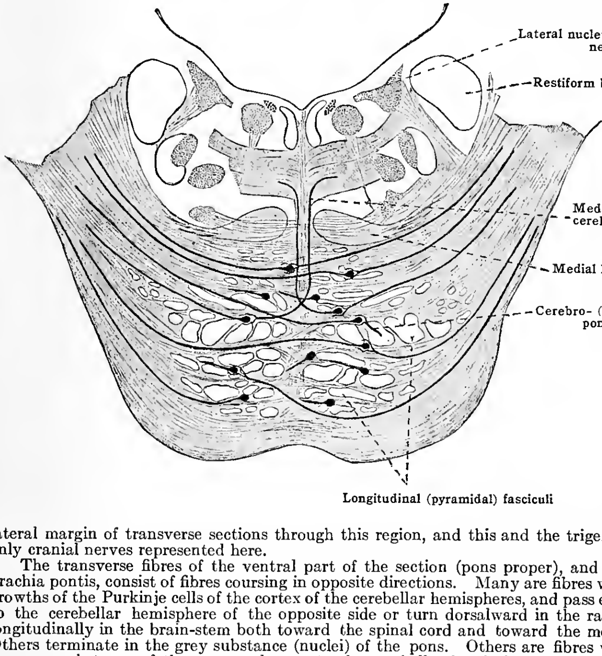
The ascending fibres of the restiform body are distributed to the cortex of the vermis, the nucleus of the roof (*fastigii*), the nucleus dentatus, nucleus emboliformis, and nucleus globosus.

Very few if any of the fibres ascending the cord in *Gowers' tract* enter the cerebellum by way of the restiform body. This tract (the superficial antero-lateral spino-cerebellar fasciculus) ascends the medulla, dispersed in the reticular formation, and therefore in a more ventral position than that of the direct cerebellar tract. In this position it becomes enclosed by the fibres of the pons, and so it passes upward, beyond the pons, around the lateral lemniscus to the brachium conjunctivum, and there turns back to enter the cerebellum by way of its superior peduncle. Certain clinical phenomena, probably purely psychological, have been alleged to indicate that some of the fibres of Gowers' tract pass on to the cerebrum instead of turning in the medullary velum to enter the cerebellum.

The dorsal part of a transverse section through the *upper part* of the pons contains the **superior cerebellar peduncles** [brachia conjunctiva] instead of the restiform bodies or inferior peduncles. Instead of the cerebellum forming the roof of the fourth ventricle, in this region the roof is formed by the anterior medullary velum bridging the space between the two brachia conjunctiva. Adhering upon the medullary velum is the **lingula cerebelli**—the superior and ventral extremity of the superior vermis. This is the only portion of the cerebellum attached to this region.

The lemniscus (fillet) is found more lateral than at the inferior border of the pons, and is divided into the *medial lemniscus* and *lateral lemniscus* proper. The lateral lemniscus has shifted dorsally until in this region it courses in the dorso-lateral margin of the section external to the brachium conjunctivum. The mesencephalic root of the masticator nerve occurs in the dorso-

FIG. 657.—DIAGRAM SHOWING CONNECTIONS OF THE FIBRES OF THE PONS.
The plane of the section is obliquely transverse or parallel with the direction of the brachia pontis



lateral margin of transverse sections through this region, and this and the trigeminus are the only cranial nerves represented here.

The transverse fibres of the ventral part of the section (pons proper), and therefore the brachia pontis, consist of fibres coursing in opposite directions. Many are fibres which are outgrowths of the Purkinje cells of the cortex of the cerebellar hemispheres, and pass either directly to the cerebellar hemisphere of the opposite side or turn dorsalward in the raphe to course longitudinally in the brain-stem both toward the spinal cord and toward the mesencephalon. Others terminate in the grey substance (nuclei) of the pons. Others are fibres which arise in the grey substance of the pons and pass to the cerebellar hemispheres, and still others are the cerebro-pontile fibres, from the temporal, occipital and frontal lobes.

The **grey substance of the pons** [nuclei pontis] occurs quite abundantly. At the inferior border of the pons it is found concentrated about the then more accumulated bundles of the emerging pyramids, and serial sections show it to be a direct upward continuation of the arcuate nuclei of the medulla oblongata below. Higher up it is dispersed throughout the central area in the interspaces between the transverse pontile and longitudinal pyramidal fasciculi. A large portion of the nerve-fibres passing through it are thought to be interrupted by its cells, which thus serve as links in some of the neurone chains represented by the fibres of the pons. Of the more important of such relations, the following are said to exist:—

(1) Fibres which arise in the cortex of one cerebellar hemisphere and terminate about cells of the nucleus pontis of the same and opposite side of the mid-line. These cells give off axones which pass to the other cerebellar hemisphere. In this relation the nuclei of the pons are analogous to the arcuate nuclei, save that the cerebellar fibres interrupted in the former are connected with the cerebellum by way of the brachia pontis instead of the restiform bodies.

(2) Certain of the descending cerebro-pontile fibres terminate about cells of the nuclei of the pons. Such cells give off fibres which probably, for the most part, pass to the cerebellar hemispheres, the impulses from the cerebral hemisphere of one side being conveyed to the opposite cerebellar hemisphere. Most of the descending cerebro-pontile fibres are thought to cross the mid-line to terminate about cells of the nuclei of the pons of the opposite side, a relation not sufficiently emphasised in the accompanying diagram (fig. 657).

Of the cerebro-pontile paths, the **frontal pontile path** (Arnold's bundle) is described as arising in the cortex of the frontal lobe (frontal operculum) passing in the anterior portion of the internal capsule down into the medial part of the base of the cerebral peduncle, and terminating in the grey substance of the pons. The descending **temporal pontile path,** sometimes called Türk's bundle, arises in the cortex of the temporal lobe, traverses the posterior portion of the internal capsule, lies lateral in the pyramidal portion of the cerebral peduncle, and terminates in the grey substance of the pons. In the posterior part of the internal capsule, the temporal pontile path is joined by a small bundle arising in the occipital lobe and going to the pons nuclei. This, supposedly smaller than the other two, adds an **occipito-pontile path.**

The total area in cross section of the pyramidal fasciculi as they enter the pons above is considerably greater than that which they possess as they emerge as the pyramids of the medulla below. The difference is considered very appreciably greater than can be explained as due to the loss of pyramidal fibres supplied to the nuclei of origin of the cranial nerves lying within the level of the pons, and the additional difference is explained as due to the termination within the pons of the cerebro-pontile paths.

THE ISTHMUS OF THE RHOMBENCEPHALON

The isthmus of the rhombencephalon is nothing more than the transition of the metencephalon into the mesencephalon above. It is quite short and comprised of only the structures which run through it, namely, the *brachia conjunctiva* (superior peduncles of the cerebellum), the anterior medullary velum, the lateral sulcus of the mesencephalon, the cerebral peduncles, and the inferior end of the interpeduncular fossa. It surrounds the superior extremity of the fourth ventricle. The lateral and medial lemnisci, the superior extension of the nucleus of the trigeminus, the mesencephalic nucleus and root of the masticator nerve and Gowers' tract extend through it. At the mid-line, just inferior to the inferior quadrigeminate bodies is the **frenulum** of the anterior medullary velum and the trochlear nerves, emerging at the sides of this, course ventrally around the sides of the isthmus. In the lateral sulcus, the isthmus shows usually a small triangular elevation known as the **trigonum lemnisci** from the fact that the lateral lemniscus tends toward the surface in this region.

Functions of the cerebellum.—From the above descriptions involving the structures of the metencephalon, it may be noted (1) that a given side of the cerebellum is associated chiefly with the same side of the general body and with the opposite side of the cerebrum. (2) That it receives afferent impulses from the spinal cord (brought into the cord by the dorsal roots of the spinal nerves) by way of the direct cerebellar fasciculus of the same side, and by Gowers' tract and from the nuclei of the fasciculus gracilis and cuneatus of the same and opposite sides. It further receives afferent impulses from the nuclei of termination of the trigeminus, glossopharyngeal and vagus of the same side chiefly, and especially does it receive afferent impulses from the nuclei of the vestibular nerve of the opposite and same side. (3) That the cerebellum sends impulses to the red nucleus, the thalamus and the cerebral cortex of the opposite side, and some of its fibres terminate in the nuclei of termination of the vestibular nerve and probably some fibres arising in its roof nuclei descend into the spinal cord direct. (4) That the cerebellum receives impulses from the thalamus of the opposite side by way of the thalamo-olivary tract and the inferior olive, and especially from the cerebral cortex of the opposite side by way of the frontal, temporal and occipital pontile paths and the nuclei of the pons. Further, fibres from the general pyramidal fasciculi are described as terminating about cells of the nuclei of the pons.

Taking into consideration these known associations of the cerebellum, the anatomically possible paths which in part may distribute cerebellar impulses to the grey substance sending efferent fibres to the peripheral tissues are (1) the general pyramidal fasciculi whose cortex of origin may receive impulses by *fibræ propriæ* from the cortical areas receiving impulses from the cerebellum. The pyramidal fasciculi, decussating, distribute impulses to the grey substance of the medulla and cord of the same side as that from which the cerebello-cerebral impulses passed to the cortex. (2) The lateral vestibulo-spinal and the anterior marginal fasciculi to the ventral horn of the spinal cord of the same side, probably carrying impulses descending from the cerebellum as well as impulses brought in by the vestibular nerve and descending direct from its nuclei of termination into the spinal cord. (3) The rubro-spinal tract of the cord and probably some of the thalamo-spinal fibres (corpora-quadrigemina-thalamus path), the red nuclei and thalami being associated abundantly with the cerebellum. These tracts likewise decussate in descending but likewise do the cerebellar impulses ascending to their cells of origin.

Whatever other functions it may possess, developmental defects and pathologic lesions show that the cerebellum has to do with the equilibration of the body and the finer coördinations, adjustive control of the contractions of functionally correlated groups of muscles. Making this possible, in part at least, it is seen above that is it associated (1) directly with the special nerve of equilibration, the vestibular; (2) with the optic apparatus by way of the thalamus, and (3) with the afferent impulses from the general body, by way of the direct cerebellar and Gowers' tracts, by way of the nuclei of the fasciculus gracilis and cuneatus, and the nuclei of termination of the trigeminus, glosso-pharyngeal and vagus. It has been suggested that by way of these latter paths the cerebellum deals especially with those general afferent impulses which arise within the muscles of the body (neuro-muscular spindles, etc.) and which are grouped under the name "muscular sense." The cerebellum can be considered as an enlarged and modified portion of the grey substance of the spinal cord, receiving a greater number and variety of afferent impulses and with them mediating more comprehensive and complicated reflex activities than is possible with the less abundant grey substance of a given portion of the cord proper.

SUMMARY OF PRINCIPAL STRUCTURES IN RHOMBENCEPHALON

A. Gross Exterior.

1. Medulla Oblongata (Myelencephalon).
2. Metencephalon
   - Cerebellum
     - Hemispheres—lobes and lobules.
     - Vermis—lobules and lingula.
   - Pons
     - Dorsal part (preoblongata).
     - Ventral part (pons proper).
   - Cerebellar peduncles
     - superior—brachium conjunctivum.
     - middle—brachium of pons.
     - inferior—restiform body.
3. Isthmus of Rhombencephalon.
4. Fourth Ventricle and its Chorioid tela.
5. Anterior and Posterior Medullary Vela.

B. Grey and White Substance.

1. Funiculus gracilis, nucleus of fasciculus gracilis, funiculus cuneatus, nucleus of fasciculus cuneatus.
2. Internal and external arcuate fibres, decussation of lemnisci, lemniscus, medial lemniscus, lateral lemniscus.
3. Cerebral peduncles, pyramidal fasciculi, pyramids, decussation of pyramids, arcuate nuclei.
4. Superficial and deep strata of pons, nuclei of pons, branchia of pons.
5. Inferior olivary nuclei, cerebello-olivary fibres, thalamo-olivary tract, spino-olivary tract.
6. Nuclei emboliformis, globosus and fastigii (of the roof), and nucleus dentatus with brachium conjunctivum of cerebellum.
7. Central gelatinous substance and gelatinous substance of Rolando.
8. Reticular formation.
9. Hypoglossal nerve and nucleus of hypoglossal.
10. Spinal accessory nerve and lateral nucleus.
11. Vagus and glossopharyngeal nerves, nucleus of ala cinerea, solitary tract and nucleus of solitary tract, commissural nucleus of ala cinerea, nucleus ambiguus, dorsal efferent nucleus of vagus.
12. Vestibular nerve—its superior nucleus (Bechterew), its medial nucleus (Schwalbe), its lateral nucleus (Deiters), and the nucleus of its descending (spinal) root.
13. Cochlear nerve, dorsal nucleus and ventral nucleus of cochlear, acoustic medullary striæ, nucleus of superior olive, trapezoid body, nucleus trapezoidei, lateral lemniscus, nucleus of lateral lemniscus.
14. Facial nerve and nucleus of facial nerve.
15. Glosso-palatine nerve, nucleus of glosso-palatine and nucleus salivatorius.
16. Abducens and nucleus of abducens.
17. Trigeminus, "sensory nucleus" of trigeminus, spinal tract and nucleus of spinal tract of trigeminus.
18. Masticator nerve, chief nucleus and (so-called) mesencephalic nucleus and root of masticator.
19. Medial longitudinal fasciculus.
20. Nucleus intercalatus, nucleus of median eminence, nucleus incertus.

THE CEREBRUM

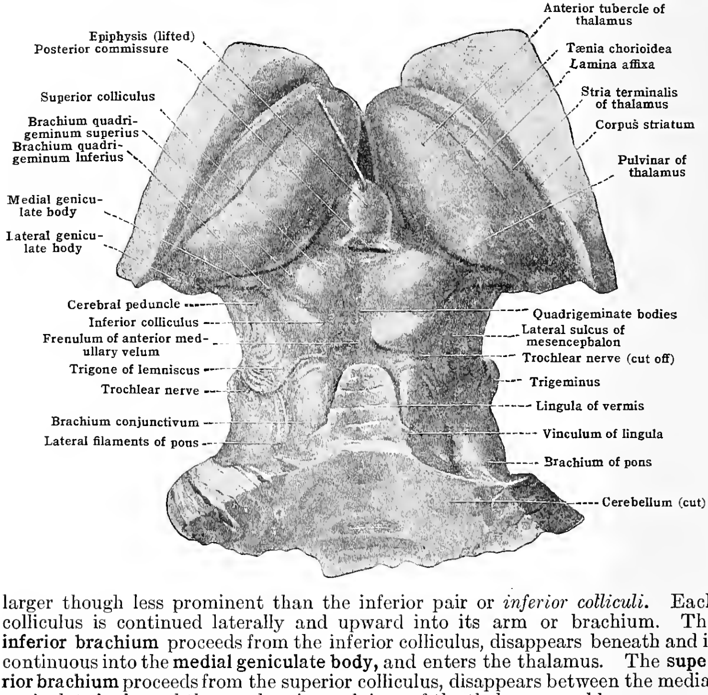
1. THE MESENCEPHALON

The mesencephalon or mid-brain is that small portion of the encephalon which is situated between and connects the rhombencephalon below with the prosencephalon above. It is continuous with the isthmus rhombencephali, and occupies the tentorial notch, the aperture of the dura mater which connects the meningeal cavity containing the cerebellum with that occupied by the prosencephalon. Its greatest length is about 18 mm., and it is broader ventrally than dorsally. Its dorsal surface is hidden by the overlapping occipital lobes of the cerebral hemispheres. It consists of—(1) the **lamina quadrigemina,** a plate of mixed grey and white substance which goes over lateralward and below into (2), the **cerebral**

peduncles (crura) and their tegmental structures, and it contains (3), the *nuclei of origin* of the *trochlear* and *oculomotor* nerves. It arises from thickenings of the walls of the middle cerebral vesicle of the embryo, the lamina quadrigemina arising from the dorsal or alar lamina of this portion of the neural tube, while the basal lamina thickens to form the nuclei of the nerves, the substantia nigra, etc., and by the ingrowing of the cerebral peduncles. By means of the lamina quadrigemina roofing it over, the neural canal throughout the mesencephalon retains its tubular form and is known as the **aquæductus cerebri** (Sylvii), connecting the cavity of the fourth ventricle below with that of the third ventricle above.

External features.—*Dorsal surface.*—The lamina quadrigemina shows four well-rounded elevations, the quadrigeminate bodies [**corpora quadrigemina**], divided by a flat median groove crossed at right angles by a transverse groove. The anterior pair of these, the *superior quadrigeminate bodies* [colliculi], are

Fig. 658.—Dorsal Surface of Mesencephalon and Adjacent Parts. (After Spalteholz.)



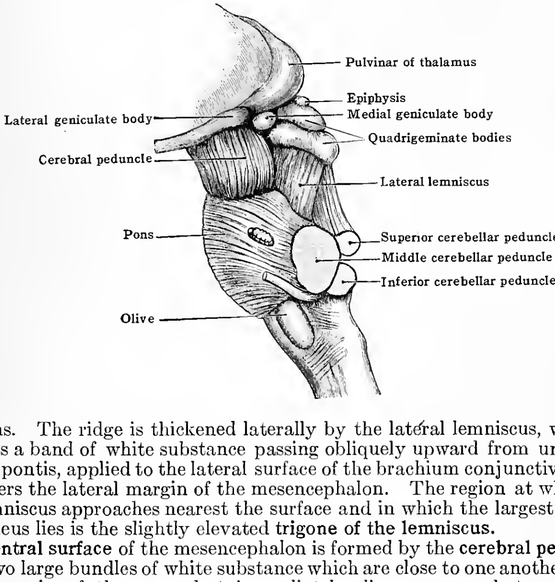
larger though less prominent than the inferior pair or *inferior colliculi.* Each colliculus is continued laterally and upward into its arm or brachium. The **inferior brachium** proceeds from the inferior colliculus, disappears beneath and is continuous into the **medial geniculate body,** and enters the thalamus. The **superior brachium** proceeds from the superior colliculus, disappears between the medial geniculate body and the overlapping pulvinar of the thalamus, and becomes continuous with the **lateral geniculate body** and thus with the lateral root of the optic tract.

The geniculate bodies are rounded elevations of grey substance which arise as detached portions of the thalami, and therefore belong to the thalamencephalon rather than to the mesencephalon. The superior quadrigeminate body or superior colliculus and the lateral geniculate body are a part of the *optic apparatus,* while the inferior colliculus and the medial geniculate body belong chiefly to the *auditory apparatus* (see Central Connections of Cochlear Nerve). Just as the terminal cochlear nuclei are connected by a few fibres with the superior colliculus, so do some fibres from the optic tract pass into the inferior colliculus. Also some fibres form the optic tract (mesial root) are said to terminate in the medial geniculate body. Resting in the broadened medial groove between the superior quadrigeminate bodies lies the non-nervous **epiphysis** or pineal body. This also belongs to the thalamencephalon. Under the stem of the epiphysis is a strong transverse band of white substance crossing the mid-line as a bridge over the opening of the cerebral aqueduct into the third ventricle. This is the **posterior commissure** of the cerebrum, and contains commissural fibres arising in both the thalamencephalon and mesencephalon. The triangular area bounded by the stem of the epiphysis, the thalamus, and the superior colliculus with its brachium, is known as the **habenular trigone.**

Inferiorly, the lamina quadrigemina is continuous with the isthmus of the rhombencephalon by way of the brachia conjunctiva or superior cerebellar peduncles, and the anterior medullary velum which bridges between the mesial margins of these peduncles. The narrowed upper end of the velum, the part directly below the inferior quadrigeminate bodies, is thickened into a well-defined white band known as the **frenulum veli.** From the lateral margins of this band on each side and just below the inferior quadrigeminate bodies emerge the **trochlear nerves** (the fourth pair of cranial nerves), and the increased thickness of the band is largely due to the decussation of this pair of nerves taking place within it.

The brachium conjunctivum, together with the inferior and superior colliculi of each side, form a marked ridge which results in the *lateral sulcus* of the mesencephalon, a lateral depression between the base of this ridge and the cerebral peduncle below and continuous into the transverse sulcus at the superior border

FIG. 659.—DIAGRAM OF LATERAL VIEW OF MESENCEPHALON AND ADJACENT STRUCTURES. (After Gegenbaur, modified.)



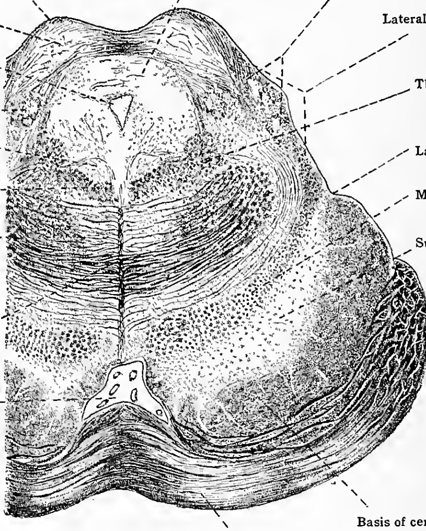
of the pons. The ridge is thickened laterally by the lateral lemniscus, which is disposed as a band of white substance passing obliquely upward from under the brachium pontis, applied to the lateral surface of the brachium conjunctivum and which enters the lateral margin of the mesencephalon. The region at which the lateral lemniscus approaches nearest the surface and in which the largest portion of its nucleus lies is the slightly elevated **trigone of the lemniscus.**

The **ventral surface** of the mesencephalon is formed by the **cerebral peduncles** (crura), two large bundles of white substance which are close to one another at the superior margin of the pons, but immediately diverge somewhat, producing the **interpeduncular fossa,** and in so doing pass upward and lateralward to disappear beneath the optic tracts (fig. 629). The *posterior recess* of the interpeduncular fossa extends slightly under the superior margin of the pons, while its *anterior recess* is occupied by the corpora mammillaria of the prosencephalon. The triangular floor of the fossa is the **posterior perforated substance,** a greyish area presenting numerous openings for the passage of blood-vessels. It is divided by a shallow median groove and is marked off from the medial surface of each peduncle by the *oculomotor sulcus*, out of which emerge the roots of the **oculomotor nerves.** The ventral surface of each peduncle is rounded and has a somewhat twisted appearance, indicating that its fibres curve from above medialward and downward. Sometimes two small, more or less transverse bands of fibres may be noted crossing the peduncle—an inferior, the *tænia pontis*, and a superior, the *transverse pedun-*

cular tract. The inferior represents detached fibres of the pons; the superior, running from the brachium of the inferior quadrigeminate body and disappearing in the oculomotor sulcus, appears to be derived from the quadrigeminate bodies. Since it is well developed in the cat, dog, sheep, and rabbit, but is absent or little marked in the mole, it is supposed to be concerned with the optic apparatus.

Internal structure.—Transverse sections of the mesencephalon throughout are composed of—(1) a *dorsal part,* consisting of the lamina quadrigemina or the grey substance of the corpora quadrigemina, with the strata and bundles of nerve-fibres connected with them, and the abundant central grey substance surrounding the aqueduct; (2) a *tegmental part,* consisting of the upward continuation of the reticular formation of the medulla oblongata and that of the

Fig. 660.—Transverse Section Through the Inferior Quadrigeminate Bodies.



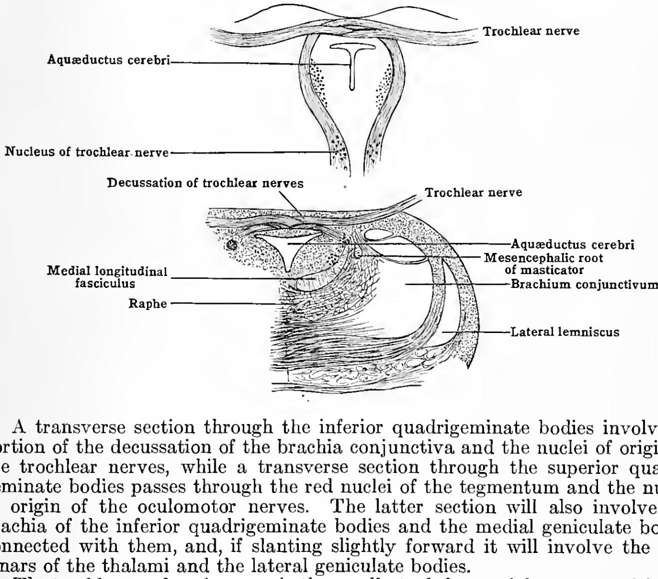
dorsal (tegmental) portion of the pons region, to which are added the superior cerebellar peduncles and the red nuclei of the tegmentum in which these peduncles terminate; (3) a paired *ventral part,* the cerebral peduncles, each of which consists of a thick, pigmented stratum of grey substance, the *substantia nigra,* spread upon the large, superficial, and somewhat crescentic tract of white substance known as the *basis* of the peduncle. The cerebral peduncles correspond to the longitudinal or pyramidal fasciculi of the pons and medulla. Likewise the lemniscus and the medial longitudinal fasciculus of the medulla and pons continue through all sections of the mesencephalon.

The **central grey substance** is a continuation of the central gelatinous substance of the spinal cord and the similar stratum of the medulla and that which immediately underlies the ependyma of the fourth ventricle. As in the spinal cord and medulla, it is largely composed of gelatinous substance. It is much more abundant in the mesencephalon, and in sections appears as a circumscribed area comparatively void of nerve-fibres.

The nucleus of the *mesencephalic root of the masticator nerve* may likewise be traced throughout the mesencephalon. It consists of a few small bundles of fibres surrounding a thin strand of nerve-cells which give origin to its fibres. It courses caudalward close to the lateral margin of the central grey substance, and is quite small at its beginning in the extreme superior part of the mesencephalon, but as it descends toward the exit of its fibres from the pons, it increases slightly in size, due to the progressive addition of fibres. Its nucleus also increases slightly in bulk in approaching the region of the chief motor nucleus of the nerve. As mentioned above, the investigations of Johnston and Willems in lower animals suggest that the cells of the mesencephalic nucleus may be sensory instead of motor in character. The sensory nucleus (nucleus of termination) of the trigeminus tapers rapidly and probably does not extend throughout the mesencephalon.

The nuclei of the *trochlear* and *oculomotor* nerves form a practically continuous column of nerve-cells extending close to the mid-line and ventral to the aqueduct of the cerebrum. They are in line with the nuclei of origin of the abducens and hypoglossus, and, like them, may be regarded as an upward continuation of the ventral group of the cells of the ventral horn of the spinal cord. The portion of the column giving origin to the oculomotor nerve is considerably larger than that for the trochlear.

Fig. 661.—Diagrams showing the Course of Origin of the Trochlear Nerves. (Stilling. The upper figure shows roughly the entire central course of the trochlear nerves; the lower represents their region of exit in transverse section.



A transverse section through the inferior quadrigeminate bodies involves a portion of the decussation of the brachia conjunctiva and the nuclei of origin of the trochlear nerves, while a transverse section through the superior quadrigeminate bodies passes through the red nuclei of the tegmentum and the nuclei of origin of the oculomotor nerves. The latter section will also involve the brachia of the inferior quadrigeminate bodies and the medial geniculate bodies connected with them, and, if slanting slightly forward it will involve the pulvinars of the thalami and the lateral geniculate bodies.

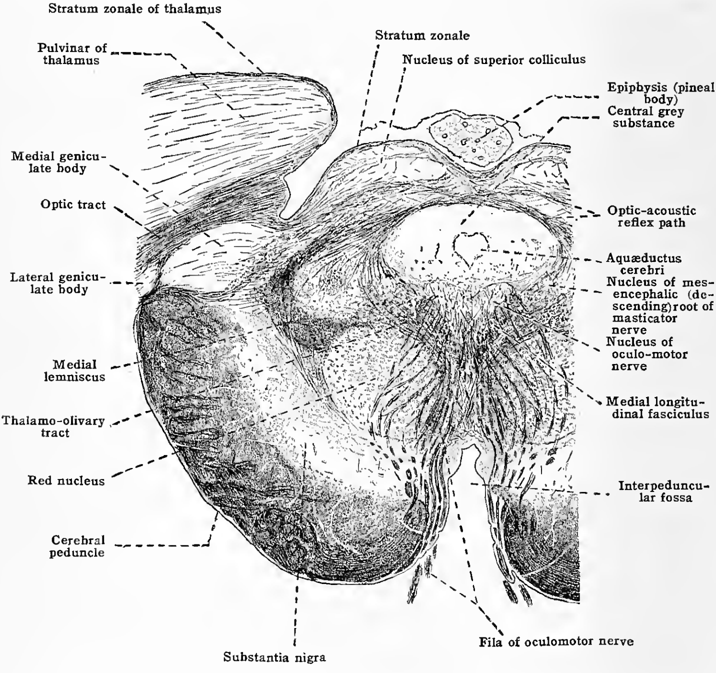
The **trochlear or fourth nerve** is the smallest of the cranial nerves, and is the only one which makes its exit from the dorsal surface of the brain, as well as the only one whose fibres undergo a total decussation.

Its nucleus of origin is situated beneath the inferior quadrigeminate bodies in the ventral margin of the central grey substance, quite close to the mid-line and to its fellow nucleus of the opposite side, and it is closely associated with the dorso-mesial margin of the medial longitudinal fasciculus. Its root-fibres pass lateralward and dorsalward, curving around the margin of the central grey substance, mesial to the mesencephalic root of the masticator nerve. As the root curves toward the mid-line in the dorsal region just beneath the inferior quadrigeminate bodies, it turns sharply and courses inferiorly to approach the surface in the superior portion of the anterior medullary velum, the frenulum veli. In this it meets and undergoes a total decussation with the root of its fellow nerve, and then emerges at the medial margin of the superior cerebellar peduncle of the opposite side. Having emerged, it then passes ventrally around the cerebral peduncle, and thence pursues its course to the superior oblique muscle of the eye. It receives optic impulses from the superior quadrigeminate bodies and impulses from the cerebral cortex of chiefly the same side, and it is associated with the nuclei of other cranial nerves by way of the medial longitudinal fasciculus.

The **oculomotor or third nerve,** like the trochlear, is purely motor. It is the largest of the eye-muscle nerves. It supplies in all seven muscles of the optic apparatus:—two intrinsic, the sphincter iridis and the ciliary muscle, and five extrinsic. Of the latter, the levator palpebræ superioris is of the upper eyelid, while the remaining four, the superior, medial, and inferior recti and the obliquus inferior, are attached to the bulb of the eye. As is to be expected, its nucleus of origin is larger and much more complicated than that of the trochlear nerve.

Practically continuous with that of the trochlear below, the nucleus is 5 or 6 mm. in length and extends anteriorly a short distance beyond the bounds of the mesencephalon into the grey substance by the side of the third ventricle. It lies in the ventral part of the central grey substance, and is very intimately associated with the medial longitudinal fasciculus. Its thickest

FIG. 662.—TRANSVERSE SECTION THROUGH LEVEL OF SUPERIOR QUADRIGEMINATE BODIES.

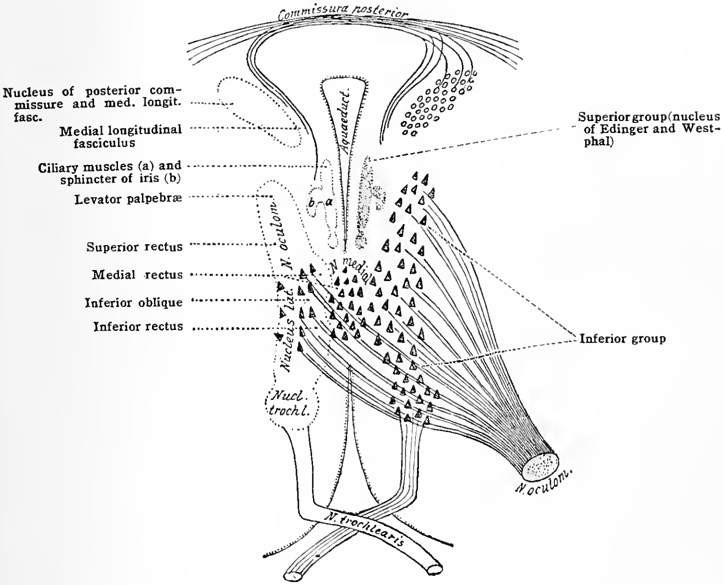


portion is beneath the summit of the superior quadrigeminate body. The root-fibres leave the nucleus from its ventral side and collect into bundles which pass through the medial longitudinal fasciculus and course ventrally to the mesial portion of the substantia nigra, where they emerge in from six to fifteen rootlets which blend to form the trunk of the nerve in the oculomotor sulcus of the cerebral peduncles. Those bundles which arise from the more lateral portion of the nucleus course in a series of curves through and around the substance of the red nucleus below and, in the substantia nigra, join those which pursue the more direct course. The trunk thus assembled passes lateralward around the mesial border of the cerebral peduncle.

A portion of the fibres of the oculomotor nerve upon leaving the nucleus decussate in the tegmentum immediately below and pass into the nerve of the opposite side, in which they are believed to be distributed to the opposite medial rectus muscle. The cells of the nucleus have been variously grouped and subdivided with reference to the different muscles supplied by the nerve. Perlia has divided them into eight cell-groups. The nucleus may be more easily considered as composed of an inferior and a superior medial group. The inferior group consists of a long lateral portion continuous with the nucleus of the trochlear nerve below, and a smaller medial portion, situated in the medial plane and continuous across the mid-line with its fellow of the opposite side. The superior medial group consists of cells of smaller size than the inferior, and is known as the *nucleus of Edinger and Westphal.* It is believed to give origin to the fibres (visceral efferent fibres) which terminate in the ciliary ganglion, axones from which supply the two intrinsic muscles concerned, viz., the ciliary muscle and the sphincter iridis.

The nucleus of the oculomotor is associated with the remainder of the optic apparatus—(1) by way of the neurones of the superior quadrigeminate body with the optic tract (retina) and it receives impulses from the occipital part of the cerebral cortex of the same and the opposite sides, and probably from the motor cortex of the frontal lobe; (2) by way of the medial longitudinal fasciculus with the nuclei of the trochlear and abducens (the latter making possible the co-ordinate action of the lateral and medial recti for the conjugate eye movements produced by these muscles), and with the nucleus of the facial (associating the innervation of the levator palpebræ with that of the orbicularis oculi); (3) with the nuclei of termination of the sensory nerves, especially the auditory, by way of the lateral lemniscus and medial longitudinal fasciculus. It is probably connected with the cerebellum by way of the brachia conjunctiva and red nuclei.

Fig. 663.—Diagram of Longitudinal Section of Nucleus of Oculomotor Nerve. (After Edinger.)



The eminence representing the **inferior quadrigeminate body** proper consists of an oval mass of grey substance, the *nucleus of the inferior colliculus*, containing numerous nerve-cells, most of which are of small size. A thin superficial lamina of white substance, the **stratum zonale,** forms its outermost boundary, and fibres from the lateral lemniscus enter it laterally and from below (*stratum lemnisci*). Near the lateral margin of the central grey substance occurs the beginning of the *inferior brachium*, a bundle containing fibres to and from the medial geniculate body and the inferior quadrigeminate body.

The **lemniscus** in the mesencephalon is considered in two parts. The more lateral portion of the lemniscal plate occuring in the pons has here spread dorso-laterally, and occupies a position in the lateral margin of the section, and is known as the **lateral lemniscus,** while the medial portion which remains practically unchanged in the tegmentum is distinguished as the **medial lemniscus.** (See fig. 660). In the upper portion of the lateral lemniscus occurs a small, scattered mass of grey substance, the *nucleus of the lateral lemniscus*, in which many of its fibres are interrupted.

The upper and greater portion of the **lateral lemniscus** with its nucleus belongs to the auditory apparatus, being connected with the nucleus of termination of the cochlear nerve, chiefly of the opposite side. (See fig. 650.) A large part of the fibres of this portion terminate in the inferior quadrigeminate bodies. Many of the latter enter at once the nucleus of the body (nucleus of inferior colliculus) of the same side, and disappear among its cells; others cross the mid-line to the quadrigeminate body of the opposite side. In crossing, some pass superficially and thus contribute to the stratum zonale, while others pass either through the nucleus or below it and cross beneath the floor of the median groove between the stratum zonale and the dorsal surface of the central grey substance, forming there an evident decussation with similar fibres crossing from the opposite side. Most of the fibres arising from the cells of the nucleus of the inferior quadrigeminate body pass by way of the inferior brachium to the medial geniculate body and the thalamus; some pass ventrally to terminate in the nucleus of origin of the trochlear nerve and some pass forward and laterally to terminate in the cortex of the superior gyrus of the temporal lobe, the cortical area of hearing. Another portion of the lateral lemniscus passes obliquely forward in company with the inferior brachium, and terminates in the medial geniculate body. Thus a large portion of the lateral lemniscus, the inferior quadrigeminate bodies with their brachia and the medial geniculate bodies are concerned with the sense of hearing. The nucleus of the inferior quadrigeminate body receives fibres which arise in the cortex of the superior temporal gyrus of chiefly the same side.

Practically all the remainder of the lateral lemniscus terminates in the nucleus, or stratum cinereum, of the superior quadrigeminate body of the same and opposite sides. They approach the nucleus from below, and contribute to the well-marked band of fibres coursing on the dorso-lateral margin of the central grey substance, and known as the '*optic-acoustic reflex path*' or *stratum lemnisci* (fig. 662).

The **medial lemniscus** arises in the medulla oblongata from the nuclei (of termination) of the funiculus gracilis and funiculus cuneatus of the opposite side, and likewise from the nuclei of termination of the sensory roots of the cranial nerves of the opposite side. It is, therefore, a continuation of the central sensory pathway conveying the general bodily (including the head) sensations into the prosencephalon. Coursing still more laterally than in the pons below, it passes into the hypothalamic grey substance, in the lateral portion of which most of its fibres terminate. By axones given off from the cells of the hypothalamic nucleus the impulses borne thither by the lemniscus are conveyed by way of the internal capsule and corona radiata to the gyri of the somæsthetic area of the cerebral cortex.

The **basis** (pes) **pedunculi** comprises the great descending pathway from the cerebral cortex, and thus is continuous with the internal capsule of the telencephalon.

The principal components of each basis pedunculi are as follows:—(1) The *pyramidal fibres*, which occupy the middle portion of the peduncle and comprise three-fifths of its bulk, and which are outgrowths of the giant pyramidal cells of the somæsthetic area of the cerebral cortex, chiefly the anterior central gyrus. These supply 'voluntary' impulses to the motor nuclei of the cranial nerves on the opposite side, form the pyramids of the medulla, and are distributed to the ventral horn cells of the spinal cord of the opposite side. (2) The *frontal pontile fibres*, which course in the mesial part of the peduncle from the cortex of the frontal lobe to their termination in the grey substance of the pons. (3) The *occipital and temporal pontile fibres*, which run in the ventral and lateral portion of the peduncle from their origin in the occipital and temporal lobes to their termination in the grey substance of the pons.

The **substantia nigra** is continuous with the grey substance of the pons and that of the reticular formation below, and with that of the hypothalamic region above. Its remarkable abundance begins at the superior border of the pons, and it conforms to the crescentic inner contour of the cerebral peduncle, sending numerous processes which occupy the inter-fascicular spaces of the latter. It contains numerous deeply pigmented nerve-cells, which in the fresh specimen give the appearance suggesting its name.

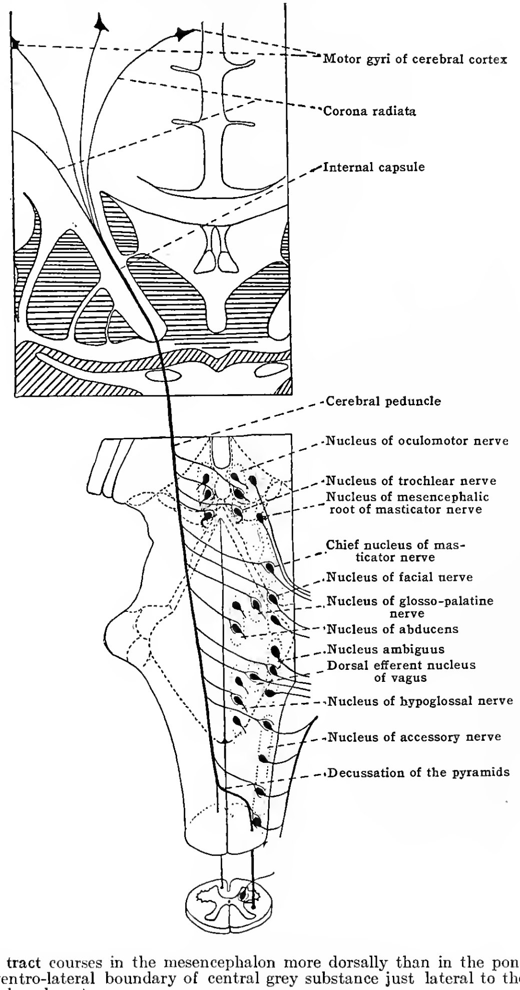
Its anatomical significance is not well understood. It is known that some fibres of the medial lemniscus terminate about its cells instead of in the hypothalamus higher up, and Mellus has found in the monkey that a large portion of the pyramidal fibres arising in the thumb area of the cerebral cortex are interrupted in the substantia nigra. It is probable that other fibres of the peduncle also terminate here.

The **brachia conjunctiva** or superior cerebellar peduncles, in passing from their origin in the dentate nuclei, lose their flattened form and enter the mesencephalon as rounded bundles. In the tegmentum, under the inferior colliculi, the two brachia come together and undergo a sudden and complete decussation. Through this decussation the fibres of the brachium of one side pass forward to terminate, most of them, in the red nucleus [nucleus ruber] of the tegmentum of the opposite side (fig. 589). Some fibres are said to pass the red nucleus and terminate in the ventrolateral part of the thalamus.

The **red nuclei** are two large, globular masses of nerve-cells situated in the tegmentum under the superior quadrigeminate bodies. At all levels they are considerably mixed with the entering bundles of the brachia conjunctiva, and they contain a pigment which in the fresh condition gives them a reddish colour, suggesting their name.

They receive in addition descending fibres from the cerebral cortex (frontal operculum) and from the nuclei of the corpus striatum. From the cells of each red nucleus arise fibres which pass—(1) into the thalamus and to the telencephalon (prosencephalic continuation of the cerebellar path), and (2) fibres which descend into the spinal cord, the 'rubro-spinal tract,' in the lateral funiculus (fig. 619). The latter cross from the red nucleus of the opposite side and descend in the tegmentum. The red nuclei are also in relation with the *fasciculus retroflexus* of Meynert, which belongs to the inter-brain.

Fig. 664.—Scheme to Illustrate the Principal or Crossed Relations of the Descending Cortical (Pyramidal) Fibres to the Nuclei of Origin of the Cranial Nerves.



The **thalamo-olivary tract** courses in the mesencephalon more dorsally than in the pons region. It runs in the ventro-lateral boundary of central grey substance just lateral to the nuclei of the trochlear and oculomotor nerves.

A small *quadrigemino-pontile* strand of fibres has been described as arising in the quadrigemina, especially the inferior pair, and terminating in the nuclei of the pons. Impulses carried by these fibres are probably destined for the cerebellar hemisphere of the opposite side.

The **superior quadrigeminate bodies (superior colliculi)** are phylogenetically more important than the inferior. In certain of the lower vertebrates they are enormously developed and in most of the mammals they are relatively larger and appear more complicated in structure than in man. They are concerned almost wholly with the visual apparatus, mediating most of the reflexes with which it is concerned.

The *nucleus* of the superior colliculus is of somewhat greater bulk than that of the inferior. It is capped by a strong *stratum zonale* (fig. 662), which has been described as composed chiefly of retinal fibres, passing to it from the optic tract by way of the superior brachium, but, since Cajal found in the rabbit that extirpation of the eye is followed by very slight degeneration of the stratum zonale, it is probable that it is composed of other than retinal fibres—possibly fibres from the occipital cortex and fibres arising within the nucleus itself. The nucleus is separated from the central grey substance by a well-marked band of fibres, the *stratum album profundum.* This contains fibres from two sources:—(1) fibres from the lateral lemniscus which approach the nucleus from the under side, some to terminate within it, others to cross to the nucleus of the opposite side; (2) fibres which arise within the nucleus and course ventrally around the central grey substance, both to terminate in the nucleus of the oculomotor nerve and to join the medial longitudinal fasciculus and pass probably to the nuclei of the trochlear and abducens. The lemniscus fibres often course less deeply than (2) and give the *stratum lemnisci.* The optic fibres proper approach the nucleus by way of the *superior brachium,* and are dispersed directly among its cells; only a small proportion of them cross over to terminate in the nucleus of the opposite side. They consist of two varieties:—(1) retinal fibres which arise in the ganglion-cell layer of the retina and enter the superior brachium at its junction with the lateral root of the optic tract, and (2) fibres from the visual area of the occipital lobe of the cerebral hemisphere. Sometimes the optic fibres in their course within the nucleus of the superior colliculus form a more or less evident stratum near the stratum album profundum. This is known as the *stratum opticum* (stratum album medium). The portion of the nucleus between this stratum and the stratum zonale is called the *stratum cinereum.*

The fibres entering the nucleus from the lateral lemniscus probably all represent auditory connections. The stratum album profundum, composed of the lemniscus fibres and fibres from cells of the nucleus, and the stratum opticum together, form the so-called **'optic-acoustic reflex path'** (fig. 662).

The **mesencephalo-spinal** amd the **spino-mesencephalic** (spino-tectal) paths course together ventro-lateral to the nuclei of the colliculi. In the superior quadrigeminate bodies they course in the dorsal edge of the median lemniscus, between the stratum opticum and stratum album profundum.

From the various studies that have been made it appears that the superior colliculus of the corpora quadrigemina is merely the central reflex organ concerned in the control of the eye muscles—eye muscle reflexes which result from retinal and cochlear stimulation, and from some general body sensations by way of the spinal cord. Fibres from its nucleus to the visual area of the occipital cortex have been claimed for certain mammals, but in man the superior colliculus may be entirely destroyed without disturbance of the perception of light or color and fibres arising from its nucleus to terminate in the cerebral cortex are denied.

In the level of the anterior part of the superior colliculus the fibres which arise from the cells of its nucleus and course ventrally in the stratum album profundum collect into a strong bundle. This bundle passes ventral to the medial longitudinal fasciculus and, in the space between the two red nuclei, it forms a dense decussation with the similar bundle from the opposite side. In decussating the fibres turn in spray-like curves downward and soon join the medial longitudinal fasciculus. This is the **'fountain decussation'** of Forel. It is said to be augmented by decussating fibres from the two red nuclei.

There is abundant evidence that fibres arising in the corpora quadrigemina descend into the spinal cord. Various studies make it appear that at least part of these are fibres from the fountain decussation, and that these course through the medulla oblongata in the ventral part of the medial longitudinal fasciculus, and thence descend into the cord in the 'quadrigemino-thalamus path' (lateral mesencephalo-spinal tract) (fig. 619). The medial longitudinal fasciculus is continuous with the ventral fasciculus proprius of the spinal cord and most of these fibres arising in the superior quadrigeminate bodies retain their ventral position in the cord as the sulco-marginal fasciculus of the opposite side. Their termination about those ventral horn cells of the cervical cord which send fibres through the rami communicantes probably establishes the pathway by which the superior quadrigeminate bodies are connected with the cervical sympathetic ganglia, and by which may be explained the disturbances in pupillary contraction induced by lesions of the lower cervical cord.

The medial geniculate body and the medial root of the optic tract, which runs into the former, probably have nothing to do with the functions of the optic apparatus. Both remain intact after extirpation of the eyes. The medial root of the optic tract is apparently nothing more than the beginning of the *inferior cerebral* (*Gudden's*) *commissure,* a bundle passing by way of the optic tract, connecting the medial geniculate body of one side with that of the other side, and probably with the inferior colliculus.

The **medial longitudinal fasciculus** (posterior longitudinal fasciculus), continuous into the ventral fasciculus proprius and the sulco-marginal fasciculus of the spinal cord, extends throughout the rhombencephalon and mesencephalon, and is represented in the hypothalamic region of the prosencephalon. Deserted by the lemniscus at the inferior border of the pons, it maintains its closely medial position and courses throughout in the immediate ventral margin of the central grey substance of the medulla and floor of the fourth ventricle, and likewise in the ventral margin of the central grey substance of the mesencephalon.

The two fasciculi constitute the principal association pathways of the brain-stem, and, true to their nature as such, they are among the first of its pathways to acquire medullation. In the mesencephalon they become two of its most conspicuous tracts, and their course, in most intimate association with the nuclei of origin of the nerves supplying the eye muscles, suggests what is probably one of their most important functions, viz., that of associating these nuclei with each other and of bearing to them fibres from the nuclei of the other cranial nerves necessary for the co-ordinate action of the muscles of the optic apparatus associated with the functions of these other nerves.

Fibres from each medial longitudinal fasciculus terminate either by collaterals or terminal arborisations about the cells of the motor nuclei of all the cranial nerves, and each nucleus probably contributes fibres to it. It also receives fibres from the nuclei of termination of the sensory nerves especially the vestibular. Thus it contains fibres coursing in both directions, and, while it is continually losing fibres by termination, it is being continually recruited and so maintains a practically uniform bulk. Thus, a given lesion never results in its total degeneration. Many of the fibres coursing in it arise from the opposite side of the mid-line. A special contribution of fibres of this kind is received by way of the fountain decussation from the nucleus of the superior colliculus of the opposite side. As noted above, it is in part continuous into the spinal cord as the ventral fasciculus proprius. It receives some fibres by way of the posterior commissure of the prosencephalon from a small nucleus common to it and the posterior commissure situated in the superior extension of the central grey substance of the mesencephalon. Van Gehuchten and Edinger describe for it a special *nucleus of the medial longitudinal fasciculus* situated beyond this commissure in the hypothalamic rsgion. This nucleus may be explained as an accumulation of the gray substance of the reticular formation below and as receiving impulses from the structures of the prosencephalon which are distributed by its axones to the structures below by way of the medial longitudinal fasciculus.

Scattered in the posterior part of the posterior perforated substance, near the superior border of the pons, is a small group of cell-bodies forming the **inter-peduncular nucleus** (inter-peduncular ganglion of von Gudden). Fibres arising in the habenular nucleus of the diencephalon curve posteriorly, forming the *fasciculus retroflexus of Meynert*, and terminate about its cells. Fibres arising from its cells course dorsalward and terminate about association neurones in the ventral periphery of the central grey substance. It is concerned with olfactory impulses.

SUMMARY OF THE MESENCEPHALON

1. Quadrigeminate bodies:
   (*a*) Inferior colliculi, their nuclei and brachia.
   (*b*) Superior colliculi, their nuclei and brachia.
2. Peduncles of the cerebrum
3. Aqueduct of the cerebrum.
4. Central grey substance.
5. Substantia nigra.
6. Decussation of superior cerebellar peduncles and the red nuclei.
7. Medial lemniscus, lateral lemniscus and nucleus of lateral lemniscus.
8. Mesencephalic nucleus and root of masticator nerve.
9. Trochlear nerve and its nucleus.
10. Oculomotor nerve and its nucleus.
11. Mesencephalo-spinal and rubro-spinal tracts.
12. Medial longitudinal fasciculus, its nucleus, the nucleus of the posterior commissure.
13. The fountain decussation.
14. Interpeduncular nucleus.

As frequently realized in the above, the structures of the mesencephalon are both overlapped by, and are of necessity functionally continuous with, the structures of the next and most anterior division of the encephalon, the prosencephalon.

2. THE PROSENCEPHALON

The **prosencephalon** or **fore-brain** includes those portions of the encephalon derived from the walls of the anterior of the three embryonic brain-vesicles. In its adult architecture it consists of—(1) the **diencephalon (interbrain)**, comprising the thalamencephalon or the thalami and the structures derived from and immediately adjacent to them, and, in addition, the mammillary portion of the hypothalamic region; (2) the **telencephalon (end-brain)**, comprising the optic portion of the hypothalamic region and the cerebral hemispheres proper. The last mentioned consist of the entire cerebral cortex or superficial mantle of grey substance, including the rhinencephalon, and also the basal ganglia or buried nuclei (corpus striatum), together with the tracts of white substance connecting and associating the different regions of the hemispheres with each other and with the structures of the other divisions of the central nervous system.

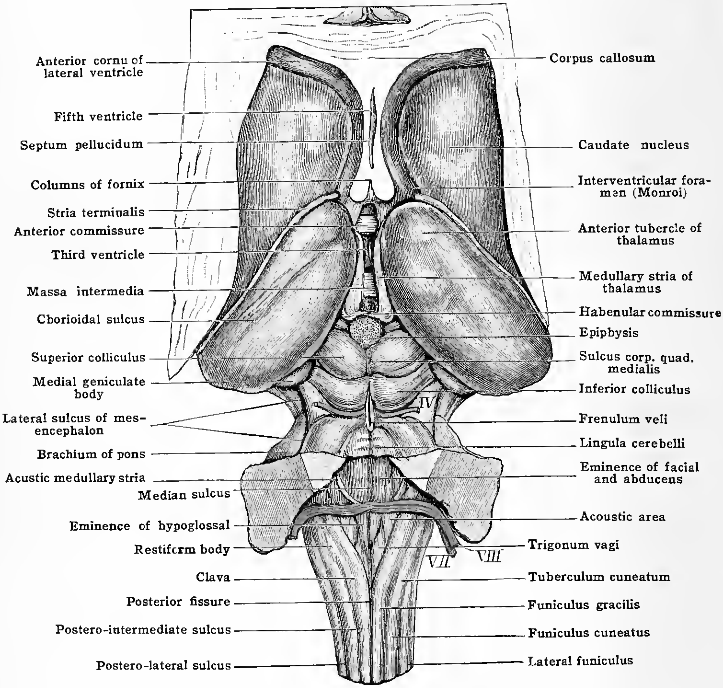
EXTERNAL FEATURES OF THE PROSENCEPHALON

A. THE DIENCEPHALON.—The *basal surface* of this division of the brain consists of only the mammillary portion of the hypothalamic region (fig. 668).

This comprises—(1) the mammillary bodies [**corpora mammillaria**] (albicantia), the two rounded projections situated in the anterior part of the interpeduncular fossa, and (2) the anterior portion of the **posterior perforated substance** or the small triangle of grey substance forming the floor of the posterior part of the third ventricle, and which represents numerous openings for the passage of branches of the posterior cerebral arteries (fig. 668). The hypothalamic portions of the cerebral peduncles might be included. The structures of the optic or remaining portion of the hypothalamus belong to the telencephalon.

The upper or *dorsal surface* of the diencephalon is completely overlapped and hidden by the telencephalon, and covered by the intervening ingrowth of the

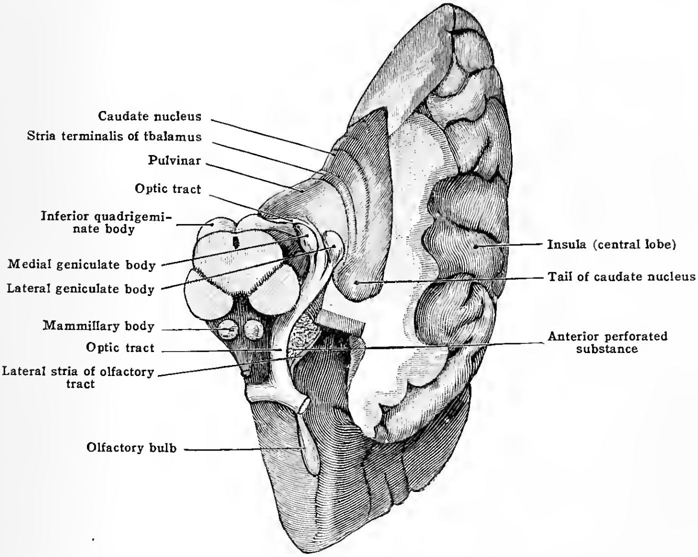
FIG. 665.—DORSAL SURFACE OF DIENCEPHALON WITH ADJACENT STRUCTURES. (After Obersteiner.)



cerebral meninges, the tela chorioidea of the third ventricle (velum interpositum). These removed (fig. 665), it is seen that the thalami on either side are by far the most conspicuous objects of the diencephalon. They, together with the parts developed in connection with them, are distinguished as the **thalamencpehalon.** The thalamencephalon consists of—(1) the *thalami;* (2) the *metathalamus* or geniculate bodies; and (3) the *epithalamus*, comprising the *epiphysis* with the posterior commissure below it and the habenular trigone on either side.

The **thalami** are two ovoid, couch-like masses of grey substance which form the lateral walls of the third ventricle. The cavity of the ventricle is narrow, and quite frequently the thalami are continuous through it across the mid-line by a small but variable neck of grey substance, the **massa intermedia** ("middle commissure"). The upper surfaces of the thalami are free. The edges of the tela chorioidea of the third ventricle are attached to the lateral part of the surface of each thalamus, and, when removed, leave the *tœnia chorioidea* lying in the chorioidal sulcus. Each thalamus is separated laterally from the caudate nucleus of the telencephalon, by a linear continuation of the white substance below, known as the **stria terminalis thalami** (tænia semicircularis). Like the quadrigemina, each thalamus is covered by a thin capsule of white substance, the **stratum zonale.** The average length of the thalamus is about 38 mm., and its width about 14 mm.; its inferior extremity is directed obliquely lateralward. The dorsal surface usually shows four eminences, indicating the position of the so-called nuclei of the thalamus within. These are the anterior nucleus or *anterior tubercle*, the *medial nucleus* or tubercle, the *lateral nucleus*, and the *pulvinar*, the tubercle of the posterior extremity. The pulvinar of the human brain is peculiar in the fact that it is so developed as to project inferiorly and slightly overhang the level of the quadrigeminate bodies. The projecting portion assumes relations with the optic tract and the metathalamus.

FIG. 666.—DISSECTION OF BRAIN SHOWING METATHALAMUS AND PULVINAR WITH ADJACENT STRUCTURES.

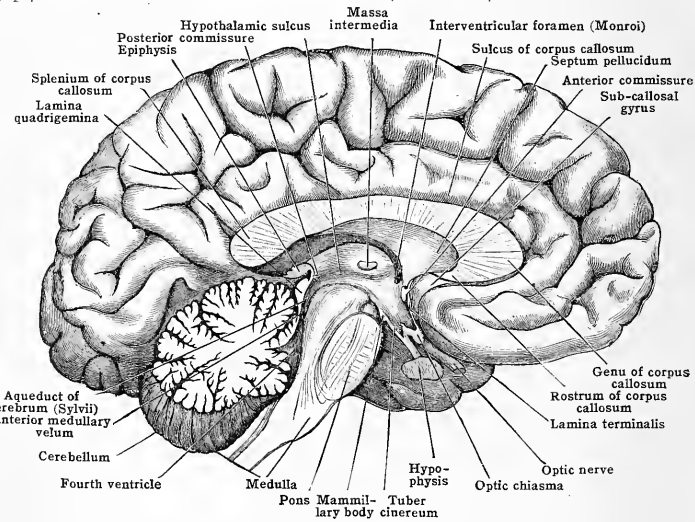


Both the structures of the **metathalamus,** the lateral and medial geniculate bodies, are connected with the optic tract, but it is thought that actual visual axones terminate only in the lateral genticulate body. As the optic tract curves around the cerebral peduncle it divides into two main roots. The *lateral geniculate body* receives a small portion of the fibres of the lateral root of the optic tract; the remainder pass under this body and enter the pulvinar of the thalamus. The *medial geniculate body* is connected with the medial root of the optic tract, which root consists largely, not of retinal fibres, as does the lateral root, but of the fibres forming Gudden's commissure (the inferior cerebral commissure). The retinal fibres contained in the medial root pass to terminate in the superior quadrigeminate bodies.

Of the **epithalamus,** the *epiphysis* (pineal body, conarium) is the most conspicuous external feature. This is an unpaired, cone-shaped structure, about 7 mm. long and 4 mm. broad, which also projects upon the mesencephalon so that its body rests in the groove between the superior quadrigeminate bodies. Its stem is attached in the mid-line at the posterior extremity of the third ventricle, and therefore just above the posterior commissure of the cerebrum (fig. 658). It is covered by pia mater, and is involved in a continuation of the tela chorioidea of the third ventricle. Though it develops as a diverticulum of that portion of the anterior primary vesicle which gives origin to the thalamencephalon, it is wholly a non-nervous structure, other than the sympathetic fibres which enter it for the supply of its blood-vessels.

It consists of a dense capsule of fibrous tissue (pia mater) from which numerous septa pass inward, dividing the interior into a number of intercommunicating compartments filled with epithelial (ependymal) cells of the same origin as the ependyma lining the ventricles and aqueduct below. Among these cells are frequently found small accretions (brain-sand, acervulus cerebri), consisting of mixed phosphates of lime, magnesia, and ammonia and carbonates of lime. The compartments form a closed system. In function the epiphysis ranks as one of the glands of internal secretion of the body, and it is often referred to as the 'pineal gland.' However, it is perhaps functionless in man.

Fig. 667.—Mesial Section of Entire Brain, showing Mesial Surface of Diencephalon and Telencephalon. (After Henle.)



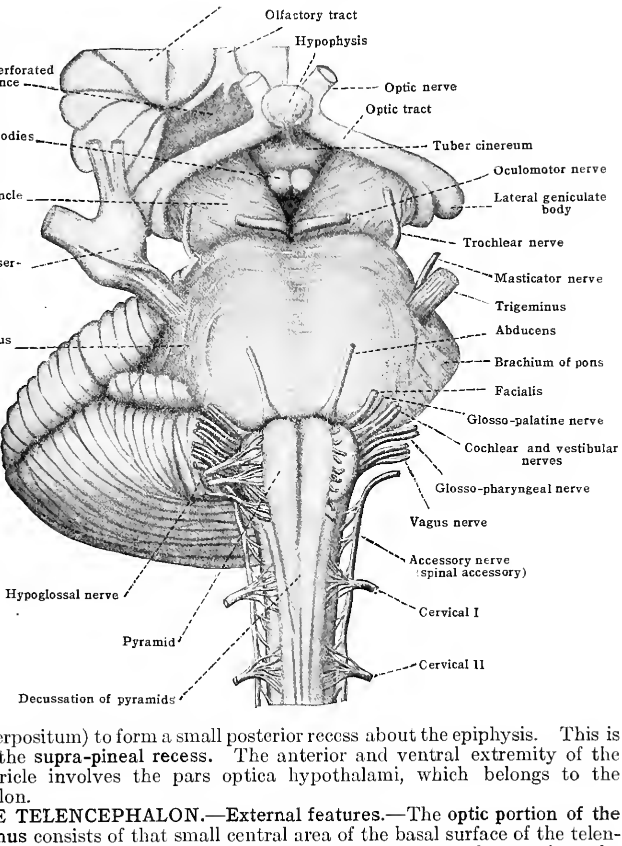
Apparently arising from the base of the epiphysis, but having practically nothing to do with it, are the **striæ medullares of the thalamus** (striæ pineales, pedunculi conarii, tænia thalami, habenulæ). These are two thin bands of white substance which extend from under the epiphysis anteriorly upon the thalamus, along the superior border of each lateral wall of the third ventricle, and thus form the boundaries between the superior and mesial surfaces of each thalamus.

They have been called the *habenulæ*, from their relation to the habenular nucleus, situated in the mesial grey substance at their inferior ends. They are continuous across the mid-line in the *habenular commissure*, just below the neck of the epiphysis, and between it and the posterior cerebral commissure, or, rather the superior part of the latter (figs. 631, 665). It will be seen below that each habenula contains olfactory fibers from the fornix, the anterior perforated substance and the septum pellucidum, as well as fibres out of the thalamus, and that most of its fibres terminate in the habenular nucleus.

The ventro-lateral surface of the thalamencephalon is continuous into the hypothalamic tegmental region, the upward continuation of the tegmental grey substance of the mesencephalon. It is also adjacent to a portion of the internal capsule. Both these relationships, as well as the fibre connections of the diencephalon with the structures above and below it, are deferred until the discussion of the internal structure of the prosencephalon.

The **mesial surface** of the diencephalon (fig. 667), allows a better view of the shape and relations of the **third ventricle.** Below the line of the massa intermedia the ventricle is usually somewhat wider than it is along the upper margins of the thalami. This greater width is occasioned by a groove in the ventromesial surface of each thalamus, known as the **hypothalamic sulcus** (sulcus of Monro). It is along the line of this sulcus that the third ventricle is continuous with the aqueduct of the cerebrum, and thus with the fourth ventricle below, and, likewise, with the two lateral ventricles of the cerebral hemispheres at its anterior end. The latter junction occurs through a small oblique aperture, the **interventricular foramen** (foramen of Monro), one into each lateral ventricle. The dorsal or upper portion of the third ventricle extends posteriorly beneath its chorioid tela

Fig. 668.—Ventral Aspect of Brain-stem Including Mammillary and Optic Portions of the Hypothalamus.



(velum interpositum) to form a small posterior recess about the epiphysis. This is known as the **supra-pineal recess.** The anterior and ventral extremity of the third ventricle involves the pars optica hypothalami, which belongs to the telencephalon.

B. THE TELENCEPHALON.—External features.—The **optic portion of the hypothalamus** consists of that small central area of the basal surface of the telencephalon which includes and surrounds the **optic chiasma,** and comprises the structures of the floor of the anterior and ventral portion of the third ventricle. The area extends anteriorly from the mammillary bodies in the interpeduncular fossa, and includes the **tuber cinereum** and **hypophysis** behind the optic chiasma, and some of the **anterior perforated substance** in front of it.

The most anterior portion of the third ventricle is in the form of a ventral extension. The wall of this portion is almost wholly non-nervous and quite thin, and thus the cavity of the ventricle is but thinly separated from the exterior of the brain. The front portion of this wall is the **lamina terminalis** and in the ventricular side of the upper part of this lamina the **anterior commissure** of the cerebrum is apparent.

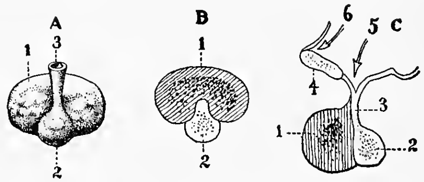
The **optic chiasma** lies across and presses into the lower portion of the lamina terminalis, and in so doing produces an anterior recess in the cavity of the ventricle known as the **optic recess.** Behind the optic chiasma the floor of the third ventricle bulges slightly, giving the outward appearance known as the **tuber cinereum,** and the cavity bounded by this terminates in the **infundibular recess.**

The **tuber cinereum** then is a hollow, conical projection of the floor of the third ventricle, between the corpora mammillaria and the optic chiasma. Its wall is continuous anteriorly with the lamina terminalis and laterally with the anterior perforated substance.

The **infundibulum** is but the attenuated apex of the conical tuber cinereum, and forms the neck connecting it with the hypophysis. It is so drawn out that it is referred to as the stalk of the hypophysis. The cavity of the tuber cinereum (infundibular recess) is sometimes maintained throughout the greater part of the length of the infundibulum, giving it the form of a long-necked funnel. Near the hypophysis the cavity is always occluded.

FIG. 669.—DIAGRAMS OF THE HYPOPHYSIS CEREBRI. (After Testut.)

A, posterior surface; B. transverse section; C, sagittal section; 1, anterior lobe; 2, posterior lobe; 3, infundibulum; 4, optic chiasma; 5, infundibular recess; 6, optic recess. In C the infundibulum is relatively much shorter than in the actual specimen.



The **hypophysis cerebri** (pituitary body or gland) is an ovoid mass terminating the infundibulum. It lies in the sella turcica of the sphenoid bone, where it is held down and roofed in by the *diaphragma sellæ,* a spheroid pocket of the dura mater. It consists of two lobes, a large *anterior lobe,* the glandular or buccal lobe, and a smaller *posterior* or *cerebral lobe.* The posterior lobe is usually enclasped in a concavity of the anterior lobe.

Development.—The posterior or cerebral lobe alone is originally continuous with and a part of the infundibulum. It alone represents the termination of the hollow diverticulum which, in the embryo, grows downward from that part of the anterior cerebral vesicle which later becomes the third ventricle. The original cavity afterward becomes obliterated except in the upper part of the infundibulum. It is, therefore, of cerebral origin. The anterior or buccal lobe arises quite differently. It is developed from an upward tubular diverticulum (Rathke's pouch) of the primitive buccal cavity. In the higher vertebrates, including man, its connection with the buccal cavity becomes obliterated as the cartilaginous base of the cranium is consolidated, but in the myxinoid fishes the connection remains patent in the adult. Cut off within the cranial cavity, the embryonic buccal lobe assumes its intimate association with the cerebral lobe. In about the second month of fetal life it begins to develop numerous secondary diverticula which become the epithelial structures evident in the adult human subject.

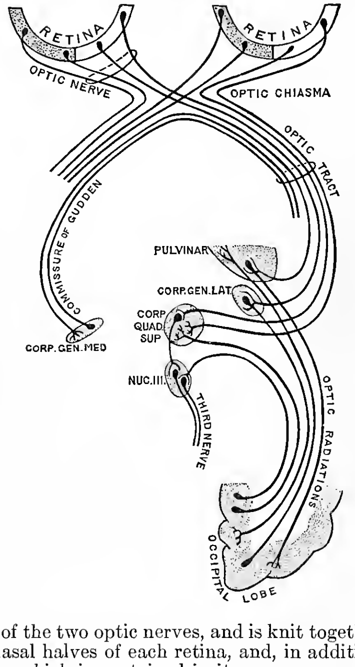
Structure.—The posterior or cerebral lobe retains no organized structure. It may be said to consist of a mass of neuroglia and other fibrous connective tissue with the cells belonging to these and a moderate supply of blood-vessels, with some sympathetic cell-bodies and fibres for the blood-vessels. The anterior or glandular lobe is probably the functional part of the organ. In addition to its abundant supporting tissue, it consists of compartments lined with two kinds of cuboidal cells—cells of different size and different staining properties. The *principal* or more numerous cells are smaller, with thickly granular cytoplasm. In mixtures containing orange G and fuchsin these cells stain orange, while the *chromophile cells,* the larger and less numerous variety, take the fuchsin deeply. The compartments have an abundant blood supply. Near the interlobar septum, the cells frequently are arranged to form small vesicles which contain colloid substance, resembling the typical structure of the thyreoid body.

Like the epiphysis, the hypophysis must be regarded as glandular—a gland with internal secretion. In the case of giants and in acromegaly it is usually greatly enlarged. The principal cells increase greatly in number after removal of the thyreoid body.

The fundaments of the **optic nerve** are derived from this portion of the telencephalon, though the nuclei of termination of its fibres are located in the thalamencephalon and mesencephalon. The optic apparatus consists of the retinæ and optic nerves, the optic chiasma, the optic tracts, the superior quadrigeminate bodies with their relations with the nuclei of the eye-moving nerves, the metathalamus, the pulvinar of the thalamus, and the visual area of the cerebral cortex of the occipital lobe. The fibres of the optic nerves arise from the cells of the ganglion-cell layer of the retinæ. The fibres which arise in the mesial or nasal halves of each retina cross the mid-line to find their nuclei of termination in the central grey substance of the opposite side, while those from the outer or lateral halves terminate on the same side (fig. 670.)

The **optic chiasma** (optic commissure) is functionally independent of the structures of the optic portion of the hypothalamus adjacent to it. It is formed by the

Fig. 670.—Diagram of the Principal Components of the Optic Apparatus. (After Cunningham.)



approach and fusion of the two optic nerves, and is knit together by the decussating fibres from the nasal halves of each retina, and, in addition, by the fibres of Gudden's commissure which is contained in it.

Beyond the chiasma the optic fibres continue as the **optic tracts** which course posteriorly around the cerebral peduncles to attain their entrance into the thalamenchephalon and mesencephalon. Upon reaching the pulvinar of the thalamus each optic tract divides into two roots, a lateral and mesial.

The *lateral root* contains practically all of the true visual fibres—fibres arising from the latera half of the retina of the same side and the nasal half of the retina of the opposite side. These fibres are distributed to three localities:—(1) part of them terminate in the lateral geniculate body; (2) the greater portion pass over and around the lateral geniculate body and enter the pulvinar; (3) a considerable portion enter the superior quadrigeminal brachium and course in it to terminate in the nucleus of the superior quadrigeminate body. The most evident function of this latter portion is to bear impulses which, by way of the neurones of the quadrigeminate body, are distributed to the nuclei of the oculomotor, trochlear, and abducent nerves, and thus mediate eye-moving reflexes. The cells of the lateral geniculate body and the pulvinar, about which the retinal fibres terminate, give off axones which terminate in the cortex of the visual area, chiefly the gyri about the calcarine fissure of the occipital lobe. In reaching this area they curve upward and backward, coursing in a compact band of white substance known as the optic radiation (radiatio occipito-thalamica, fig. 699). Whether any fibres of the optic radiation arise in the superor quadrigeminate body is doubtful. It also is in large part composed of fibres arising from the cells of the visual area, which pass from the cortex to the pulvinar, superior quadrigeminate bodies, and possibly some to the medulla oblongata and spinal cord.

The *mesial root* of the optic tract contains few true visual fibres. It runs into the medial geniculate body, and neither it nor this body are appreciably affected after extirpation of both eyes. It may be considered as largely representing the fibres of **Gudden's commissure** (inferior cerebral commissure). This commissure consists of fibres which connect the medial geniculate bodies of the two sides with each other, and which, instead of crossing the mid-line through the mesencephalon, course in the optic tracts and cross by way of the posterior portion of the optic chiasma. It consists of fibres which both arise and terminate in each of the bodies, and, therefore, of fibres coursing in both directions. It is also claimed that the fibres of Gudden's commissure connect the medial geniculate body of each side with the inferior colliculus of the opposite side.

THE CEREBRAL HEMISPHERES

The cerebral hemispheres in man form by far the largest part of the central nervous system. Together, when viewed from above, they present an ovoid surface, markedly convex upward, which corresponds to the inner surface of the vault of the cranium. The greater transverse diameter of this surface lies posteriorly in the vicinity of the parietal eminences of the cranium. The outline of the superior aspect varies according to the form of the cranium, being more spheroidal in the brachycephalic and more ellipsoidal in the dolichocephalic forms. The hemispheres are separated from each other superiorly by a deep median slit, the **longitudinal fissure,** into which fits a duplication of the inner layer of the dura mater known as the falx cerebri. The posterior or occipital extremities of the hemispheres overlap the cerebellum, and thus entirely conceal the mesencephalon and thalamencephalon. They are separated from the superior surface of the cerebellum and the corpora quadrigemina by the deep **transverse fissure.** This is occupied by the tentorium cerebelli, which is similar to and continuous with the falx cerebri and is connected with the tela chorioidea of the third ventricle below.

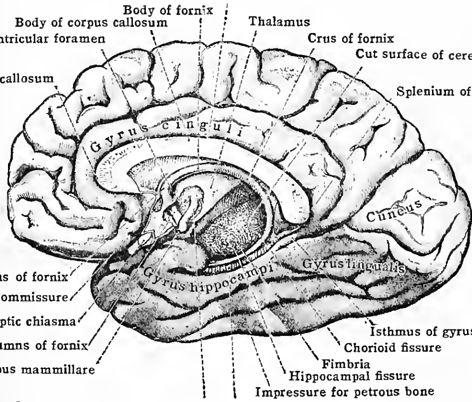
Each of the hemispheres is usually described as having three poles or projecting extremities, and three surfaces bounded by intervening borders. The most anterior projection is the **frontal pole.** This is near the mid-line, and with its fellow of the other hemisphere, forms the frontal end of the ovoid contour of the cerebrum. The **occipital pole** is the most projecting portion of the posterior and inferior end, and is more pointed than the frontal pole. The infero-lateral portion of the hemisphere is separated anteriorly by the deep **lateral fissure** (fissure of Sylvius) into a distinct division, the temporal lobe, and the anterior portion of this lobe projects prominently forward and is known as the **temporal pole.**

The **surfaces** of the hemisphere are—(1) the lateral or *convex surface;* (2) the *medial surface;* and (3) the *basal surface.* The convex surface comprises the entire rounded aspect of the hemisphere visible previous to manipulation or dissection, and is the surface subjacent to the vault of the cranium. The mesial surface is perpendicular, flat, and parallel with that of the other hemisphere, the two bounding the longitudinal fissure and for the most part in contact with the falx cerebri. The **superomesial border** intervenes between the convex and medial surfaces, and is thus convex and extends from the frontal to the occipital pole.

The more complex *basal surface* fits into the anterior and middle cranial fossæ, and posteriorly rests upon the tentorium cerebelli. Thus it is subdivided into—(*a*) an *orbital area,* which is slightly concave, since it is adapted to the orbital plate of the frontal bone, and is separated from the convex surface by the necessarily arched **superciliary border** and from the mesial surface by the **medial orbital border,** the latter being straight and extending from the frontal pole mesial to the olfactory bulb and tract; (*b*) a *tentorial area* or surface, which is arched in conformity with the dorsal surface of the cerebellum. This is separated from the convex surface by the **infero-lateral border,** which runs from the occipital to the temporal pole; and from the mesial surface by the **medial occipital border,** which is a more or less rounded ridge extending from the occipital pole obliquely upward in the angle formed by the junction of the perpendicular falx cerebri and the horizontal tentorium cerebelli. This border is best seen in brains which have been hardened with the membranes *in situ.* The remainder of the basal surface includes the optic portion of the hypothalamus already considered, and the small depressed and punctate area, the anterior perforated substance, which is penetrated by the antero-lateral group of the central branches of the anterior and middle cerebral arteries and into which the striæ of the olfactory trigone disappear. In addition to the orbital area the basal surface of the hemisphere shows signs of the impress of the petrous portion of the temporal bone and of the great wing of the sphenoid.

The corpus callosum.—In their early development as lateral dilations of the anterior primary brain-vesicles, the hemispheres are connected with each other only at the anterior end of the thalamencephalon, where they are both continuous with the lamina terminalis. As development proceeds and the hemispheres extend upward, backward, forward, and laterally to completely conceal the base, and as the pallium, or cortex, thickens and its folds begin to appear, the two hemispheres become united across the mid-line above the thalamencephalon and the third ventricle by the inter-growth of the great cerebral commissure, the **corpus callosum.** After removal of the falx cerebri from the longitudinal fissure, the

FIG. 671.—MESIAL AND TENTORIAL SURFACES OF RIGHT CEREBRAL HEMISPHERE, VIEWED FROM THE LEFT. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

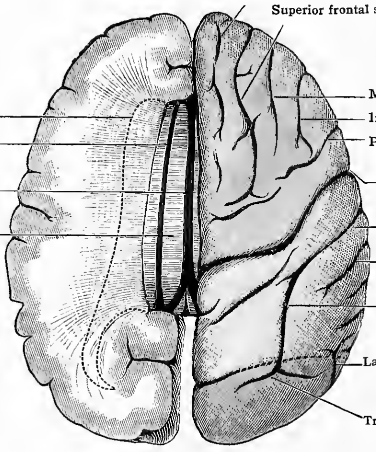


dorsal surface of the corpus callosum may be exposed by drawing apart the contiguous mesial surfaces of the hemispheres. It consists of a dense mass of pure white substance coursing transversely, and arises as out-growths from the cortical cells of both hemispheres. Thus it is the great pathway which associates the cortex of the two sides of the telencephalon. Only the smaller medial portion of the body lies free in the floor of the longitudinal fissure, by far the greater part being concealed in the substance of the hemispheres, where its fibres radiate to and from different localities of the pallium, forming the *radiation of the corpus callosum.* Its surface shows numerous transverse markings, the *transverse striæ,* which indicate the course of its component bundles of fibres. In addition there may be seen two delicate, variable longitudinal bands running over its surface on each side of the mid-line. The **medial longitudinal stria** (*stria Lancisii*) runs close to the median plane, around the anterior end from the gyrus subcallosus (fig. 672), and over the posterior end downward and lateralward to disappear in the hippocampal gyrus of the base of the telencephalon. The **lateral longitudinal stria** is more delicate than the mesial stria, courses lateral to the medial stria, and can be seen only within the sulcus of the corpus callosum (fig. 672). Both striæ are composed largely of axones having to do with the olfactory apparatus.

When severed along the median plane, it may be seen that the anterior margin of the corpus callosum is turned abruptly downward, forming the **genu,** and that this turn continues, so that the tapering edge of the body points posteriorly and constitutes the **rostrum** (figs. 667, 671). The rostrum is in contact with the lamina terminalis of the third ventricle below by a short, thin, dorso-frontal continuation of this lamina, known as the **rostral lamina.** The rostral lamina may be considered as beginning at the anterior cerebral commissure with the anterior aspect of which it is in contact, and extending to the rostrum. Beginning with the rostrum and genu, the corpus callosum arches backward as the **body of the corpus callosum,** and ends over the quadrigeminate region in its rounded, thickened posterior margin, the **splenium.** It is bounded above by the sulcus of the corpus callosum, and, attached to its concave inferior surface, are the chorioid tela of the third ventricle, the fornix, the septum pellucidum, and the medial walls of the lateral ventricles.

Each cerebral hemisphere includes—(1) a superficial and much folded mantle or *pallium,* divided into lobes and gyri, and consisting of grey substance, the *cortex,* covering an abundant mass of white substance; (2) a modified portion, the

Fig. 672.—Diagram of Convex Surface of Right Cerebral Hemisphere and Part of Upper Surface of Corpus Callosum.



rhinencephalon, having especially to do with the impulses brought in by the olfactory nerve; (3) a cavity , the *lateral ventricle;* and (4) a buried mass of grey substance, the *caudate* and *lenticular nuclei,* which together with the *internal capsule* of white substance, are known as the *corpus striatum.*

Gyri, fissures, and sulci.—The cerebral pallium is thrown into numerous and variable folds or *gyri* (convolutions). These are separated from each other by corresponding furrows, the deeper and most constant of which are called *fissures;* the remainder, *sulci.* All the fissures and the main sulci are named. There are, however, numerous small and shallow sulci to which names are seldom given. These occur as short branches of main sulci or as short, isolated furrows bounding small gyri which connect adjacent gyri. These small gyri are likewise seldom given individual names. They are very variable both in different specimens and in the two hemispheres of the same specimen. Collectively, they are the so-called transitory gyri (gyri transitivi). Certain groups of them are named according to their locality, such as *orbital gyri* and *lateral occipital gyri.* Even the main gyri [gyri profundi] (and sulci) are very irregular in detail. Some of the main and deeper fissures are considerably deeper than others. Some are infoldings of the grey cortex so deep that a portion of their course may be indicated as slight bulgings in the walls of the lateral ventricles, e. g., the hippocampal and collateral fissures. While the general surface pattern is similar for all normal human brains, yet when a detailed comparison is made, the given gyri of different specimens are found to vary greatly. The main gyri of the two hemispheres of the same brain, however, are nearly alike.

Origin of the gyri.—The gyri (and sulci) are the result of processes of unequal growth—folds necessarily resulting from the surface portion of the hemispheres increasing much more rapidly than the central core. In the early periods of fetal life the surfaces of the hemispheres are quite smooth. In many of the smaller mammals this condition is retained throughout life, but in the larger mammals, including man, as development proceeds the cerebral cortex becomes thrown into folds. The absolute amount of the grey substance of the hemispheres varies with the bulk of the animal, and apparently with its mental capabilities. This is especially true of the cortex, for in the larger brains, and that of man especially, by far the greater amount of the cerebral grey substance lies on the surface. Therefore, in either the growth or evolution of a small animal into a large one the amount of cerebral grey substance is increased, and in this increase the surface area of the brain is necessarily enlarged. It is a geometrical law that in the growth of a body the surface increases with the square, while the volume increases with the cube of the diameter. The cerebral hemisphere is a mass the increase of whose volume does not keep the required pace with the increase of its surface area or cortical layer. The white substance which forms the pallium arises in large measure as outgrowths from the cells of the cortical layer, and thus it can only increase in a certain proportion to the grey substance. Therefore, the surface mantle of grey substance of a hemisphere, enlarged in accordance with an increased bulk of body, is greater than is necessary to cover the surface of the geometrical figure formed by the combined white and grey substance. Consequently, in order to possess the preponderant amount of grey substance, the surface of the hemisphere is of necessity thrown into folds. It follows also that the thinner the cortical layer in proportion to the volume of the hemisphere, the greater and more folded will be the surface area. In accordance with this theory small animals have smooth or relatively smooth hemispheres, and that independently of their position in the animal scale or the amount of their intelligence, while large animals have convoluted brains.

The sulci in general begin to appear with the fifth month of fetal life, the larger of them, the fissures, appearing first and in a more or less regular order. Up to the fifth month the encephalon, due to its rapid growth, closely occupies the cranial capsule. During the fifth month the cranium begins to grow more rapidly than the encephalon, and a space is formed between the cerebrum and the inner surface of the cranium. This space allows further expansion of the pallium, and at the time the space is relatively greatest (during the sixth month) the form and direction of the principal gyri and sulci begin to be indicated. As growth proceeds the unrestricted expansion of the pallium results in the gyri again approaching the wall of the cranium, and during the eighth month of fetal life they again come in contact with it. Finally, the later relative growth of the cranium results in the space found between it and the cortex in the adult. It is obvious that the relation of the cranium may be a factor in the causation of the gyri, for the increase of surface area necessitated by the increased amount of cortical grey substance might be limited by a cranial cavity of small size. It is probable that the second contact of the cortex with the cranium (during the eighth month) may at least cause a deepening and accentuation of the gyri already begun. Evidently the form of the cranium modifies the gyri, and to a certain extent probably determines their direction, for in long, dolichocephalic crania the antero-posterior gyri are most accentuated, and in the wide, brachycephalic crania the transverse gyri are most marked. At birth all the main fissures and sulci are present, but some of the smaller sulci appear later. In the growing pallium both the bottoms of the sulci as well as the summits of the gyri move away from the geometrical center of the hemisphere, the summits more rapidly, and hence the sulci or fissures first formed grow gradually deeper as long as growth continues.

The mechanical factors in the growth processes which result in the more or less regular arrangement of the gyri of the hemispheres of a given group of animals have not been satisfactorily determined. It has been suggested that the differences in arrangement of the gyri in different groups of animals may be in part dependent upon the functional importance of the various regions—the amount of grey substance of a region varying with the functional importance, and the consequent local increases being accompanied by resultant local foldings. This idea is supported by the fact that while the somæsthetic (sensory-motor) area of the cortex varies with the bulk of the body, the frontal gyri, so much developed in man and which are one of the chief regions of the associational phenomena, are relatively independent of and do not vary with the weight of either the body or the brain.

Surface area.—The total surface area of the adult human telencephalon is about 2300 sq. cm. Of this area almost exactly one-third is contained on the outer or exposed surfaces of the gyri, while the other two-thirds is found in the walls of the sulci and fissures.

Lobes of the Telencephalon and the Gyri and Sulci

The folded pallium of each hemisphere is arbitrarily divided into lobes, partly by the use of certain of the main fissures and sulci as boundaries and partly by the use of imaginary lines (figs. 672, 673). These divisions are six in number, themselves subdivided into their component gyri:—

(1) Temporal lobe.
(2) Insula (Central lobe or Island of Reil).
(3) Frontal lobe.
(4) Parietal lobe.
(5) Occipital lobe.

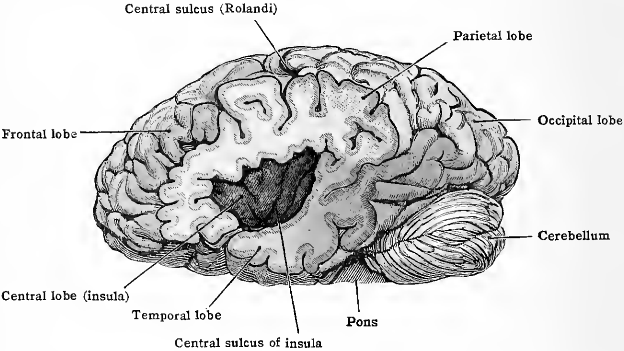
(6) Olfactory brain or rhinencephalon (including structures comprised in the other lobes and often grouped under the two names *olfactory lobe* and *limbic lobe*).

This division of the cortex of the hemisphere is largely a merely topographical one. With the exception of the temporal lobe and the rhinencephalon, it has little of either morphological or functional value. The occipital lobe contains the recognised visual area of the cortex, but this area, as such, does not involve all of the lobe. In their functional significance, the frontal and parietal lobes, especially, overlap each other.

The temporal lobe.—This is the first lobe whose demarcation is indicated. During the second month of intra-uterine life there appears a slight depression on the lateral aspect of the then smooth hemisphere. As the pallium further grows, this depression deepens into a well-marked fossa with a relatively broad floor. This fossa marks the beginning of the lateral cerebral fissure or fissure of Sylvius, and is, therefore, known as the *Sylvian fossa*. As the pallium continues to project outward, the folds which form the margins of the Sylvian fossa increase in size and height and begin to overlap and conceal its broad floor, which is the beginning

Fig. 673.—Diagram of the Convex Surface of the Left Cerebral Hemisphere showing the Five Principal Lobes of the Pallium.

The opercular regions of the frontal, parietal, and temporal lobes are removed to show the central lobe or island of Reil.



of the insula. The overlapping folds thus become the **opercula,** and as their lips approach each other, there results the deep fissure of Sylvius, which marks off anteriorly an infero-lateral limb of the pallium, termed by position the temporal lobe. As growth proceeds further, the temporal lobe thickens, the temporal pole extends further forward and becomes a free projection, thus lengthening the fissure of Sylvius and resulting in the inferior extension or stem of this fissure, which runs between the temporal pole and the frontal lobe and curves under so as to appear on the basal surface of the hemisphere. Finally the cortex of the lobe itself is thrown into folds or gyri. Its posterior end is never marked off from the lobes above and behind, except by arbitrary lines which will be mentioned in connection with those lobes.

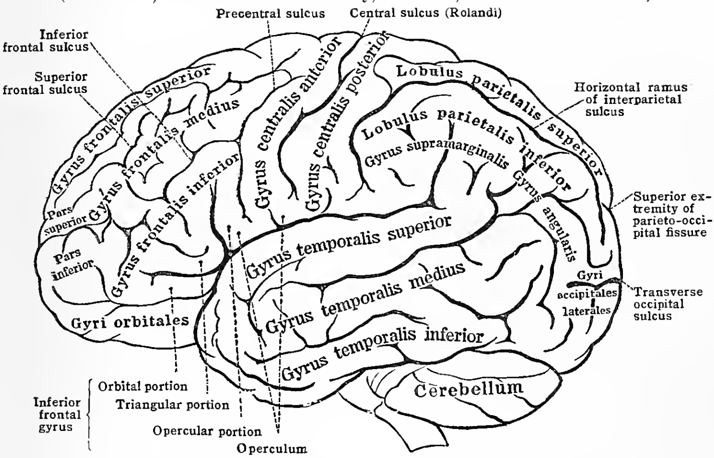
The temporal lobe forms part of the lateral convex and tentorial surfaces of the hemisphere, and its anterior portion is adapted to the surface of the middle cranial fossa. It thus has a superior and lateral surface and a basal and tentorial surface. In these surfaces are the following gyri with their intervening and bounding sulci (fig. 674):—

The **superior temporal gyrus** is bounded by the posterior ramus of the lateral fissure, and extends from the temporal pole backward into the supra-marginal region of the parietal lobe above. The upper margin of this gyrus constitutes the **temporal operculum,** in that it aids in overlapping and enclosing the insula in the floor of the lateral fissure. This margin is for the most part smooth, being occasionally interrupted by a few weak twigs of the lateral fissure. It is separated from the gyrus below by the **superior temporal sulcus,** which is parallel with the posterior ramus of the lateral fissure and is frequently called the *parallel sulcus.* The posterior extremity of this sulcus divides the angular gyrus of the parietal lobe, and its anterior end disappears in the temporal pole, sometimes as a continuous groove, sometimes in isolated pieces.

The **middle temporal gyrus** likewise begins in the temporal pole and is continuous backward into the angular gyrus of the parietal lobe.

The **inferior temporal gyrus** forms the infero-lateral border of the temporal lobe, and is usually more broken up than the two gyri above it. It begins continuous with them in the frontal pole, and extends horizontally backward into the lateral gyri of the occipital lobe. It is separated from the middle gyrus by the **middle temporal sulcus,** which likewise is never so continuous a furrow as the superior temporal sulcus. Frequently this sulcus occurs in detached portions and often terminates within the temporal lobe.

Fig. 674.—Outline Drawing of Convex Surface of Left Cerebral Hemisphere. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **fusiform gyrus** is in the basal and tentorial surface of the temporal lobe (fig. 676). Its usual somewhat spindle shape suggests its name, and it is continuous backward into the occipital gyri, or its posterior end may be completely isolated by a union of the *inferior temporal sulcus* and the **collateral fissure,** which two furrows separate it from its neighbours on either side. Anteriorly the fusiform gyrus runs into the common substance of the other three gyri at the temporal pole.

The **lingual gyrus** is usually included in the tentorial surface of the temporal lobe, though in some texts it is regarded as a part of the occipital lobe. Its larger, posterior portion lies within the boundaries of the occipital lobe. Bounded laterally by the collateral fissure, it is continuous anteriorly into the hippocampal gyrus of the rhinencephalon (fig. 676).

All of the sulci give off occasional lateral twigs (*transverse temporal sulci*) which themselves may or may not branch, and which tend to divide the main gyri into **transverse temporal gyri.**

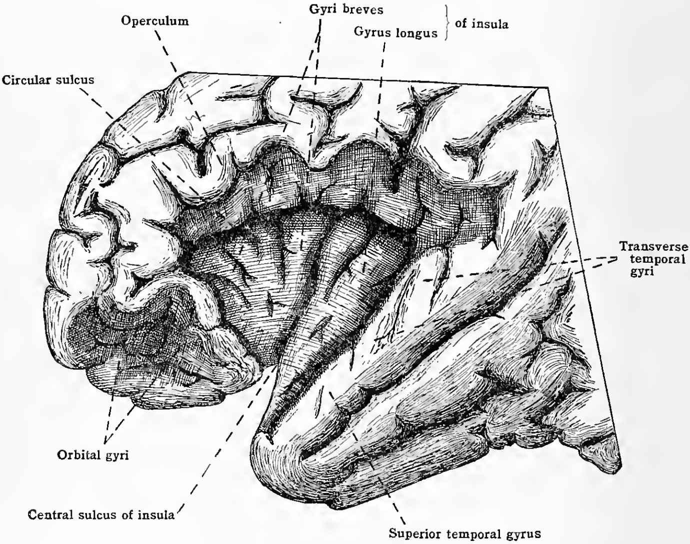
The lateral fissure (fissure of Sylvius).—As promised in its origin by the overlapping and enclosing of the broad floor of the Sylvian fossa by the adjacent folds of the pallium, the lateral fissure is the deepest and most conspicuous fissure of the cerebral hemisphere. Its main divisions are a short stem and three main branches. The **stem** lies in the basal surface of the hemisphere, where it begins in a depression in the anterior perforated substance, the *vallecula Sylvii*, and passes forward and upward between and separating the temporal pole and the superciliary border of the frontal lobe. It corresponds in direction with the posterior border of the lesser wing of the sphenoid bone, which projects backward into it, and it contains the middle cerebral artery, the Sylvian vein, and the sinus alæ parvæ. It appears on the upper surface at a point known in cranial topography as the *Sylvian point*, where it divides into its three main branches:—

(1) The **posterior ramus** is the linear continuation of the fissure, and runs horizontally backward and upward to terminate in the supra-marginal gyrus of the parietal lobe.

(2) The **anterior ascending ramus** passes upward for about 10 mm., subdividing the inferior gyrus of the frontal lobe.

(3) The **anterior horizontal ramus** passes forward from the stem of the fissure about 10 mm., and likewise into the inferior frontal gyrus, but parallel with the superciliary border.

Fig. 675.—The Insula with its Gyri and Sulci. (Shown by widely separating the opercula.)



These branches, together with certain smaller collateral twigs, divide the overlapping or opercular portions of the adjacent pallium into (*a*) the *temporal operculum*, which lies below the posterior ramus; (*b*) the fronto-parietal operculum, or *operculum proper*, which lies above and behind the anterior ascending ramus; (*c*) the *frontal operculum*, between the latter and the anterior horizontal ramus; (*d*) and the *orbital operculum*, below the anterior horizontal ramus. Collectively the opercula are known as the *opercula of the insula*.

The insula (central lobe).—The insula or island of Reil is a triangular area of the cerebral cortex lying in the floor of the lateral fissure, and concealed by the opercula. Of these, the temporal operculum overlaps the insula to a greater extent than either the frontal or parietal. More than half of it may, therefore, be exposed, by gently pressing away the temporal lobe. The insula corresponds to the broad floor of the Sylvian fossa of the embryonic brain. In the developed condition its surface is convex lateralward and is itself folded into gyri. The apex of the triangle appears upon the basal surface of the hemisphere, and is the only portion which may be seen without disturbing the specimen. The apex appears as the end of a small gyrus under the temporal pole, and in close relation with the anterior perforated substance and the vallecula Sylvii, and is known as the **limen of the insula.** In the folding process by which the opercula accomplish the overlapping and enclosing of the island, there results a deep sulcus which surrounds its entire area except at the limen insulæ. This is known as the **circular sulcus,** or limiting sulcus of Reil. The gyri (and sulci) of the insula radiate from the apex of the triangle. The **central sulcus** of the insula is the deepest. It runs from below backward and upward, parallel with the central sulcus of Rolando above and divides the insula into a larger anterior and a smaller posterior portion. The anterior portion consists of from three to five short irregular **gyri breves** or precentral gyri, separated by **sulci brevis;** the posterior portion consists of a single, slightly furrowed gyrus, which is long and arched and extends from the apex to the base of the triangle, the **gyrus longus.**

In a recent study of the insula of more than 200 human brains, including a few of idiots and paralytics and a series of young fœtuses, Nelidoff finds that the left island is more deeply marked by sulci and averages 11 mm. longer than the right; that, of the sulci in the island, the central sulcus is the first to appear, is the most persistent sulcus in defective brains, though occasionally absent in microcephalic idiots, and that in the average it is more pronounced in males than in females.

The frontal lobe.—This is the most anterior of the lobes of the hemisphere, and like the two lobes behind, it has a convex or lateral, a basal, and a mesial surface. The convex surface begins with the frontal pole, and is bounded posteriorly by the *central sulcus* (*Rolandi*). The basal surface extends backward to the stem of the lateral fissure, covered by the frontal pole. The mesial surface is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the subfrontal part of the **sulcus cinguli** (calloso-marginal fissure), and from the parietal lobe by a line drawn perpendicularly from the upper extremity of the central sulcus (Rolandi) to the sulcus cinguli. These surfaces include the following gyri and sulci:—

	Gyri.		Sulci.	
Convex surface	Anterior central gyrus.		Precentral sulcus	Superior. Inferior.
	Superior frontal gyrus.			
	Middle frontal gyrus	Superior portion. Inferior portion.	Superior frontal sulcus. Middle frontal sulcus.	
	Inferior frontal gyrus	Opercular portion. Triangular portion. Orbital portion.	Inferior frontal sulcus. Anterior ascending ramus of lateral fissure. Anterior horizontal ramus of lateral fissure.	
Basal surface	Orbital gyri	Lateral. Anterior. Posterior. Medial.	Orbital sulci	Lateral. Medial. Transverse.
	Gyrus rectus.		Olfactory sulcus.	
Mesial surface	Superior frontal gyrus.			
	Marginal gyrus.			
	Paracentral lobule (anterior part).		Rostral sulci.	

Many of the sulci, especially the superior frontal and the rostral sulci, often give off twigs or are broken up into short furrows which give rise to small folds [gyri transitivi], too inconstant to be given special names.

The **anterior central gyrus** (ascending frontal convolution) is the only gyrus of the frontal lobe having a vertical direction. It lies parallel to the central sulcus (Rolandi), and thus extends obliquely across the convex surface from the posterior ramus of the lateral fissure (frontal operculum) to the supero-mesial border, and is continuous on the mesial surface with the anterior portion of the *para-central lobule.* It comprises the larger part of the motor portion of the somæsthetic (sensory-motor) area of the cerebral cortex. It is separated from the horizontal frontal gyri in front of it by the **precentral sulcus.**

This sulcus is developed in three parts, but the upper and middle parts in the fœtal brain usually fuse together, so that in the later condition it consists of a superior and an inferior segment. The superior cuts the supero-mesial border of the hemisphere and appears on the mesial surface in the paracentral lobule. On the convex surface it is usually connected with the posterior end of the superior frontal sulcus (fig. 674).

The **superior frontal gyrus** is a relatively broad, uneven convolution, comprising the anterior portion of the supero-mesial border of the hemisphere, and therefore extends horizontally from the precentral sulcus to the frontal pole. It is sometimes inperfectly divided into a superior and an inferior part by a series of detached, irregular furrows, spoken of collectively as the *para-medial sulcus.* The resulting transitory gyri are of considerable interest in that they are peculiar to the human brain, and are said to be more marked in the higher than in the lower types.

The **middle frontal gyrus** is likewise a broad strip of pallium extending from the precentral sulcus to the temporal pole. It is separated from the superior frontal gyrus by the **superior frontal sulcus,** which is usually continuous into the superior section of the precentral sulcus and thence extends horizontally to the frontal pole. The middle frontal gyrus is in most cases subdivided anteriorly into a *superior* and an *inferior portion* by a **middle frontal sulcus.** This sulcus begins above and runs into the frontal pole, where, upon reaching the superciliary border, it frequently bifurcates into a transverse furrow, known as the *fronto-marginal sulcus.*

The **inferior frontal gyrus** forms the superior wall of the lateral fissure, and is separated from the middle frontal gyrus by the **inferior frontal sulcus.** This sulcus usually begins continuous with the inferior section of the precentral sulcus, and extends, very irregularly and frequently interrupted, toward the frontal pole. The gyrus abuts upon the anterior central gyrus, and its posterior portion is divided into three parts (the frontal opercula) by the anterior ascending and horizontal rami of the lateral fissure. The part behind the anterior ascending ramus is the **opercular portion** (a part of the fronto-parietal operculum or operculum proper), sometimes referred to as the *basilar portion.* In most brains this part is traversed by a short oblique furrow, the **diagonal sulcus.** The part between the two anterior rami of the lateral fissure is the cap-shaped **triangular portion.** This portion frequently involves one and sometimes two descending twigs of the inferior frontal sulcus. The part below the anterior horizontal ramus is by position the **orbital portion.**

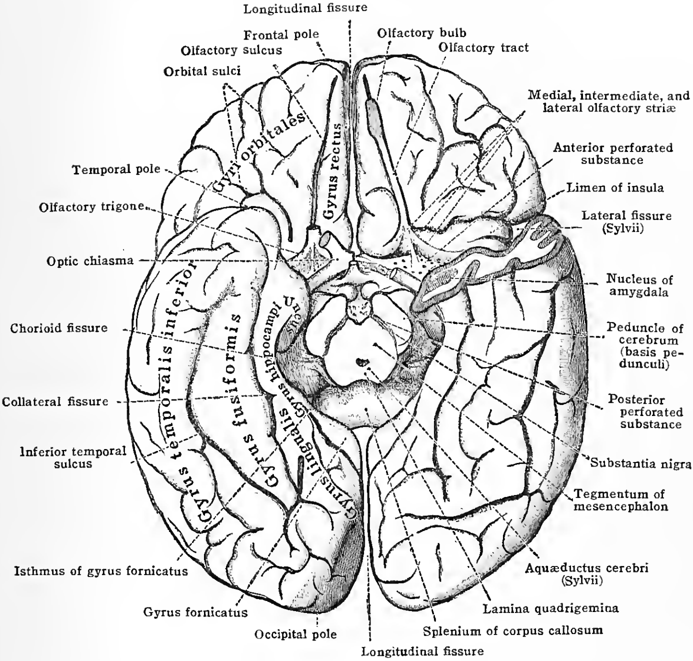
It is seen that the inferior frontal gyrus gives rise to the whole of the frontal operculum and the anterior half of the fronto-parietal operculum. The opercular portion is of special interest in that in the left hemisphere it constitutes the celebrated **convolution of Broca,** the motor area for the function of speech. The area controlling speech, however, involves that part of the triangular portion bounding the anterior ascending ramus of the lateral fissure as well, and both these parts often appear more developed on the left hemisphere. The development of the opercula of the inferior frontal gyrus is a distinctive characteristic of the human brain. This gyrus does not develop opercula even in the highest varieties of apes. The development of the function of speech in man no doubt influences the development of the frontal opercula.

On the *basal surface* (fig. 676) of the frontal lobe is the orbital area and the gyrus rectus. The more pronounced of the **orbital sulci** are often so joined with each other as to form an H-shaped figure standing parallel to the mesial plane, and thus they comprise a *medial,* a *lateral* and a *transverse orbtial sulcus.* This figure naturally divides the orbital area into four gyri:—(1) The **lateral orbital gyrus** is the basal continuation of the inferior frontal gyrus, and is thus related to the orbital portion of the frontal operculum; (2) the **anterior orbital gyrus** is continuous at the pole with the middle frontal gyrus; (3) the **posterior orbital gyrus** is closely related to the limen insulæ and the stem of the lateral fissure, and its outer part is in relation with the orbital portion of the operculum; (4) the **medial orbital gyrus** is continuous over the superciliary border with the superior frontal gyrus. It frequently contains one or two short, isolated sulci. Its mesial boundary is the straight **olfactory sulcus,** in which lies the olfactory bulb and tract of the rhinencephalon. This sulcus marks off a narrow straight strip of cortex between it and the mesial border of the lobe known as the **gyrus rectus.** The posterior portion of the gyrus rectus comprises a part of the **parolfactory area** or Broca's area, which functionally belongs to the rhinencephalon. As an area or field, this appears mesially lying between the anterior and posterior parolfactory sulci.

On the *mesial surface* (fig. 679), of the frontal lobe the superior frontal gyrus is separated from the gyrus cinguli of the rhinencephalon (limbic lobe) by the well-marked **sulcus cinguli.** Anteriorly the superior frontal gyrus is subdivided by the main stem of the **rostral sulci** into a **marginal gyrus,** and what may be termed a **submarginal gyrus.** The marginal gyrus is usually broken into smaller parts by twigs of the rostral sulci, most of which are perpendicular to the main stem, while the submarginal gyrus is less frequently interrupted. Posteriorly the superior frontal gyrus constitutes the anterior portion of the *paracentral lobule,* a part of the somæsthetic area of the mesial surface of the hemisphere. This lobule is usually marked off anteriorly by a vertical twig from the sulcus cinguli.

The **sulcus cinguli** (calloso-marginal fissure) is the longest and one of the most prominent sulci on the mesial surface of the hemisphere. It divides the anterior portion of the mesial surface into a marginal part above and a callosal part below —in other words, it separates the superior frontal gyrus from the gyrus cinguli. Its **subfrontal portion** begins below the rostrum of the corpus callosum and curves forward and upward around the genu, and then turns backward above the body of the corpus callosum. Before it reaches the level of the splenium, it turns upward and cuts and terminates in the supero-mesial border of the hemisphere, as the next sulcus behind the upper termination of the central sulcus. This upward

FIG. 676.—BASAL SURFACE OF THE CEREBRAL HEMISPHERES. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

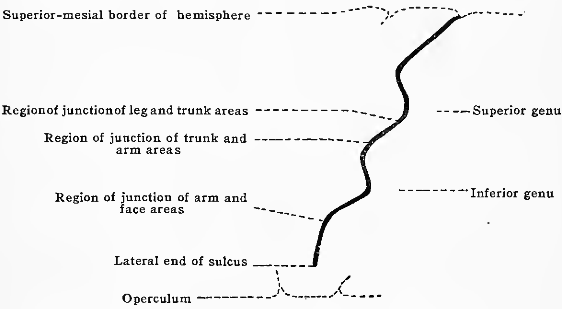


turn is the **marginal portion** of the sulcus cinguli. It is sometimes an abrupt curve and sometimes curves gradually, but its marginal relation to the upper end of the central sulcus is so constant that it serves as a means by which either of the sulci may be identified. The marginal portion separates the paracentral lobule from the precuneus (quadrate lobule), and is wholly within the parietal lobe. One of the most constant twigs of the sulcus cinguli is that which marks off the paracentral lobule from the superior frontal gyrus. Another sometimes divides the paracentral lobule into its frontal and parietal portions.

The sulcus cinguli is developed from two and sometimes three (anterior, middle, and posterior) separate furrows, which later extend and fuse into continuity. This method of its development may explain the irregularities frequently met with and the fact that sometimes in the adult the sulcus occurs in separate pieces.

The **central sulcus** (fissure of Rolando) (figs. 674, 678) is one of the principal landmarks of the convex surface of the hemisphere. It separates the frontal from the parietal lobe, and likewise divides the somæsthetic area of the pallium. Its upper end terminates in and usually cuts the supero-mesial border of the hemisphere immediately in front of the termination of the marginal portion of the sulcus cinguli. Thence it pursues an oblique though sinuous course forward across the convex surface of the hemisphere, forming on the average an angle of about 72° with the supero-mesial border (**Rolandic angle**), and terminates in the fronto-parietal operculum immediately above the posterior ramus, and about 2.5 cm. behind the point of origin of the anterior rami of the lateral fissure. It rarely cuts through the fronto-parietal operculum. In its sinuous course, varying from the line of its supero-mesial end, two bends are marked (fig. 677):—(1) The **superior genu** occurs at about the junction of the upper and middle thirds of the sulcus and is concave forward. It accommodates the greater part of that portion of the cortex which is the motor area for the muscles of the leg and trunk, and the development of this area in man probably aids in producing it. (2) The **inferior genu** occurs below, is concave forward and is commonly a little more marked than the superior genu. It is probably in part a result of the superior genu—the turn of the sulcus in resuming its general course, but it may further result from the development of the shoulder and arm area of the cortex which occupies its concavity.

Fig. 677.—Diagram Representing the Most Common Form of the Central Sulcus and Indicating the Regions of Junction upon it of the Areas of the Precentral Gyrus Devoted to the Different Regions of the Body, as Estimated by Symington and Crymble.



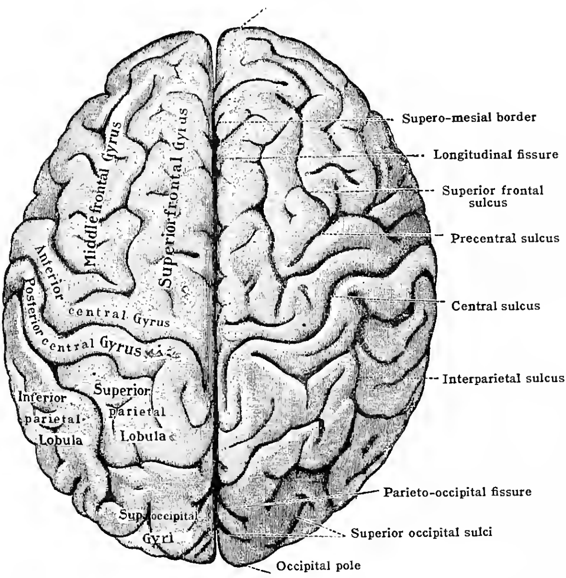
The **central sulcus** (**Rolandi**) appears in the pallium of the fœtus during the latter part of the fifth month. It then consists of a lower longer and an upper shorter part. Usually these two parts become continuous before birth; very rarely do they remain separate in the adult. The point of their fusion is sometimes manifest within the depth of the sulcus. If the lips of the sulcus be pressed widely apart at about the region of the junction of its middle and upper thirds, it will be found that the opposing walls give off a number of protuberances or lateral gyri, which dovetail into each other when the sulcus is closed. Sometimes two of these lateral gyri appear fused across the floor of the sulcus, so as to form a bridge of grey substance known as the **deep annectant gyrus.** This interruption of the continuity of the sulcus, when present, represents the point at which the two parts of the sulcus in the fœtal brain joined each other without the continuity becoming wholly completed in the adult. The genua of the adult sulcus may often be due to the precedent parts not being in line at the time of their fusion.

From a special study of the central sulcus of 237 normal adult hemispheres, Symington and Crymble (1913) give the following details: (1) that the most common course of the sulcus is that illustrated in fig. 677, above; (2) that it varies in depth both in a given specimen and in different specimens—the greatest variations in depth reported for a given sulcus being from 22 to 12 millimeters, the shallowest part being in the region of the deep annectant gyrus; (3) that the average length from the supero-mesial border of the hemisphere to the opercular end of the sulcus is about 9 cm. in direct line and 10.4 cm. following the curves of the sulcus. The average length of the curved floor is 7.9 cm. (4) From the supro-meisal end of the sulcus to the points of junction of the general areas of the precentral gyrus, direct line measurements give averages, (a) to the junction of leg and trunk areas, 3.5 cm.; (b) to junction of trunk and arm areas, 4.5 cm.; (c) to junction of arm and face areas, 7.5 cm.

The parietal lobe.—The parietal lobe occupies a somewhat smaller area of the human telencephalon than either the frontal or the temporal lobe. It has a convex and a mesial surface, but no basal surface. It is separated from the frontal lobe in front by the central sulcus; from the occipital lobe behind, on the mesial surface by the *parieto-occipital fissure* (fig. 650), and, on the convex surface, by an arbitrary line drawn transversely around the convex surface of the hemisphere from the superior extremity of this fissure to the infero-lateral border; and it is separated from the temporal lobe below by the horizontal part of the posterior ramus of the lateral fissure, and by a line drawn in continuity with this horizontal part to intersect the transverse line drawn to limit it from the occipital lobe.

The preoccipital notch.—*In situ*, the infero-lateral border of the posterior portion of the hemisphere rests over a small portion of the parieto-mastoid suture of the cranium, and upon this structure occurs a fold or vertical thickening of the dura mater, which slightly indents the infero-lateral border. This indentation occurs about 4 cm. from the occipital pole, and is considered one of the points of limitation of the parietal from the occipital lobe, and is therefore called the preoccipital notch. While during late fœtal life and early childhood it is well marked, it is usually very slight in the adult brain, and is, as a rule, evident only in brains hardened

FIG. 678.—CONVEX SURFACE OF THE CEREBRAL HEMISPHERES AS VIEWED FROM ABOVE. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



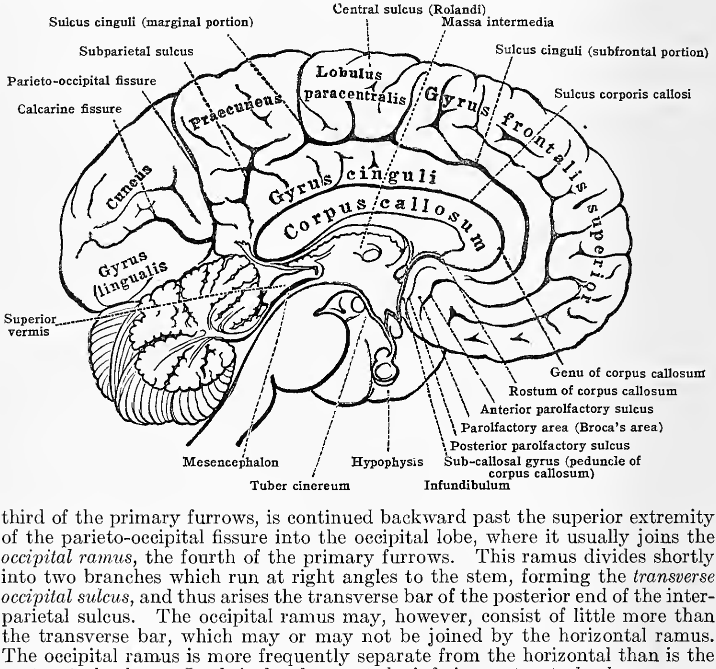
in situ. When it is visible, the arbitrary transverse line from the superior extremity of the parieto-occipital fissure, used as a boundary between the convex surfaces of the parietal and occipital lobes, should be so drawn as to bisect the preoccipital notch.

The *convex surface* of the parietal lobe comprises the following gyri and sulci:—

The **posterior central gyrus** (ascending parietal) extends obliquely across the hemisphere parallel with the anterior central gyrus of the frontal lobe, from which it is separated by the central sulcus. Its inferior end is bounded by the posterior ramus of the lateral fissure, and constitutes the posterior or parietal portion of the fronto-parietal operculum. Its upper end takes part in the supero-mesial border of the hemisphere, and is bounded posteriorly by the tip end of the marginal portion of the sulcus cinguli. Its postero-lateral boundary consists of the two more or less vertical rami or factors of the interparietal sulcus, viz., the inferior and superior portions of the *postcentral sulcus,* either continuous with each other or detached.

The **interparietal sulcus** (intraparietal) is often the most complicated sulcus of the pallium. Its development usually begins as four different furrows in the fœtal brain, and the difficulty with which it is traced in the adult brain depends upon the extent to which these four factors become continuous in the later development. When continuity of the furrows is well established, the entire sulcus may be described as consisting of a convex *horizontal ramus*, which gives off a few short collateral twigs and whose either end is in the form of an irregular, reclining ⊣. The transverse bar of the anterior end arises fron two of the four factors of the entire sulcus:—(1) an inferior furrow, the *inferior postcentral sulcus*, commencing above the posterior ramus of the lateral fissure and ascending as the boundary of the lower half of the posterior central gyrus, and (2) a superior furrow, the *superior postcentral sulcus*, lying behind the upper portion of the posterior central gyrus, and which, upon approaching the supero-mesial border, may turn backward a short distance parallel with the horizontal ramus, as in fig. 674. When confluent, these two factors form together a continuous **postcentral sulcus.** In the adult the inferior of the two is always continuous with the horizontal ramus; when confluent, the two figures join so as to form the transverse bar of the anterior end of this ramus. The horizontal ramus, which represents the

FIG. 679.—OUTLINE DRAWING OF MESIAL SURFACE OF LEFT CEREBRAL HEMISPHERE. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



third of the primary furrows, is continued backward past the superior extremity of the parieto-occipital fissure into the occipital lobe, where it usually joins the *occipital ramus*, the fourth of the primary furrows. This ramus divides shortly into two branches which run at right angles to the stem, forming the *transverse occipital sulcus*, and thus arises the transverse bar of the posterior end of the interparietal sulcus. The occipital ramus may, however, consist of little more than the transverse bar, which may or may not be joined by the horizontal ramus. The occipital ramus is more frequently separate from the horizontal than is the postcentral sulcus. In their development the inferior postcentral sulcus appears first (during the latter part of the sixth month), the occipital ramus second, the horizontal ramus third, and last, the superior postcentral sulcus.

The **superior parietal lobule** (*gyrus*) is the area of the supero-mesial border of the parietal lobe. It is limited in front by the superior postcentral sulcus, below by the horizontal ramus of the interparietal sulcus, and posteriorly it is continuous around the superior end of the parieto-occipital fissure into the cortex of the occipital lobe. It is a relatively wide area (lobule), always invaded by collateral twigs of its limiting sulci, and usually contains a few short, isolated furrows. When the parieto-occipital fissure is considerably prolonged over the supero-mesial border (*external parieto-occipital fissure*), the continuation of the lobule about the end of this fissure presents the appearance described as the **parieto-occipital arch.**

The **inferior parietal lobule** is limited in front by the inferior postcentral sulcus, and above by the horizontal ramus of the interparietal sulcus. It is continuous with the cortex of the temporal lobe below, and with that of the occipital lobe behind, and is therefore invaded by the ends of the sulci belonging to these lobes. Its anterior portion is separated from the temporal lobe by the horizontal portion of the posterior ramus of the lateral fissure. The upturned end of this ramus invades the anterior portion of the lobule and the broad fold, arched around this end and continuous behind it into the superior temporal gyrus, is known as the **supramarginal gryus**—the area to which auditory word- and tone-images are attributed. The **angular gyrus** is the portion which embraces the posterior end of the superior temporal sulcus, and is continuous behind this into the middle temporal gyrus and in front with the superior temporal gyrus. It is the area for visual word images. Its shape is usually such as to suggest its name. The most posterior part of the inferior parietal lobule, when arching in a similar way about the end of the middle temporal sulcus and continuous with the temporal gyri on its either side, is known as the **post-parietal gyrus.** This is a smaller area than either of the other two, and, owing to the variability of the end of the middle temporal sulcus, is not always evident.

The *mesial surface* of the parietal lobe is divided into two parts by the marginal portion of the sulcus cinguli. The anterior and smaller part is the mesial continuation of the posterior central gyrus, and comprises the posterior portion of the **paracentral lobule.** It is limited from the part of this lobule belonging to the frontal lobe by a vertical line drawn from the marginal extremity of the central sulcus. The **præcuneus** (*quadrate lobule*) is the posterior and larger part of the mesial surface of the parietal lobe. It is separatd from the cuneus of the occipital lobe by the parieto-occipital fissure, and is imperfectly separated from the gyrus cinguli (limbic lobe) below by the *subparietal sulcus* (postlimbic fissure), branches of which invade it extensively.

The occipital lobe.—This is a relatively small, trifacial, pyramidal segment, comprising the posterior extremity of the hemisphere, its apex being the occipital pole. Though one of the natural divisions of the cerebral hemisphere, it is very indefinitely marked off from the lobes anterior to it. Though it contains the cortical area of the visual apparatus, only in the brains of man and the apes does it occur as a well-defined posterior projection. In most of the mammalia it is not differentiated at all. Its three surfaces comprise a convex, a mesial, and a tentorial surface.

Its *convex surface* is separated from that of the parietal and temporal lobes by the superior and external extremity of the parieto-occipital fissure, and by an arbitrary line drawn transversely from this extremity to the infero-lateral border of the hemisphere, or so drawn as to bisect the pre-occipital notch when this is evident. The sulci which occur on the convex surface may be described as two, though both of these are very variable in their extent and shape, and their branches are inconstant both as to number and length. (1) the **transverse occipital sulcus** is the most constant in shape. It extends a variable distance transversely across the superior portion of the lobe, and, as noted above, it is frequently continuous with the interparietal sulcus through its occipital ramus, and when so, it appears as the posterior terminal bifurcation of this sulcus (fig. 674). When detached, it often occurs merely as a definite furrow with few rami, and sometimes the ramus by which it otherwise would join the interparietal sulcus is entirely absent. (2) The **lateral occipital sulcus** is always short, and has its deepest portion below the transverse sulcus. It usually has a somewhat oblique course toward the supero-mesial border. Sometimes it occurs in several detached pieces, then known collectively as the *lateral occipital sulci*.

Therefore, the gyri of the convex surface of the lobe are also variable. They are not sufficiently constant to merit individual names. The lateral occipital sulcus or sulci roughly divide them into an inferior and lateral area, known as the **lateral occipital gyri,** and into a uperior larea, the **superior occipital gyri.** The lateral area is continuous into the gyri of the temporal lobe, while the superior area is continuous into the gyri of the parietal lobe.

The *mesial surface* of the occipital lobe is separated from that of the parietal lobe (precuneus) and from the gyrus cinguli of the limbic lobe by the well-marked parieto-occipital fissure. It comprises the constantly defined, wedge-shaped lobule known as the **cuneus,** and the posterior and mesial extremity of the **lingual gyrus.** Since the greater portion of the length of the lingual gyrus is involved in the basal surface of the temporal lobe, this gyrus as a whole has been considered as belonging to the temporal lobe (see figs. 671, 676). The cuneus is separated from the lingual gyrus by the posterior portion of the **calcarine fissure,** which always terminates in a bifurcation, one limb of which invades the cuneus near the superomesial border. In addition the cuneus may contain other twigs from both the fissures bounding it, and also, when wide, may contain one or more short, detached **sulci cunei.**

The **calcarine fissure** and the **parieto-occipital fissure** are almost invariably joined in the human brain, forming a Y-shaped figure, the prongs of which give the cuneus its shape. The calcarine fissure begins on the tentorial surface in the posterior portion of the hippocampal gyrus of the limbic lobe, below the splenium of the corpus callosum, and extends backward across the internal occipital border of the hemisphere. It then bends downward and proceeds to its terminal bifurcation in the polar portion of the occipital lobe. The stem or hippocampal portion of the fissure is deeper than the posterior or occipital portion. It produces a well-marked eminence in the medial wall of the posterior cornu of the lateral ventricle, known as the *calcar avis* or *hippocampus minor*. It is developed separately from the posterior portion, which itself first appears as two grooves. All three parts are usually continuous with each other before birth.

The **parieto-occipital fissure** usually appears from the first as a continuous groove. It begins in the supero-mesial border of the hemisphere, rarely extending into the convex surface more than 10 mm. (*external parieto-occipital fissure*), thence it extends vertically downward across the mesial surface (*internal parieto-occipital fissure*), and terminates by joining the calcarine fissure at the region of the downward bend of the latter, or at about the junction of its anterior and middle thirds. In certain of the lower apes and in the brain of the chimpanzee there is no junction between the two fissures, they being kept apart by a narrow neck of cortex, the **gyrus cunei.** Neither are they joined in the human fœtus. If in the adult human brain the region of their junction be opened widely, there will be found a submerged transitory *gyrus* (deep annectant gyrus), which is the gyrus cunei, superficial in the fœtus. In the higher apes and in micro-cephalic idiots this gyrus may be on the surface or partially submerged. Two other transitory gyri (annectant gyri) are to be found by pressing open the calcarine fissure, and they mark the points at which its three original grooves became continuous during its development into a boundary between the cuneus and the lingual gyrus. Of these, the **anterior cuneo-lingual gyrus** crosses the floor of the calcarine fissure on the posterior side of its junction with the parieto-occipital fissure, and therefore near the gyrus cunei. The **posterior cuneo-lingual gyrus** occurs near the region of the terminal bifurcation of the fissure.

The *tentorial surface* of the occipital lobe is blended intimately with that of the temporal lobe, from which it is separated only by an arbitrary line drawn to join the line of demarcation for the convex surface, at the region of the pre-occipital notch, and thence to the isthmus of the gyrus fornicatus—the narrow neck of cortex connecting the gyrus cinguli with the hippocampal gyrus, just below the splenium of the corpus callosum (see fig. 671). The gyri blending the occipital and temporal lobes across this line are the *lingual gyrus*, already mentioned, and the **fusiform gyrus** (occipito-temporal convolution). In fact, the tentorial surface of the lobe may be considered as nothing more than the posterior extremity of the fusiform gyrus, and the inferior portion of the same extremity of the lingual gyrus. The former is often somewhat broken up and is then continuous into the lateral occipital gyri. The two gyri are separated by the *collateral fissure* the posterior end of which extends into the occipital lobe. The fusiform gyrus is bounded laterally by the inferior temporal sulcus, which sometimes is continuous by a lateral twig, across the posterior end of this gyrus, with the collateral fissure.

The Rhinencephalon

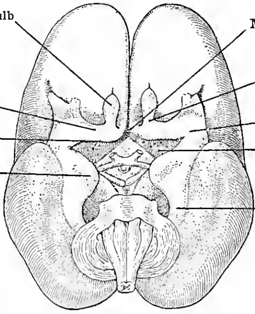
The rhinencephalon or *olfactory brain* includes those portions of the cerebral hemisphere which are chiefly concerned as the central components of the olfactory apparatus. Owing to the preponderant development of the other divisions of the hemisphere, the parts comprising this division appear relatively but feebly developed in the human brain. In most of the mammals the sense of smell is relatively much more highly developed, and in many of the larger mammals the parts comprising the rhinencephalon are of greater absolute size than in man, though their cerebral hemispheres may be considerably smaller. In the human fœtus the parts of the rhinencephalon are relatively much more prominent than after the completed differentiations into the adult condition. In the broader sense of the term the rhinencephalon includes those parts of the hemisphere usually classed as comprising two lobes, viz., the **olfactory lobe** and the **limbic lobe.** Neither of these is a 'lobe' in the sense of comprising a definite segment of the hemisphere, as do the other lobes, and therefore the rhinencephalon cannot be called a distinct lobe. It is so strung out that by one or the other of its parts it is either in contact or continuity with each of the other lobes of the hemisphere.

Morphologically, the rhinencephalon may be divided into an **anterior** and a **posterior division.**

The anterior division.—the *olfactory lobe* proper, belongs almost wholly to the base of the encephalon, and consists of the following parts:—

(1) The **olfactory bulb** is an elongated, oval enlargement of grey substance which lies upon the lamina cribrosa of the ethmoid bone, and, practically free, it presses under the anterior end of the olfactory sulcus in the basal surface of the frontal lobe. The numerous thin filaments of nonmedullated axones of the *olfactory nerve* enter the cranium through the foramina of the lamina cribrosa and pass into the ventral surface of the bulb.

Fig. 680.—Brain of Human Fœtus of 22.5 Cm. (Beginning of Fifth Month), showing the Parts of the Developing Rhinencephalon Apparent on the Basal Surface. (After Retzius.)



(2) The **olfactory tract** is a triangular band of white substance which arises in the olfactory bulb, and continues backward about 20 mm. to the region of the anterior perforated substance. It appears triangular in transverse section from the fact that its upper side fits into the olfactory sulcus. It becomes somewhat broader at its posterior end.

(3) The **olfactory trigone** (*olfactory tubercle*) is the small triangular ridge, the posterior continuation of the olfactory tract joining the anterior perforated substance. In it the olfactory tract breaks up into three roots, the *lateral, intermediate,* and *medial olfactory striæ* (*gyri*). The lateral olfactory stria emphasizes the lateral portion of the trigone into the **lateral olfactory gyrus,** a portion of which is directly continuous into the *limen insulæ* (figs. 676, 680).

While a few of the fibres of the lateral stria penetrate this region, the greater mass of them pass obliquely lateralward over it and gradually disappear in the antero-lateral portion of the anterior perforated substance, in which some of them terminate, but through which most of them pass to curve into the anterior end of the hippocampal gyrus and terminate there, chiefly in the uncus. In most of the mammals the lateral stria is so strong that it appears as a superficial white band passing directly into the uncus. In the early fœtus it is seen to enter the uncus in two branches, forming the medial **semilunar gyrus** and the lateral **gyrus ambiens** upon the uncus. A portion of the *limen insulæ* belongs to the rhinencephalon.

(4) The **parolfactory** area (Broca's area) involves the mesial extension of the olfactory trigone, and is concerned with the *medial olfactory* stria. On the basal surface of the hemisphere this area involves the posterior extremity of the gyrus rectus—a portion of which is sometimes separated from the remainder of the gyrus by a ventral prolongation of the *anterior parolfactory sulcus* of the medial surface (see figs. 679, 706). This prolongation when present has been called the **fissura serotina.** On the medial surface the parolfactory area appears as a

definite gyrus. In front this is separated from the superior frontal gyrus by the *anterior parolfactory sulcus*, and from the subcallosal gyrus behind by the deeper *posterior parolfactory sulcus* (fig. 679). It is continuous above into the gyrus cinguli of the limbic lobe, a portion of the posterior part of the rhinencephalon.

A large portion of the fibres of the medial stria are lost in the parolfactory area, and are known to terminate about the cells there. This stria or root of the olfactory tract forms a slight ridge on the ventral surface of the area, which is frequently prominent enough to retain the name **medial olfactory gyrus** applied to it in the fœtal brain (fig. 680).

(5) The **subcallosal gyrus** (peduncle of the corpus callosum) is the narrow fold of the pallium which lies between the posterior parolfactory sulcus and the rostral lamina and the ventral continuation of the latter into the lamina terminalis. It begins above, in part fused to the rostrum of the corpus callosum, and in part continuous with the gyrus cinguli, and ventrally it goes over lateralward and posteriorly into that portion of the anterior perforated substance known as the *diagonal band* of Broca, and in this way it extends into the uncus. Mesially, it approaches its fellow of the opposite side so closely that the groove separating the two is known as the *median subcallosal sulcus* of Retzius. Some fibres of the medial olfactory stria disappear in the substance of the subcallosal gyrus.

(6) The **anterior perforated substance** must be considered with the rhinencephalon, but, like the limen insulæ, it can only be considered as belonging in part to this division of the brain. It comprises the basal region between the optic chiasma and tract and the olfactory trigone. Usually the posterior parolfactory sulcus (*fissura prima* of the embryo) is sufficiently evident to more or less distinctly separate it from the latter. Its postero-lateral area is occupied by the diagonal band of Broca. A few fibres from the medial stria are known to disappear within its depths, and, as mentioned above, many fibres from the lateral stria also pass into it. The intermediate *olfactory stria* is always much the weakest of the three striæ, and in many specimens is apparently absent. The fibres of this stria run almost straight backward and plunge directly into the anterior area of the anterior perforated substance, where some of them are known to terminate, while others continue into the uncus.

On embryological grounds, the subcallosal gyrus and the anterior perforated substance are classed with the posterior division of the 'olfactory' lobe or anterior division of the rhinencephalon.

The olfactory bulb and tract arise as a hollow outgrowth from the lower and anterior part of the anterior of the three primary vesicles. It is a tubular structure at first, and in many of the mammals the cavity maintains throughout life as the *olfactory ventricle*. In man the cavity becomes occluded and the ependyma and gelatinous substance which surround it become the grey core of the bulb and tract of the adult.

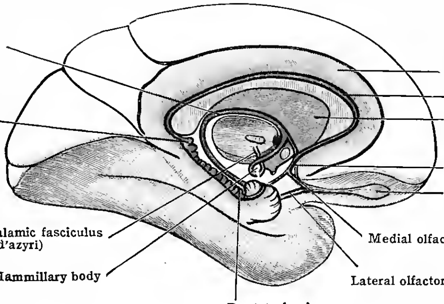
The grey substance persists and develops chiefly in the bulb, and in fact produces it as such. It is much thicker on the inferior surface of the bulb than on the superior surface, and in section shows definite layers. From within outward, the principal of these layers are—(1) the layer of large cells whose shape suggests their name, *mitral cells;* (2) large dendrites of the mitral cells project toward the inferior surface of the bulb and there break up into numerous telodendria which copiously form synapses with like telodendria of the entering fibres of the olfactory nerve, thus forming rounded, much tangled glomeruli and the layer containing these, the *glomerular layer;* (3) the superficial layer, or *olfactory layer*, consists of the fibres of the olfactory nerve which form a dense interlacement with each other on the inferior surface of the bulb before they pass into its interior. The superior surface of the bulb becomes formed almost wholly of the fibres which arise as axones of the mitral cells and pass backward to form the olfactory tract, and thence to their localities of termination, chiefly by way of the three striæ. Along the dorsal, covered, aspect of the olfactory tract the gelatinous substance of the core may show through as a grey ridge.

The posterior division of the rhinencephalon or the so-called **limbic lobe** (a name introduced by Broca in 1878) takes part in both the medial and tentorial surfaces of the hemisphere (fig. 681). Seen from the medial surface, it forms an irregular elliptical figure which encloses the corpus callosum and the extremities of which approach each other at the anterior perforated substance, where they are continuous with the structures of the anterior division of the rhinencephalon. The figure is bounded externally by the sulcus cinguli above, by the subparietal sulcus (postlimbic sulcus) and the anterior limb of the calcarine fissure behind, and by the collateral fissure below. These respectively separate it from the frontal, parietal, occipital, and temporal lobes. It comprises the following structures which are either wholly or in part devoted to the functions of the olfactory apparatus:—

1. Gyrus fornicatus
   - Part of gyrus cinguli and cingulum.
   - Isthmus of the gyrus fornicatus.
   - Hippocampus
     - hippocampal gyrus.
     - uncus.
     - dentate gyrus (fascia).
     - fimbria.
2. The medial and lateral longitudinal striæ upon the corpus callosum.
3. The fornix.
4. The mammillary body, the mammillo-thalamic fasciculus to the anterior nucleus of the thalamus and the mammillo-peduncular fasciculus.
5. Part of anterior cerebral commissure.
6. Part of septum pellucidum.
7. Most of medullary stria of thalamus.
8. Most of habenular nucleus.

The **gyrus fornicatus** comprises the greater mass of the limbic lobe. As seen above, it is a term used to collectively represent a number of conjoined structures.

Fig. 681.—Diagram showing Position of Structures Comprising the Limbic Lobe as Seen from the Mesial Aspect of the Cerebral Hemisphere.



Being an incomplete ellipse in form, its two ends are united to form a closed ring by means of the connection of the parolfactory area with the gyrus cinguli and the connection of the anterior perforated substance with the uncus of the hippocampal gyrus. It is best described in terms of its three component parts indicated above:

The **gyrus cinguli** begins in junction with the area parolfactoria below the anterior end of the corpus callosum, and curves above so as to entirely embrace the upper surface of the latter. It is separated from the frontal lobe by the sulcus cinguli (calloso-marginal fissure), from the parietal lobe by the subparietal sulcus, and from the corpus callosum below by the **sulcus of the corpus callosum.** By the latter it is separated from the longitudinal striæ of the upper surface of the corpus callosum.

The gyrus cinguli covers over, and its cells are closely associated with, the **cingulum,** a well-marked arcuate band of white substance, which follows the gyrus in its bend around the rostrum and backward to turn around the splenium of the corpus callosum in the isthmus of the gyrus fornicatus, and then to course forward into the hippocampal gyrus and the uncus. The cingulum is largely an association fasciculus between the gyri of the temporal lobe and those gyri on the mesial surface of the cerebral hemisphere, its fibres for the most part running short courses, being continually added to it and continually leaving it. However, it contains olfactory axones running in two directions: (1) fibres from the medial olfactory stria and fibres arising in the parolfactory area, the gyrus subcallosus and the anterior perforated substance which course posteriorly for distribution in the cortex of the gyrus cinguli and hippocampal gyrus; (2)fibres arising in the hippocampal gyrus, especially the uncus, to course dorsalward through the isthmus and then forward as association fibres. Some fibres arising from the cortical cells of the gyrus cinguli pass inferiorly through the cingulum, through the corpus callosum and, anteriorly, through the septum pellucidum to join the fornix below (*perforating fibres of the fornix*).

The **isthmus of the gyrus fornicatus** is the constricted portion connecting the posterior end of the gyrus cinguli with that of the hippocampal gyrus (fig. 619

and 671). It is bounded externally by the anterior end of the calcarine fissure, and incloses the posterior turn of the cingulum.

The **hippocampus** is the name applied to the curved appearances produced in the floor of the lateral ventricle by the peculiar foldings of this part of the cerebral cortex. The *hippocampal gyrus* (gyrus of the hippocampus) is the main gyrus of the tentorial surface of the limbic lobe. Externally it is separated from the fusiform gyrus by the collateral fissure, and it is bounded internally by the **hippocampal** or, more inclusive, the **chorioid fissure.** Posteriorly it is partially divided by the calcarine fissure into the lingual gyrus (of the temporal lobe) and the isthmus of the gyrus fornicatus. Its anterior extremity is hooked backward and is known as the **uncus** (*gyrus uncinatus*). This is almost entirely separated from the temporal lobe by a groove, the **temporal notch.** If the hippocampal fissure be opened up, the **dentate gyrus** or fascia and the *fimbria* will be seen. These lie side by side, separated by the shallow **fimbrio-dentate sulcus** (fig. 690.)

The free edge of the dentate gyrus presents a peculiarly notched appearance, produced by numerous parallel grooves cutting it transversely. Its posterior end, sometimes called the *fasciola cinerea*, continues backward over the splenium of the corpus callosum, and upon the upper surface of the corpus callosum appears as a thin strip of grey substance which contains embedded in it the *medial* and *lateral longitudinal striæ*. This thin strip is sometimes called the **supracallosal gyrus** (*gyrus epicallosus, induseum griseum*), and is thought to represent a vestigial part of the hippocampal gyrus. Closely beneath the splenium of the corpus callosum, on the supero-mesial side of the hippocampal gyrus and mesial to the dentate gyrus, there sometimes occur suggestions of round or oval elevations of the grey substance which have been called the "**callosal convolutions**" or *gyri Andreæ Retzii*. Rarely are they strongly developed, but when so they often produce a spiral appearance.

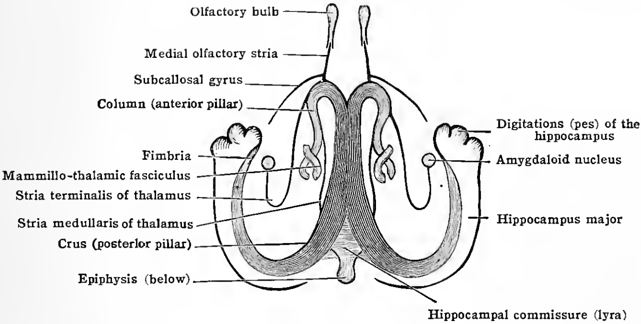
The **fimbria** is but the fimbriated, free border of the posterior end or origin of the fornix, so folded as to project into the hippocampal fissure, parallel with the dentate gyrus (fig. 690). It is a conspicuous band composed almost entirely of white substance, continuous laterally with the thick stratum covering the ventricular surface of the hippocampus. It begins anteriorly in the hook or recurved extremity of the uncus. Traced backward, it is seen so curve upward, and within the ventricle it becomes part of the general accumulation of the white substance (*alveus*) of the surface of the hippocampus, which accumulation is the beginning of the fornix. The free border of the fimbria (seen in section) is known as the *tænia fimbriæ*. The fimbria is separated from the cerebral peduncles by the **chorioid fissure,** the thin, non-nervous floor of which alone intervenes between the exterior of the brain and the cavity of the lateral ventricle within.

The hippocampal fissure attains its greatest depth between the dentate gyrus and the hippocampal gyrus, and the resulting eminence produced in the floor of the lateral ventricle is known as the **hippocampus major,** as distinguished from the lesser eminence produced posteriorly by the end of the calcarine fissure and known as the *hippocampus minor* [calcar avis]. The collateral fissure may likewise produce a bulging in the wall of the ventricle, the *collateral eminence*. In transverse sections of the hippocampus major, the layers of grey and white substance present a coiled appearance known as the **cornu ammonis.** Externally the medial surface of the hippocampal gyrus adjoining the dentate gyrus has reflected over it a delicate reticular layer of white substance known as the *substantia reticularis alba* (*Arnoldi*).

The fornix is the great association pathway of the limbic lobe, and appears to be wholly concerned in the apparatus of the rhinencephalon. It is a bilateral structure arched beneath the corpus callosum, with which it is connected anteriorly by the septum pellucidum. Posteriorly it passes in contact with the splenium. It consists of two prominent strips of white substance, one for each hemisphere, the ends of which are separate from each other, while their intermediate parts are fused across the mid-line. These run above the chorioid tela of the third ventricle, and their lateral edges (*tæniæ fornicis*) rest, on each side, along the line of the tænia chorioidea. The posterior, separate ends are known as the posterior pillars or crura of the fornix; the fused, intermediate portion is the body, and the separate, anterior ends are the anterior pillars or columns of the fornix.

The posterior pillars [crura] of the fornix.—When seen from the medial aspect of the hemisphere, the fused portion of the fornix, in the separation of the hemispheres, is split along the mid-line (fig. 671). The half under examination may be seen to course obliquely lateralward under the splenium of the corpus callosum, and then, continuous into the fimbria, to curve forward and ventralward toward the uncus. The greater mass of the fibres coursing in the fornix arise as outgrowths of the cells of the uncus, hippocampal gyrus, and dentate gyrus. They accumulate as a dense stratum on the ventricular surface of these gyri, termed the **alveus,** which crops outward as the fimbria and which passes backward and upward; upon reaching the region of the splenium it turns obliquely forward under

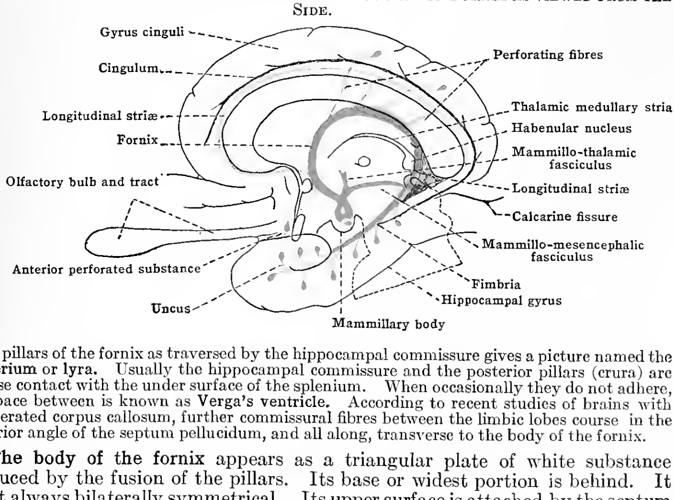
Fig. 682.—Diagram Showing Fornix and its Connections as seen from Above.



it and approaches the mid-line, to fuse with the like bundle from the gyri of the hippocampus of the opposite side. The bundles thus arising from the two sides are the pillars or crura of the fornix. They appear as two flattened bands of white substance which come in close contact with and even adhere to the splenium.

The angle formed by the mutual approach of the posterior pillars of the fornix is crossed by a lamina of commissural fibres connecting the hippocampal gyri of the two hemispheres (fig. 684). This lamina is the **hippocampal commissure** or *transverse fornix.* Like those of the fornix, its fibres arise from the cortex of the hippocampal gyri, but they serve as commissural fibres between the hippocampal gyri of the two hemispheres. Being of a different functional direction, it should not be considered a part of the fornix. The angle formed by the two pos-

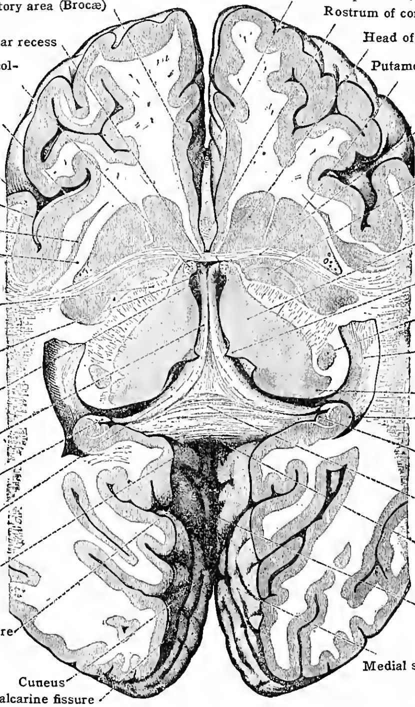
Fig. 683.—Diagram Illustrating the Origin and Course of Fornix as viewed from the Side.



terior pillars of the fornix as traversed by the hippocampal commissure gives a picture named the **psalterium or lyra.** Usually the hippocampal commissure and the posterior pillars (crura) are in close contact with the under surface of the splenium. When occasionally they do not adhere, the space between is known as **Verga's ventricle.** According to recent studies of brains with degenerated corpus callosum, further commissural fibres between the limbic lobes course in the posterior angle of the septum pellucidum, and all along, transverse to the body of the fornix.

The body of the fornix appears as a triangular plate of white substance produced by the fusion of the pillars. Its base or widest portion is behind. It is not always bilaterally symmetrical. Its upper surface is attached by the septum pellucidum to the lower surface of the corpus callosum. Below, it lies over the chorioid tela of the third ventricle, which separates it mesially from the cavity of the third ventricle and laterally from the upper surfaces of the thalami. Its sharp lateral edge or margin (tænia fornicis) projects into the lateral ventricle of either side in relation with the chorioid plexus of that ventricle, and thus the lateral portion of its upper surface forms part of the floor of the lateral ventricle—an arrangement to be expected, since the posterior pillars arise from the floor of

Fig. 684.—Horizontal Section of Telencephalon showing Body of Fornix and Hippocampal Commissure as seen from Below and the Anterior Commissure in Section. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



the ventricle, viz., the hippocampus. The ventricular portion is covered by a layer of ependyma in common with that lining the rest of the ventricle.

Along its body the fornix receives fibres arising from the cells of the cortex of the gyrus cinguli and fibres from the longitudinal striæ upon the dorsal surface of the corpus callosum. These are known as the **perforating fibres of the fornix.** In their ventral course, they pass obliquely forward through the corpus callosum and, anteriorly, through the posterior angle of the septum pellucidum to join the fornix and course in its functional direction. The fibres arising in the cortex of the gyrus cinguli may course short distances in the cingulum before perforating the corpus callosum.

The columns or anterior pillars of the fornix [columnæ fornicis], are two separate, cylindrical bundles which pass forward from the apex of the body of the fornix and then turn sharply downward along the anterior boundary of the third ventricle, just behind the anterior cerebral commissure. A part of each column, the *free portion* [pars libera], forms the anterior boundary of the interventricular foramen (Monroi). Thence the *covered portion* [pars tecta] sinks into the grey substance of the lateral wall of the third ventricle, and passes downward to the base of the brain, where it appears on the exterior as the **mammillary body** [corpus mammillare] (fig. 671).

Some of its fibres are interrupted in the nuclei of the mammillary body, chiefly in its lateral nucleus; probably most of them merely double back, forming a genu. From the mammillary body the fibres are disposed in at least three ways:—(1) The greater part perhaps pass directly upward and are lost in the *anterior nucleus of the thalamus*, where they ramify freely and terminate about its cells. These fibres form the bundle known as the **mammillo-thalamic fasciculus**, or bundle of Vicq d'Azyr; (2) A portion of the fibres go to form a **mammillo-mesencephalic fasciculus** (**tegmento-mammillary fasciculus**, *mammillo-peduncular fasciculus*. This begins in the mammillary body and passes caudalward into the mesencephalon to terminate about cell-bodies in or in the region of, the so-called *nucleus of the medial longitudinal fasciculus and posterior commissure*. Fibres given by these cell-bodies may convey impulses by way of the medial longitudinal fasciculus or the general reticular formation to the nuclei in the mesencephalon, rhombencephalon and perhaps into the spinal cord. Some of this portion of the fibres from the mammillary body are said to pass caudalward through the mesencephalon without interruption there. (3) A portion of the fibres decussate in the superior parts of the mamillary bodies and are distributed to both the thalamus and the mesencephalon of the opposite side. This decussation is the **supramamillary commissure.**

As seen above, the fornix as a whole is composed of longitudinally directed fibres, some of which, however, cross the mid-line in the region of its body and course in the columns of the opposite side. For the greater part, its fibres rise from the cells of the hippocampal gyri, but it is known to contain some fibres which arise in the anterior perforated substance and subcallosal gyrus and course through the fornix to the hippocampal gyri.

The **medial and lateral longitudinal striæ** upon the corpus callosum consist of olfactory fibres coursing in both directions: (1) fibres arising in the parolfactory area, the subcallosal gyrus and the anterior perforated substance (diagonal band of Broca) course posteriorly and then inferiorly in them to the grey substance of the gryi of the hippocampus; (2) and chiefly, fibres from the hippocampal gyri course in them anteriorly and inferiorly around the rostrum of the corpus callosum, through the ventral part of the septum pellucidum, to join the fornix. It is suggested that the striæ, especially the medial, may be considered as a part of the fornix detached upon the dorsal surface of the corpus callosum during the projection of the latter between the cerebral hemispheres. The medial stria is often called the *stria Lancisii*.

The anterior cerebral commissure is only in part concerned in the rhinencephalon; it consists in greater part of commissural fibres connecting the two temporal lobes. It forms one of the four commissures of the telencephalon, the other three being the corpus callosum, the hippocampal commissure and the inferior cerebral commissure. It is a bundle of white substance with a slightly twisted appearance, which crosses the mid-line in the anterior boundary of the third ventricle between the lamina terminalis and the columns of the fornix (figs. 671 and 684), just below the interventricular foramen (foramen of Monro). In each hemisphere its main or temporal portion passes lateralward and slightly backward beneath the head of the caudate nucleus and through the anterior end of the lenticular nucleus, and thence is dispersed to the grey substance of the temporal lobe.

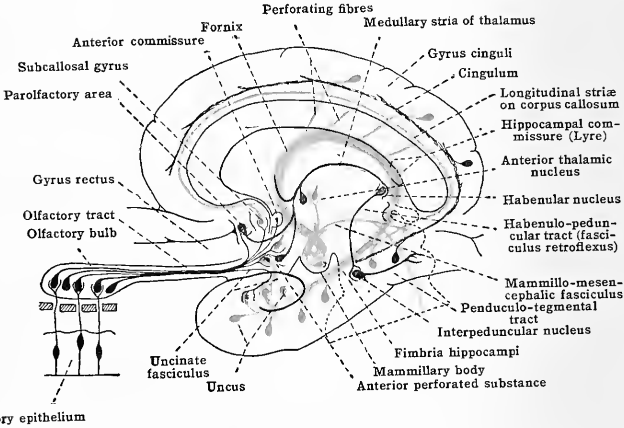
It contains fibres both to and from the temporal lobe of each side. In addition to these fibres the anterior commissure carries in its frontal side two sets of fibres belonging to the olfactory apparatus:—(1) fibres arising in the olfactory bulb of one side, which pass by way of the medial olfactory striæ through it to the olfactory bulb of the opposite side; (2) fibres which pass through it from the medial stria (olfactory bulb) of one side to the uncus of the opposite side.

The anterior commissure is a more primitive commissure than the corpus callosum, in that it is present in the lower forms when the latter is absent, and diminishes in relative size and importance as the corpus callosum appears and increases in size. In man the appearance of the anterior commissure precedes but little that of the corpus callosum. During the fifth month the lamina terminalis, which then alone unites the anterior ends of the two hemispheres, develops a thickening of its dorsal portion. In a part of this thickening, transverse fibres begin to appear and their increase in number results in the partial separation posteriorly of the part containing them from the rest of the lamina, and then follows the differentiation of this part into the anterior commissure. The remainder of the thickening of the lamina continues to increase in size with the increase of the hemispheres; its upper edge is directed posteriorly, and fibres begin to appear in it which arise in the cortex of one side and cross over to that of the other side. These fibres form the corpus callosum.

The corpus callosum, a development of fibres in the upper, expanded portion of the lamina terminalis, thus bridges over a portion of the longitudinal fissure between the hemispheres. In the mean time, the *fornix* arises as two bundles of fibres, one from the hippocampus of each side. In the complex mechanics of the development of the cerebrum these two bundles approach each other under the corpus callosum, fuse for a certain distance, and together arch the cavity of the third ventricle and come to acquire their adult position. There results from these processes of growth a completely enclosed space, a portion of the longitudinal fissure, the roof of which is the corpus callosum, its floor, the body of the fornix, and its lateral walls, portions of the mesial surfaces of the two cerebral hemispheres. The lateral walls of this space do not thicken as do the other regions of the pallium, but remain thin and constitute the *septum pellucidum* of the adult, the space itself being the so-called *fifth ventricle* or cavity of the septum pellucidum.

The **septum pellucidum** is a thin, approximately triangular, vertically placed partition which separates the anterior portions of the two lateral ventricles from each other. Its widest portion lies in front, bounded by the genu and rostrum of the corpus callosum, the rostral lamina, and the anterior pillars of the fornix, to all of which it is attached. Prolonged backward under the body of the corpus callosum, it narrows rapidly and terminates at the line of adherence between the posterior portion of the fornix and the splenium of the corpus callosum. It consists of two thin layers, the **laminæ of the septum pellucidum,** arrested developments of portions of the pallium of the hemispheres. The laminæ enclose a narrow median cavity known as the **fifth ventricle** [cavum septi pellucidi]. This cavity is of very variable size, is completely closed, and does not merit the term 'ventricle,' as applied to the other cavities of the brain, in that it has no communication with the ventricular system and has a different lining from the other ventricles.

Fig. 685.—Diagram showing Some of the Principal Tracts and Synapses of the Olfactory Apparatus.



Each lamina of the septum pellucidum consists of a layer of degenerated grey substance next to the fifth ventricle and a layer of white substance next to the lateral ventricle, the latter covered by a layer of ependyma common to that ventricle. The white substance consists in part of fibres belonging to the general association systems of the hemispheres, and in part of four varieties of fibres concerned with the rhinencephalon:—(1) fibres from each medial olfactory stria are known to reach the septum pellucidum and thence go by way of the fornix to the hippocampus major; (2) fibres are thought to be contributed by the fornix to the septum pellucidum, and through it reach the subcallosal gyrus and perhaps the parolfactory area and even the olfactory bulb; (3) the posterior angle of the septum pellucidum is preforated by some commissural fibres passing from the body of the fornix and by some perforating fibres of the fornix, passing from above through it to the fornix below; (4) anteriorly, some fibres from the longitudinal striæ upon the corpus callosum pass through its inferior portion to join the fornix.

The medullary stria of the thalamus [stria medullaris thalami] (*striæ pinealis, tænia thalami*), already described as to position, receives fibres from three sources, the majority at least of which belong to the rhinencephalon: (1) fibres from the fornix near-by and thus from the cortex of hippocampal gyrus and gryus cinguli (a cortico-habenular tract); (2) fibres from the parolfactory area and the anterior perforated substance, through the septum pellucidum and lamina terminalis (a more direct olfacto-habenular tract); (3) fibres arising from the cell-bodies in the thalamus, supposedly chiefly from its anterior (olfactory) nucleus. These latter fibres make a thalamo-habenular tract.

The majority of the fibres of the medullary striæ terminate in the **habenular nuclei,** situated at the two sides of the stalk of the epiphysis. Most terminate in the habenular nucleus of the same side. Some cross in the *habenular commissure* (dorsal part of the posterior cerebral commissure) and terminate in the nucleus of the opposite side. A few are claimed to pass to the nuclei of the quadrigeminate bodies and a few others to join the association tracts of the mesencephalon. Axones given off by the cells of the habenular nucleus curve anteriorly, inferiorly, and then course posteriorly (fasciculus retroflexus) to terminate in the *interpeduncular nucleus* (*a habenulo-peduncular tract*), and fibres arising in this latter nucleus pass to the cells about the central grey substance of the mesenecphalon (an inter-pedunculo-tegmental tract). The two mesencephalic paths here noted and the mammillo-mesencephalic fasciculus noted above give three anatomical possibilities for olfactory reflex activities, visceral (or sympathetic) and somatic, involving the motor cranial nerves and possibly the spinal nerves. Fibres arising in the cortex of the hippocampal gyrus, uncus especially, may pass by way of the cingulum and thence by any suitable association fasciculus of the cerebral hemisphere to the motor area of the cerebral cortex; also fibres may arise from the anterior nucleus of the thalamus and pass to the motor cortex by way of the internal capsule. From the motor cortex, the descending pyramidal fibres give the possibilities for any higher cortical activities induced by smell.

A more direct mesencephalic path has been suggested by Wallenberg, namely, that cells in the olfactory trigone and anterior perforated substance, about which terminates fibres of the olfactory tract, send axones directly posteriorly, around the tuber cinereum, to terminate in the mammillary body and thence the impulses may go to the mesencephalon. Such fibres, if they exist, would form an *olfacto-mammillary tract.* A path is described in the hedge-hog which arises from cells in the olfactory trigone and passes directly posteriorly to terminate in the grey substance of the mesencephalon—an *olfacto-mesencephalic tract.*

To the complicated central connections of the sense of smell, Dejerine adds yet another path, namely, a portion at least of the terminal stria [stria terminalis] of the thalamus (tænia semicircularis). This contains fibres arising from cells in the anterior perforated substance and in the septum pellucidum and fibres from the opposite side by way of the anterior commissure. It runs a crescentic course posteriorly, bounding the thalamus from the caudate nucleus, turning downward and then anteriorly in the wall of the inferior cornu of the lateral ventricle to terminate in the amygdaloid nucleus, which latter is a more or less detached bit of the cortex of the extreme anterior portion of the hippocampal gyrus (uncus). The stria is said also to contain fibres which arise in the amygdaloid nucleus and course in it forward to be given off to the thalamus and probably to the internal capsule and thence to the cerebral cortex above.

SUMMARY OF THE OLFACTORY APPARATUS

I. Peripheral part.

(1) Olfactory area of nasal epithelium containing the cell-bodies and peripheral processes of olfactory neurones (*olfactory ganglion*).

(2) Non-medullated central processes of olfactory neurones, the *olfactory nerve*, passing as numerous filaments through the cribriform plate of the ethmoid, to terminate in contact with the dendrites of the "mitral cells" (stratum glomerulosum) in the olfactory bulb.

II. The Rhinencephalon.

A. The anterior division.

(1) Olfactory bulb, olfactory tract, olfactory trigone (tubercle), lateral olfactory stria (gyrus), medial and intermediate olfactory striæ.

(2) The parolfactory area, subcallosal gyrus, anterior perforated substance including the diagonal band of Broca.

B. The posterior division.

(1) Part of anterior commissure, septum pellucidum, uncinate fasciculus, hippocampal gyrus (uncus especially), dentate gyrus, gyrus cinguli and cingulum.

(2) Fimbria, hippocampal commissure, fornix, longitudinal striæ upon corpus callosum, mammillary body, mammillo-thalamic fasciculus, mammillo-mesencephalic fasciculus.

(3) The anterior nucleus of the thalamus.

(4) The medullary stria of the thalamus, habenular nucleus, fasciculus retroflexus, interpeduncular nucleus, and interpedunculo-tegmental tract.

(5) Probably an olfacto-mammillary and an olfacto-mesencephalic tract, and a part of the terminal stria of the thalamus with the amygdaloid nucleus.

THE LATERAL VENTRICLES

Two of the four cavities of the ventricular system of the brain are in the telencephalon. From their position, one in each cerebral hemisphere, they are known as the **lateral ventricles.** They arise as lateral dilations of the cavity of the anterior of the primary vesicles, and, just as the fourth ventricle remains in communication with the third by way of the aqueduct of the cerebrum, so the lateral are connected with the third by the two interventricular foramina (Monroi). The whole ventricular system, including the central canal of the spinal cord, is lined by a continuous layer of ependyma and contains a small quantity of liquid known as the cerebro-spinal fluid.

Each lateral ventricle is of an irregular, horseshoe shape. It consists of a *central portion* or body and three cornua, which correspond to the three poles of the hemisphere. The portion projecting into the frontal lobe is known as the *anterior cornu,* that projecting into the occipital lobe is the *posterior cornu,* and the portion which sweeps anteriorly downward into the temporal lobe is the *inferior cornu.* The ventricles of different individuals vary considerably in capacity, and the cavity of a given ventricle is not uniform throughout. In some localities the space may be quite appreciable, while in other places the walls may be approximate or even in apposition. Each lateral ventricle is a completely closed cavity except at the interventricular foramen. However, a strip of the floor of the inferior cornu is separated from the exterior of the brain by only the thin, non-nervous lamina forming the floor of the chorioid fissure.

The **interventricular foramen** (foramen of Monro), by which the lateral ventricle is continuous with the cavity of the third ventricle, is a small, roundish channel, 2 to 4 mm. wide, which opens into the mesial side of the posterior end of the anterior cornu. It is bounded in front by the free portion of the anterior pillars of the fornix, and behind by the anterior tubercle of the thalamus. That the greater part of the lateral ventricle is posterior to it is due to the backward extension of the hemispheres during their growth and elaboration. Through the two foramina indirectly, the cavities of the two lateral ventricles are in communication with each other.

Fig. 686.—A Cast of the Four Ventricles of the Encephalon. (After Welcker.)

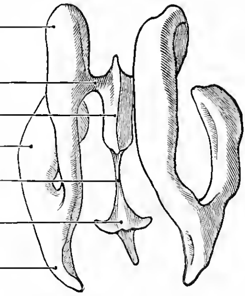


Fig. 687.—Diagram of Sagittal Section through Lateral Part of Right Hemisphere showing Lateral Ventricle from the Mesial Side of the Section.

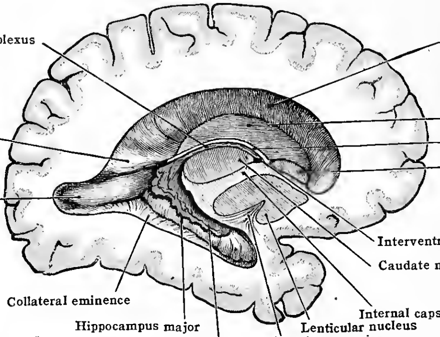
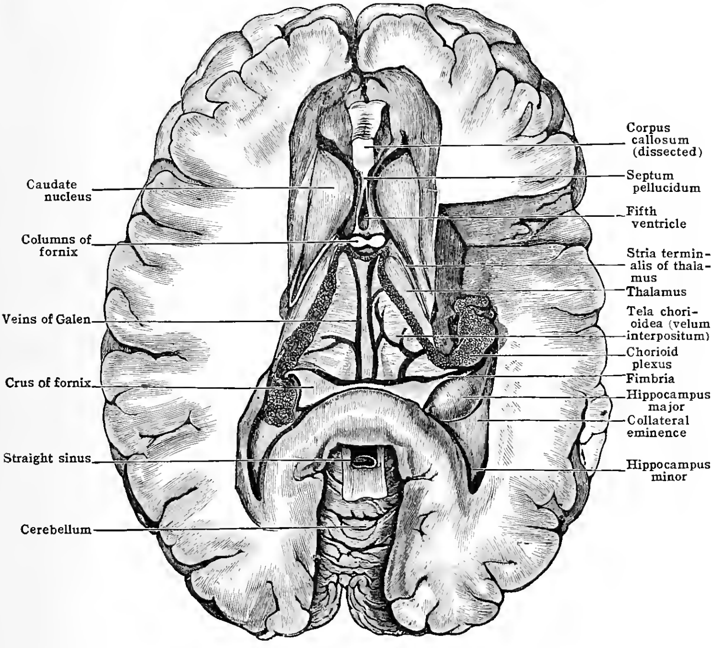


The walls of the lateral ventricle.—The **anterior cornu** is a bowl-like cavity, convex forward and extending downward and medialward into the frontal lobe. Above and anteriorly it is bounded by the under surface of the corpus callosum and the radiations of its genu into the substance of the frontal lobe. Its median boundary is the septum pellucidum; the head of the caudate nucleus (part of the corpus striatum) gives it a bulging, infero-lateral wall, and the balance of its floor is formed by the white substance of the orbital part of the frontal lobe.

The **central portion** or body is more nearly horizontal. It lies within the parietal lobe and extends from the interventricular foramen to the level of the splenium of the corpus callosum. Its roof is formed by the inferior surface of the body of the corpus callosum, and its mesial wall consists of the posterior part of the septum pellucidum, attaching the fornix to the under surface of the corpus callosum. Like the anterior horn, it is given an oblique, infero-lateral wall by the narrower, middle part of the caudate nucleus. Several structures contribute to its floor:—(1) the stria terminalis of the thalamus, a line of white substance conforming to the genu of the internal capsule without, and constituting the

Fig. 688.—Horizontal Dissection of the Cerebral Hemispheres.

The fornix has been removed to show the relation of the tela chorioidea of the third ventricle to the chorioid plexus of the lateral ventricles. (From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)



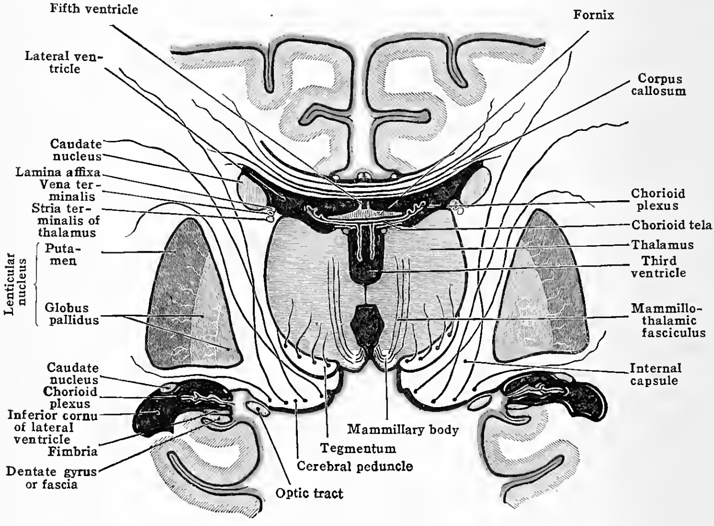
boundary between the caudate nucleus and the thalamus, and containing (2) the vena terminalis (vein of the corpus striatum); (3) the lamina affixa, a mesial continuation of the stria terminalis upon the surface of (4) the lateral part of the thalamus; (5) the medial edge of the lamina affixa, the tænia chorioidea, and the chorioid plexus continuing under (6) the edge (tænia) of the body and the beginning crura (posterior pillars) of the fornix (fig. 688).

The chorioid plexus of the lateral ventricle is continuous with that of the third ventricle. The chorioid tela of the third ventricle (velum interpositum) continues under the tænia of the fornix into the lateral ventricle, and there, along the line of the tænia chorioidea, becomes elaborated into a varicose, convoluted, villus-like fringe, rich in venous capillaries and lymphatics. This fringe is the chorioid plexus. It is continuous anteriorly, at the interventricular foramen, with the corresponding plexus of the opposite lateral ventricle and with the chorioid plexus of the third ventricle. The latter consists of two similar but smaller fringes, which project close together into the cavity of the third ventricle from the median portion of the ventral surface of the chorioid tela. Behind, the chorioid plexus of the lateral ventricle curves posteriorly and inferiorly into the inferior cornu, being especially well developed at the region of its entrance into the latter, into what is called the **chorioid glomus.**

Though apparently lying free in the ventricle, the chorioid plexus is invested throughout by a layer of epithelium, the **epithelial chorioid lamina,** which is adapted to all its unevennesses of surface and which is a continuation of the ependymal lining of the remainder of the ventricle —continuous, on the one hand, with that of the lamina affixa and thalamus, and, on the other, with the epithelial covering upon the upper surface of the tænia of the fornix and fimbria.

The **posterior cornu** of the lateral ventricle is a crescentic cleft of variable length, convex lateralward, which is carried backward from the posterior end of the body of the ventricle and, curving medialward, comes to a point in the occipital lobe. Its *roof* and *lateral wall* are formed by a portion of the posterior radiation of the corpus callosum, which forms a layer, from its appearance known as the **tapetum.** In transverse sections of the occipital lobe (fig. 699) the tapetum appears as a

Fig. 689.—Diagrammatic Transverse Section of Prosencephalon through Bodies of Lateral Ventricles and Middle of Thalamencephalon.

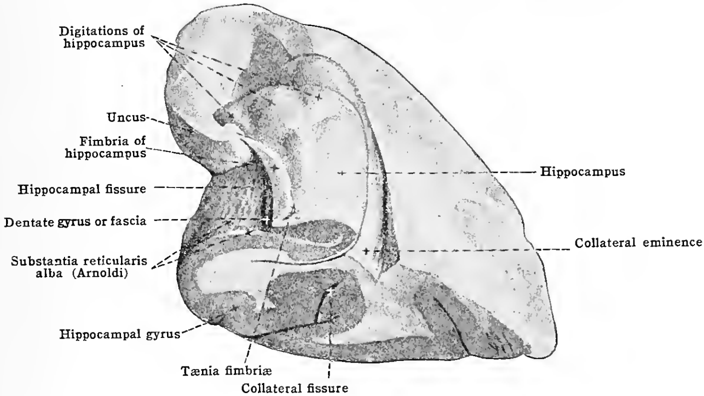


thin lamina of obliquely cut white substance immediately bounding the cavity, while outside the tapetum occurs a thicker layer of more transversely cut fibres, the occipito-thalamic radiation. In the medial or *inner wall* of the posterior horn run two variable longitudinal eminences:—(1) The superior of these is the **bulb of the posterior cornu,** and is formed by the occipital portion of the radiation of the corpus callosum (splenium), which bends around the impression of the deep parieto-occipital fissure, and, hook-like, sweeps into the occipital lobe. In horizontal sections these fibres, together with the splenium and the similar fibres into the opposite occipital lobe, form the figure known as the **forceps major.** (2) The inferior and thicker of the eminences is the **hippocampus minor [calcar avis]** (cock's spur), and is due to the anterior part of the calcarine fissure, by which the wall of the hemisphere is projected into the ventricle. The posterior horn, like the anterior, is not entered by the chorioid plexus.

The inferior cornu.—In its inferior and slightly lateral origin from the region of junction between the body of the ventricle and the posterior cornu, the inferior horn aids in producing a somewhat triangular dilation of the cavity known as the **collateral trigone.** Beginning as a part of the trigone, the cavity of this horn at first passes posteriorly and lateralward, but then suddenly curves anteriorly and inferiorly into the medial part of the temporal lobe nearly parallel with the superior temporal sulcus. Above, it follows the curved crura (posterior pillars) of the fornix and fimbria; below, it does not extend to the temporal pole by from 2 to 3 cm. The *roof* and *lateral wall* are, for the most part, like those of the posterior horn, being formed by the tapetum, but medialward a strip of the roof is formed by the attenuated, inferior prolongation, or tail, of the caudate nucleus, together with the inferior extension of the stria terminalis of the thalamus. At the end of the inferior horn the roof shows a bulging, the **amygdaloid tubercle,** situated at the termination of the tail of the caudate nucleus. This bulging is produced by the *amygdaloid nucleus,* an accumulation of grey substance continuous with that of the cortex of the hippocampal gyrus, and which gives origin to part of the longitudinal fibres coursing in the stria terminalis of the thalamus.

In the *medial wall* and floor of the inferior horn the following structures are shown:—(1) In the posterior or trigonal part of the floor is the longitudinal **collateral eminence,** a bulging, very variable in development in different specimens, produced by the collateral fissure. This is often pronouncedly in two parts, a posterior prominence corresponding to the middle portion of the collateral fissure and an anterior prominence (less frequent) produced by the anterior part of the

Fig. 690.—Dissection of Right Temporal Lobe showing the Medial Wall of the End of the Inferior Horn of the Lateral Ventricle. (From Spalteholz.)



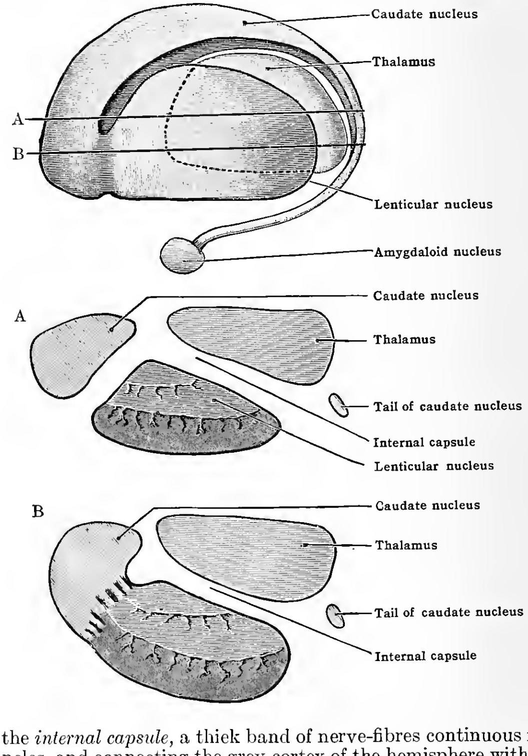
fissure. (2) Medial to this eminence lies the inferior extension of the **chorioid plexus,** usually more voluminous than the part in the body of the ventricle. (3) Partly covered by the chorioid plexus is the **hippocampus major,** a prominent, sickle-like ridge corresponding to the indentation of the hippocampal fissure. It begins as a narrow ridge posteriorly, at the end of the body of the ventricle, as the extension of the posterior pillar of the fornix, and expands anteriorly as the ventricular surface of the uncus. Its surface is not regular, but shows a concave medial margin as distinguished from a wider, convex, lateral surface. Its termination in front (*pes hippocampi*) is divided by two or three flat, radial grooves into a corresponding number of short elevations known as the *hippocampal digitations.* It is covered by a thick stratum of white substance, the *alveus,* arising from its depths and continued mesially into the fimbria. (4) The **fimbria** is so folded that its margin, *tænia fimbriæ,* lies in the cavity of the inferior horn attached to the chorioid plexus and the thin, non-nervous floor of the chorioid fissure.

The caudate nucleus (fig. 691).—As realised in the study of the lateral ventricle, the caudate nucleus is a comma-shaped mass of grey substance with a long, much-curved, and attenuated tail. Its *head* forms the bulging lateral wall of the anterior horn; thence it proceeds posteriorly in the lateral wall of the body of the ventricle and, at the collateral trigone, curves downward and its *tail* becomes a medial portion of the roof of the inferior horn. It is separated from the thalamus adjacent to it by the stria terminalis of the thalamus (tænia semicircularis). The end of its tail extends anteriorly below to the level of the anterior horn of the ventricle above. Owing to its much curved shape, both horizontal and vertical sections of the hemisphere passing through the inferior horn may contain the nucleus cut at two places (see figs. 694 and 698.)

The caudate nucleus is the intraventricular of the two masses of grey substance which together are sometimes referred to as the **basal ganglia.** The extraventricular of these masses is the *lenticular nucleus,* which is buried in the substance of the hemisphere, laterally and inferior to the caudate nucleus. The two masses

Fig. 691.—Diagrams of Lateral View and Sections of the Nuclei of the Corpus Striatum with the Internal Capsule Omitted.

A and B below represent horizontal sections along the lines A and B in the figure above. The figure also shows the relative position of the thalamus and the amygdaloid nucleus.



are separated by the *internal capsule,* a thick band of nerve-fibres continuous into the cerebral peduncles, and connecting the grey cortex of the hemisphere with the structures inferior to it. Anteriorly and below, the two nuclei become continuous and the white substance of the internal capsule, in separating them posteriorly, contributes to the striated appearance in sections, known collectively as the *corpus striatum* (figs. 692, 695). The corpus striatum as such is described below.

INTERNAL STRUCTURE OF THE PROSENCEPHALON

From the above examinations of their external and ventricular surfaces, it is apparent that the cerebral hemispheres consist of a folded, external mantle of grey substance, the cortex cerebri, spread more or less evenly over an internal mass of white substance which contains embedded within it certain masses of grey substance, the chief of which are known as the caudate and lenticular nuclei of the corpus striatum. In addition, the hemispheres of the telencephalon overlie and are in functional connection with the structures of the diencephalon below, the chief of which are the thalamencephalon and the bases of the cerebral peduncles.

The grey substance of the telencephalon.—The grey substance is in intimate relation with the white substance, and in fact its cells give origin to the greater part of the fibres composing the white substance. The accumulations of grey substance to be considered are the cerebral cortex, with its variations in thickness and arrangement, the corpus striatum, the claustrum, and the amygdaloid nucleus.

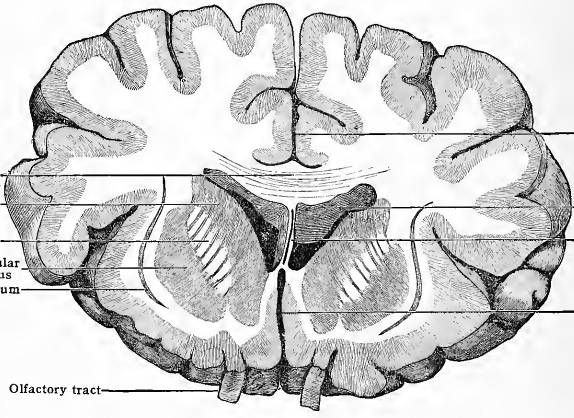
The cerebral cortex [substantia corticalis] is distributed over the entire surface of each hemisphere except the peduncular region of the base and the region of the corpus callosum and fornix of the medial surface. Numerous measurements have been made to determine its average thickness. These have shown that the mantle is not uniformly distributed:—(1) that it is thicker on the convex surface than on the basal and medial surfaces; (2) that on the convex surface it is thicker on the central region of the hemisphere, somæsthetic area, than at the poles; (3) that in the average normal specimen it averages somewhat thicker on the left than on the right hemisphere; (4) that its average thickness varies greatly in different individuals, and that the thickness decreases with old age; (5) that it is probably somewhat thicker in males than in females, and (6) that in a given specimen it averages thicker on the summits of the gyri than in the floor of the corresponding sulci. In the normal adult conditions it averages about 4 mm. thick on the anterior and posterior central gyri, in the somæsthetic area, while it attains its mimimum thickness of about 2.5 mm. on the basal surface of the occipital and frontal lobes. Its total average thickness is about 2.9 mm. The practically non-nervous floor of the third ventricle and that of the chorioid fissure are very much thinner but are not considered in these measurements.

The cerebral cortex consists of layers of the cell-bodies of neurones, chiefly of the pyramidal type (fig. 604), which receive impulses from the structures below and from other regions of the cortex by way of fibres reaching them through the internal mass of white substance, and which in turn contribute fibres to the white substance. Certain fibres of shorter course and numerous collateral branches of fibres passing out of the cortex are devoted to the association of the region of their origin with the cortex of the immediate vicinity of their origin, and most of these course within the grey cortex itself. In certain gyri, such as the anterior central gyri and those of the medial surface of the occipital lobe, these short association fibres accumulate into strata, and in vertical sections give the cortex a stratified appearance. Two such strata of white substance may be noted in the above localities, one lying about midway in the thickness of the cortex and one slightly internal to this. They are known as the inner and outer **stripes of Baillarger.** In addition, a thin, superficial or *tangential layer* of fibres may often be distinguished lying in the surface of the cortex. Transverse sections through the anterior end of the hippocampus show a coiled arrangement of the layers of white substance, to which has been given the name *cornu ammonis.* The peculiar structure and appearance of the olfactory bulb and tract, parts of the cortex, have already been mentioned.

The corpus striatum is so called on account of the appearance in section of its component parts, the caudate and lenticular nuclei (basal ganglia) and the internal capsule between them. The two nuclei are directly continuous with each other at their anterior ends (fig. 691), and in addition they are connected by numerous small bands of grey substance which pass from one to the other through the internal capsule, especially its anterior part. Also each nucleus contributes numerous fibres to, and receives fibres from, the internal capsule. These bundles of fibres both arising and terminating within the nuclei, together with the grey substance among the fibres of the capsule, produce the ribbed and striped appearance suggesting the name, corpus striatum. The **caudate nucleus**—the intraventricular part of the corpus striatum—lies with its thicker anterior part (head) closely related to the internal capsule, but its tail passes posteriorly around the posterior border of the capsule and curves downward and anteriorly into the roof of the inferior cornu of the lateral ventricle.

The lenticular nucleus [nucleus lentiformis]—the extraventricular part of the corpus striatum—is embedded in the white substance of the cerebral hemisphere. It is somewhat pyriform in shape, not being so long as the caudate nucleus, and neither having a tail nor extending so far anteriorly. Its lower surface is separated from the inferior cornu of the lateral ventricle by the white substance of the roof of that cornu, and by the tail of the caudate nucleus, and, further forward, the anterior commissure passes through its base. Its lateral surface is rounded and conforms both in extent and curvature with the surface of the insula, from which it is separated by the fibres of the external capsule and the intervening claustrum. Its oblique superior and mesial surface is adapted to the lateral surface of the internal capsule, and it comes to a rounded apex in the angle formed by the internal capsule and a plane parallel with the base of the hemisphere. In both horizontal and coronal (transverse) sections through its middle it resembles a compound biconvex lens. Internally this appearance is produced by two vertically curving laminæ of white substance, an **external** and an **internal medullary lamina,** which divide its substance into three zones:—the two medial zones together form an area, triangular in section, known as the **globus pallidus;** the lateral, larger and more grey, concavo-convex zone is the **putamen.** Radiating fibres from the medullary laminæ extend into the zones, especially those of the globus pallidus. These zones disappear in transverse sections of the anterior

Fig. 692.—Coronal Section of Telencephalon Passing Through Frontal Lobes and Anterior Portion of Corpus Striatum.
(From mounted specimen in the Anatomical Department of Trinity College, Dublin.)



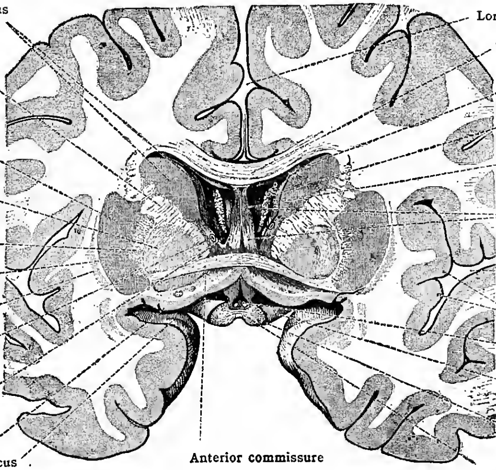
portion of the lenticular nucleus (fig. 692), due to the fact that the larger putamen alone comprises this portion and alone becomes continuous with the caudate nucleus. (See figs. 691, 696.)

Connections.—Both nuclei of the corpus striatum become continuous with the cortex in the region of the anterior perforated substance, and the putamen of the lenticular nucleus may blend with the anterior part of the base of the claustrum. The following are the principal fibre connections:—(1) Fibres arising in the nuclei which join the internal capsule to reach the cerebral cortex, and fibres arising in the cortex which descend by the same course to the cells of the nuclei. (2) Fibres which pass in both directions between the thalamus and the corpus striatum (caudate nucleus especially). These are more abundant anteriorly, and necessarily pass through the internal capsule. (3) The **ansa lenticularis,** or strio-subthalamic radiation, a usually distinct lamina, composed largely of fibres passing inferiorly between the thalamus and lenticular nucleus. It passes from the basal aspect of the anterior tubercle of the thalamus and curves below through the internal capsule to the basal surface of the lenticular nucleus, and there its fibres are distributed upward through its medullary lamina to the globus pallidus and putamen. Some enter the internal capsule and reach the cortex, chiefly that of the temporal lobe. The ansa lenticularis also contains fibres from the cortex of the temporal lobe to terminate in the inferior and mesial parts of the thalamus. The fibres associating the thalamus with the temporal lobe belong to the so-called *inferior peduncle of the thalamus.* (4) Fibres connecting both nuclei (chiefly the caudate) with the red nucleus and substantia nigra of the mesencephalon. These pass through the hypothalamic region and along the cerebral peduncle. No definitely localised functions have been with certainty ascribed to either nucleus. They serve as relays in the pathways associating the cortical grey substance with the structures below and in them the neurones concerned in these pathways are greatly increased.

The claustrum is a triangular plate of grey substance which is embedded in the white substance between the lenticular nucleus and the insula. Its medial surface is concave, conforming to the convexity of the putamen. The sheet of white substance intervening between it and the putamen is known as the **external capsule.** Its lateral surface shows ridges or projections in section which conform to the neighbouring gyri of the insula, and it is spread through an area which quite closely coincides with that of the inusla. Below and anteriorly it becomes continuous with the cortex of the anterior perforated substance and with the lenticular nucleus at the region of the junction of these. Above and posteriorly it gradually becomes thinner, and finally disappears in the white substance about it. In origin it is thought to be a detached portion of the cortical grey substance of the insula.

The amygdaloid nucleus [nucleus amygdalæ] is represented by the amygdaloid tubercle, which has already been described in the extremity of the inferior cornu of the lateral ventricle (figs. 666 and 691). It is an almond-shaped mass of cells joined to the tail of the caudate nucleus, continuous above with the putamen and anteriorly continuous with the cortex of the hippocampal gyrus.

Fig. 693.—Coronal Section of Telencephalon through the Anterior Commissure, Optic Chiasma, and Trunk of Corpus Callosum. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The chief connections of the amygdaloid nucleus by way of the *stria terminalis of the thalamus* are noted above under the description of the posterior division of the rhinencephalon. The amygdaloid nucleus, like the claustrum, is thought to represent a detached portion of the cortex, it being detached from the uncus. Considering this and its chief connections, it, with the stria terminalis of the thalamus, are concerned in the central portion of the olfactory apparatus.

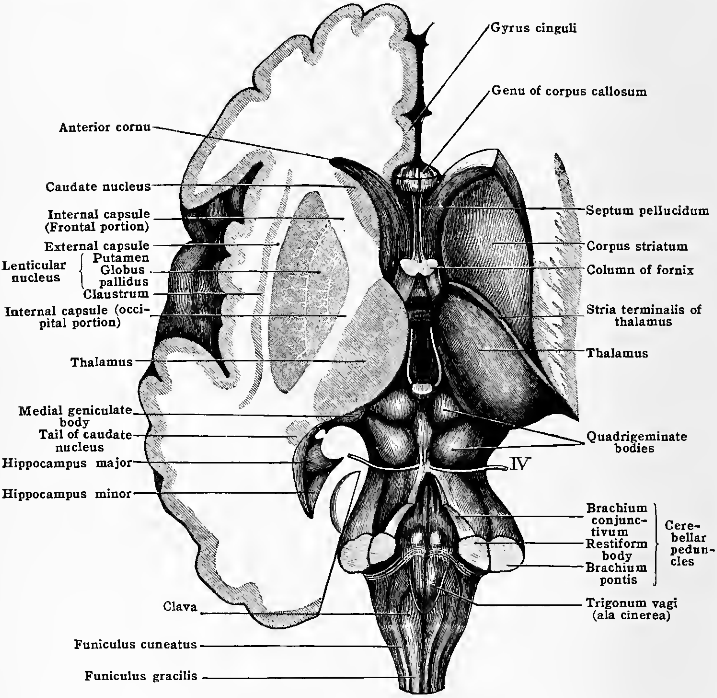
The thalamus and hypothalamus.—The external features of these portions of the prosencephalon have been described in their natural place, but inasmuch as they contain the chief relays between the telencephalon and the divisions of the nervous system caudal to the prosencephalon, the consideration of their internal structure has been deferred till now. The principal grey masses to be considered are the thalamus and the hypothalamic nucleus. The structures comprising the metathalamus and epithalamus have already been mentioned in their relations with the mesencephalon and the optic and auditory apparatus.

The thalamus has upon its upper surface, under its ependyma, a thin **stratum zonale** of white substance, derived in part from the incoming fibres and in part from its own cells. Its oblique lateral surface conforms to the medial surface of the internal capsule; its vertical medial surface forms the lateral wall of the third ventricle, and below it is continuous into the hypothalamic (tegmental) region.

Its upper surface shows a middle, an anterior, and a posterior prominence or tubercle. The **anterior tubercle** (nucleus) forms the posterior boundary of the interventricular foramen; the posterior tubercle is the cushion-like **pulvinar** which projects backward over the lateral geniculate body and the brachium of the superior quadrigeminate body.

A horizontal section through the supero-medial edge, splitting the stria medullaris of the thalamus and thus passing above the massa intermedia, shows the grey mass of the thalamus divided into segments or nuclei by a more or less distinct **internal medullary lamina.** This extends the whole length of the thalamus, dividing its middle and posterior portion into the **medial** and the **lateral nucleus.**

FIG. 694.—HORIZONTAL DISSECTION SHOWING THE GREY AND WHITE SUBSTANCE OF THE TELENCEPHALON BELOW THE CORPUS CALLOSUM AND THE RELATIVE POSITION OF THE THALAMENCEPHALON. (After Landois and Stirling.)



Anteriorly the lamina bifurcates into a medial limb, extending to the medial surface of the thalamus, and a lateral limb, extending forward to join the genu of the internal capsule (figs. 695, 700). This bifurcation results in a cup-like sheet of white substance which encloses the **anterior nucleus.** On the lateral surface of the section, next to the internal capsule, there may usually be distinguished an **external medullary lamina,** separated from the white substance of the capsule by a *reticular layer* of mixed white and grey substance.

The anterior nucleus, lying partially encapsulated in the bifurcation of the internal medullary lamina, is somewhat wedge-shaped and points backward between the anterior portions of the lateral and medial nuclei.

It is composed chiefly of large cells, and constitutes the anterior tubercle of the superior aspect. Its principal connection from below is with the nuclei of the mammillary body of the same and opposite sides, and with uninterrupted fibres derived from the columns of the fornix.

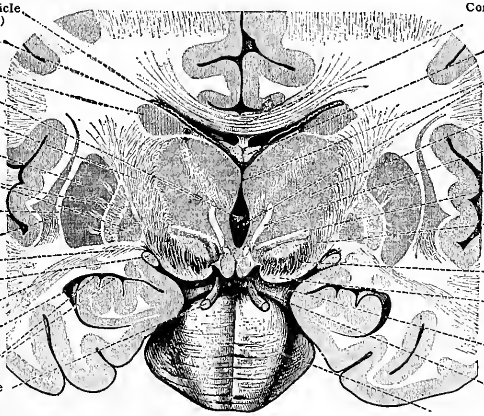
The fibres from both sources enter it by way of the *mammillo-thalamic fasciculus* (figs. 671 and 695). The significance of this connection is mentioned in the description of the limbic lobe.

The lateral nucleus, lying between the external and internal medullary laminæ, extends posteriorly to include the entire pulvinar.

The pulvinar, as already noted, together with the lateral geniculate body, constitutes the prosencephalic nucleus of termination of the optic tract, and the stratum zonale upon the surface of this nucleus might be called the stratum opticum. The anterior portion of the lateral nucleus receives fibres inferiorly from the red nucleus, from the brachium conjunctivum (cerebellum direct), and some fibres of the medial lemniscus terminate about its cells.

The medial nucleus lies medial to the internal medullary lamina and forms the posterior portion of the lateral wall of the third ventricle. It is shorter than the lateral nucleus, and is less extensively pervaded by fibres.

Fig. 695.—Coronal Section of Prosencephalon through Thalamencephalon at Region of Corpora Mammillaria. (Seen from in front.) (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



It is thought to receive fibres from the red nucleus, and perhaps some from the lemniscus, and is usually continuous across the third ventricle with the opposite medial nucleus by the massa intermedia.

In comparative anatomy, the nuclei of the thalamus have been variously subdivided by the different investigators. All the nuclei are connected with the lenticular nucleus by fibres passing between the two through the internal capsule directly, and by fibres curving from below, chiefly from the anterior, lateral and medial nuclei, and passing in the ansa lenticularis.

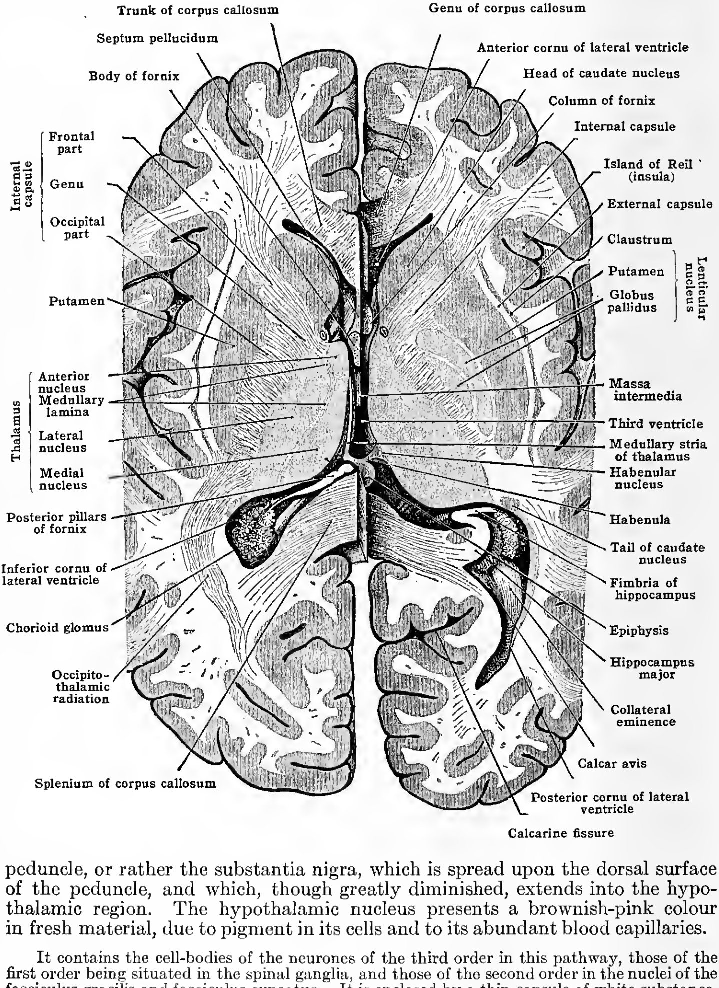
The cortical connections of the thalamus are abundant. They consist of fibres both to and from the cortex of the different lobes of the hemisphere, the greater part arising in the thalamus and terminating in the cortex. These fibres collect in the internal and external medullary laminæ and the stratum zonale; most of them enter the internal capsule and thence radiate to the different parts of the cortex.

They form the so-called peduncles of the thalamus, which have been distinguished both by the Flechsig method of investigation and by the degeneration method. The anterior or **frontal peduncle** passes from the lateral and anterior part of the thalamus through the frontal portion of the internal capsule, and radiates to the cortex of the frontal lobe. (See fig. 700.) The middle or **parietal peduncle** passes from the lateral surface of the thalamus through the intermediate part of the internal capsule, and upward to the cortex of the parietal lobe. The posterior or **occipital peduncle** passes chiefly from the pulvinar, through the occipital portion of the internal capsule, and radiates backward to the occipital lobe by way of the occipito-thalamic (optic) radiation (fig. 699). The **inferior peduncle** passes from the medial and basal surface of the thalamus (from the anterior and medial nuclei chiefly), turns outward to course beneath the lenticular nucleus, and radiates to the cortex of the temporal lobe and insula. The fibres of this peduncle course chiefly in the ansa lenticularis (fig. 695). Some turn upward in the external capsule to reach the cortex above the insula; others pass upward through the medullary laminæ of the lenticular nucleus.

The hypothalamic nuclues (fig. 698), or body of Luys, is the principal nucleus of termination of the medial lemniscus, the great sensory spino-cerebral pathwayl It is a biconvex plate of grey substance situated on the basal aspect of the latera. and anterior nuclei of the thalamus, and between these and the basis of the cerebral

FIG. 696.—HORIZONTAL SECTIONS OF THE PROSENCEPHALON THROUGH THE THALAMUS AND CORPUS STRIATUM.

The plane of the section of the left hemisphere splits the medullary stria of the thalamus and is about 15 millimeters superior to the plane through which the right hemisphere is cut. (After Toldt.)



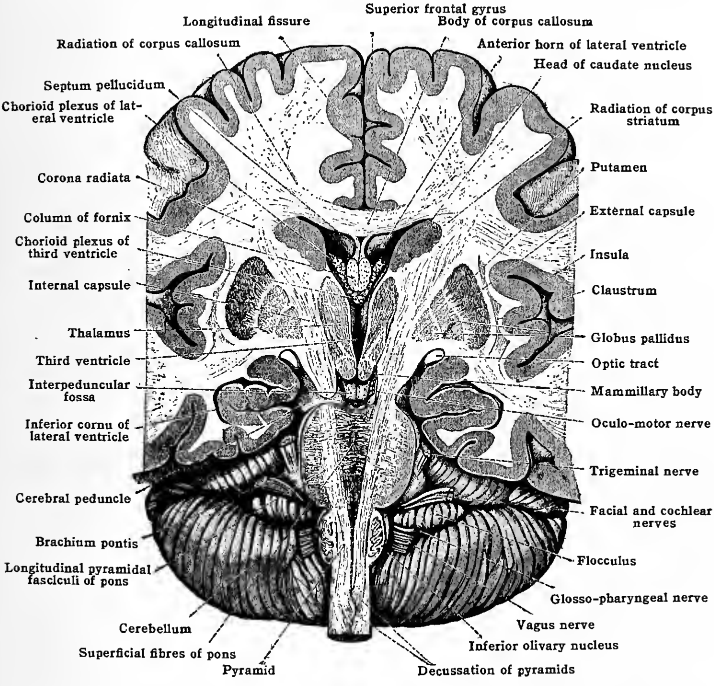
peduncle, or rather the substantia nigra, which is spread upon the dorsal surface of the peduncle, and which, though greatly diminished, extends into the hypothalamic region. The hypothalamic nucleus presents a brownish-pink colour in fresh material, due to pigment in its cells and to its abundant blood capillaries.

It contains the cell-bodies of the neurones of the third order in this pathway, those of the first order being situated in the spinal ganglia, and those of the second order in the nuclei of the fasciculus gracilis and fasciculus cuneatus. It is enclosed by a thin capsule of white substance, some of the fibres of which seem to decussate with those of the opposite side in the floor of the third ventricle, above and just behind the region of the corpora mammillaria. By far the greater part of the fibres arising from the nucleus join the internal capsule, and through it ascend to radiate to the cortex of the pre- and post-central gyri, the sensory-motor or somæsthetic area of the hemisphere. The majority terminate in the post-central gyrus.

All the fibres connecting the cerebral cortex with both the thalamus and the hypothalamic nucleus belong to the so-called *projection fibres* of the cerebral hemisphere.

The *habenular nucleus* and the *fasciculus retroflexus* of Meynert have been noted in the description of the rhinencephalon. The habenular nucleus, a part of the epithalamus, is a small group of nerve cells situated in the habenular trigone just infero-lateral to the epiphysis. The fibres of the medullary stria of the thalamus (habenula) terminate about its cells. A small bundle of fibres crossing the mid-line under the epiphysis in the superior aspect of the posterior cerebral commissure is called the *commissure of the habenulæ*, from the fact that it connects the habenular nuclei of the two sides.

Fig. 697.—Oblique Frontal Section through the Brain in the Direction of the Cerebral Peduncles and the Pyramids. (Seen from in front.) (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

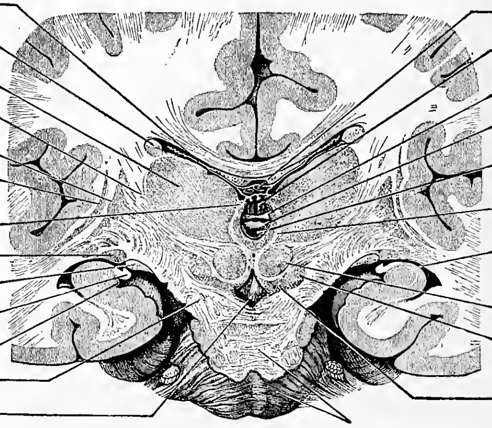


The fasciculus retroflexus (Meynerti) is a relatively strong bundle of medullated fibres which runs downward and then turns caudalward from the habenular nucleus toward the inferior portion of the interpeduncular fossa. It has been shown that many, at least, of the fibres of this bundle arise from the cells of the habenular nucleus. In its slightly caudad course, the bundle passes obliquely through the red nucleus, entering the medial superior aspect and making its exit from the ventro-mesial side of the inferior extremity of this nucleus. In the animals in which it has been studied, the bundle ends in the *interpeduncular nucleus* (ganglion), a group of nerve cells lying in the floor of the interpeduncular fossa at the level of the inferior quadrigemina. In man, the interpeduncular nucleus is not definitely assembled and the bundle seems to disappear in the posterior perforated substance. However, the microscope shows cells dispersed among the fibres of the bundle and these cells probably represent the nucleus.

The white substance of the telencephalon.—A horizontal section through the upper part of the trunk of the corpus callosum will pass above the basal grey substance of the corpus striatum, and, aided by the corpus callosum, each hemisphere in such a section will appear as if consisting of a solid, half-oval mass of white substance, bounded without by the grey layer of the cortex (fig. 672). As seen at this level, the white substance of each hemisphere is known as the **centrum semiovale.** Horizontal sections passing below the body of the corpus callosum involve the corpus striatum and thalamus, and the appearance of the white substance is modified accordingly (fig. 694).

In the white substance of the cerebral hemispheres as a whole three main systems of fibres are recognised:—projection fibres, commissural fibres, and association fibres. The *projection fibres* are those of a more or less vertical course, which pass to and from the cortex of the hemisphere, associating it with the structures below the confines of the hemisphere. The *commissural fibres* are those of a transverse or horizontal course, which cross the mid-line and functionally connect the two hemispheres with each other. The *association fibres* are those which neither cross the mid-line nor pass beyond the bounds of the hemisphere in which they arise, but instead associate the different parts of the same hemisphere—lobes with lobes and gyri with gyri. The fibres which associate the cortex with the

Fig. 698.—Coronal Section of Brain Passing Through the Pulvinar of the Thalamus and the Uncus of the Hippocampal Gyrus. (After Toldt.)

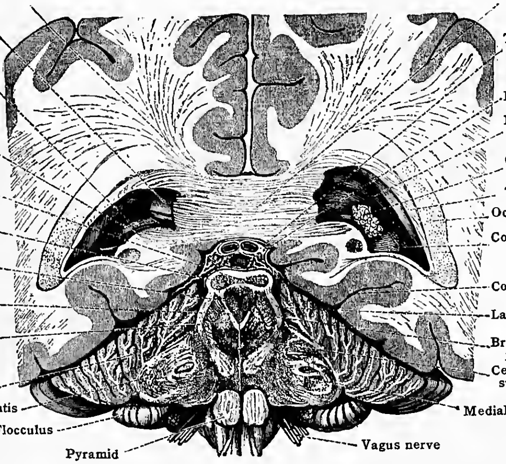


nuclei of the corpus striatum must also be classed as association fibres, since these masses of grey substance are a part of the telencephalon, while by definition those which associate the thalamus and hypothalamus with the cortex belong to the projection system. Some of the fibre bundles of the above systems have already been described in connection with the parts with which they are concerned.

The projection fibres of the hemisphere comprise both ascending and descending fibres between the cerebral cortex and structures below the bounds of the hemisphere, i.e., some arise in the structures below and terminate in the cortex; others arise from the cortical cells and terminate in the structures below, including the grey substance of the thalamencephalon, mesencephalon, rhombencephalon, and spinal cord. The projection fibres are given different names in the hemisphere according to their arrangement and the appearances to which they contribute in the dissections. Beginning with the pyramidal fasciculi and the basis of the peduncle, they contribute—(1) to the *internal capsule* and some to the *external capsule* and (2) to the *corona radiata.*

The internal capsule [capsula interna] is a band of white substance, consisting of the ascending fibres from the nuclei of the thalamus, hypothalamus, and corpus striatum, reinforced by the descending fibres from the cortex to these nuclei and by those descending in the cerebral peduncle to terminate in the mesencephalon, rhombencephalon and spinal cord. It is a broad, fan-like mass of fibres, which increases in width from the base of the hemisphere upward, and which is spread between the lenticular nucleus on its lateral aspect and the caudate nucleus and thalamus on its medial side. To reach the cortex above, the course of its fibres necessarily intersects that of the radiations of the corpus callosum, and thus, together with the corpus callosum, the fan-like bands of the two hemispheres form a capsule containing the thalami, the third ventricle, the caudate nuclei, and the anterior and central portions of the lateral ventricles. In horizontal sections, each internal capsule appears bent at an angle, the **genu,** which approaches the cavity of the lateral ventricle along the line of the boundary between the thalamus and the caudate nucleus. Along the genu runs the stria terminalis of the thalamus, and through the genu the capsule receives fibres from the internal medullary lamina of the thalamus, from the stratum zonale of the thalamus and from that of the caudate nucleus. At the genu each capsule is separable into two parts:—(1) the **anterior (frontal) portion,** spreading between the caudate and lenticular nuclei; (2) the **posterior (occipital) portion,** between the lenticular nucleus and the thalamus (fig. 700.)

Fig. 699.—Coronal Section through the Splenium of the Corpus Callosum and the Posterior Cornua of the Lateral Ventricles. (Viewed from behind.) (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



Functionally, the internal capsule may be divided into a frontal, a fronto-parietal and an occipital part. The **frontal part** consists of (1) an *anterior segment,* carrying chiefly fibres coursing in both directions between the thalamus and the cortex of the frontal lobe, and (2) a *posterior segment* carrying the frontol-pontile tract.

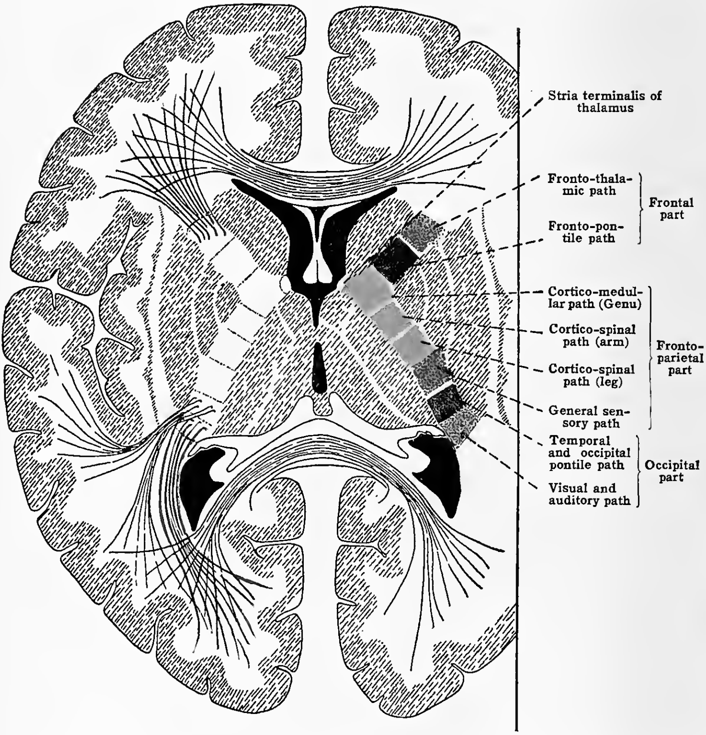
The **fronto-parietal part** may be considered in four segments:—(1) An anterior segment, the *genu,* carrying fibres from the cortex to the nuclei of the motor cranial nerves; (2) posterior to this is the *cortico-spinal segment for the arm and thorax,* descending cortical fibres to the regions of the spinal cord supplying these; (3) next is the *cortico-spinal segment for the lower extremity;* (4) a posterior segment carrying the *general sensory path* ascending from the hypothalamic nucleus, the infero-lateral part of the thalamus and the red nucleus to the cortex. All the segments of the fronto-parietal part carry in addition, fibres in both directions between the cortex above and the thalamus and the nuclei of the striate body.

The **occipital part** consists (1) of an anterior segment which carries the *temporal and occipital pontile paths,* and (2) a posterior segment carrying the *visual fibres* between the occipital cortex and the nuclei of termination of the optic nerve. This segment also carries the *auditory fibres* passing between the cortex of the superior temporal gyrus and the regions of termination of the lateral lemniscus. Thus it carries a visual and an auditory path.

The corona radiata.—Above the corpus callosum and laterally joining its radiations, the fibres of the internal capsule are dispersed in all directions. The appearance known in coronal sections of the hemispheres as the corona radiata is produced by the ascending and descending fibres of the internal capsule combined with the radiations of the corpus callosum. The radiations related to the internal capsule may be divided into a frontal, a parietal and an occipital part, corresponding to the frontal, parietal and occipital peduncles of the thalamus, or to the parts of the internal capsule.

The radiation derived from the posterior segment of the occipital part of the internal capsule, the visual path, accumulates into a well-defined band of fibres which passes posteriorly into the occipital lobe, spreading in the lateral wall of the posterior cornu of the lateral ventricle immediately lateral to the tapetum. This band consists for the most part of fibres arising in the pulvinar of the thalamus and

Fig. 700.—Diagram to Indicate the Relative positions of the Projection Fibres in the Internal Capsule. (In part after Villiger.)



in the lateral geniculate body and going to the visual area of the occipital cortex, and of fibres arising in this cortex to terminate in the thalamus and mesencephalon. Being thus concerned with the optic apparatus, it is known as the **occipito-thalamic radiation** or **optic radiation** (fig. 699).

The external capsule is, as already noted, a thin sheet of white substance spread between the claustrum and the lenticular nucleus.

It owes its appearance as such to the presence of the claustrum. It joins the internal capsule at the upper, posterior, and anterior borders of the putamen, and below the claustrum it is continuous with the general white substance of the temporal lobe. Thus it contributes to an encapsulation of the lenticular nucleus by white substance. Most of the fibres contained in it belong to the association system. Its projection fibres consist of those of the inferior peduncle of the thalamus, which pass from the basal surface of the thalamus and, instead of continuing below to the cortex of the temporal lobe and insula, turn upward, around the lenticular nucleus to the cortex above the insula. Some of these thalamus fibres are known to pass upward through the laminæ of the lenticular nucleus instead of through the external capsule.

The ascending projection fibres arise mostly from the cells of the nuclei of the thalamus and hypothalamic nucleus; some arise from nuclei in the mesencephalon and from the red nucleus.

They may be summarised as follows:—

(1) *The terminal part of the general sensory pathway of the body.* The portion of the medial lemniscus which arises in the nuclei of the fasciculus gracilis and cuneatus, of the opposite side, terminates in the hypothalamic nucleus and the inferior portion of the lateral nucleus of the thalamus. The projection fibres given off by the latter nuclei pass chiefly through the posterior segment of the fronto-parietal part of the internal capsule and radiate to and terminate in the somæsthetic area of the cortex, chiefly in the posterior central gyrus. Some few pass outside around the lenticular nucleus, and ascend by way of the external capsule.

(2) *The terminal part of the general sensory pathway of the head and neck.* The nuclei of termination of the sensory portions of the cranial nerves of the rhombencephalon (except the nuclei of the cochlear nerve) give fibres which course upward in the medial lemniscus (fillet) and reticular substance of the opposite side and terminate in the infero-lateral portions of the thalamus and in the hypothalamic nucleus. Thence arise projection fibres which ascend to the somæsthetic area by practically the same route as those of the general sensory system for the body.

(3) *The terminal part of the auditory pathway.* The ventral and dorsal nuclei of termination of the cochlear nerve send impulses which, by way of the lateral lemniscus, are distributed to the inferior quadrigeminate body, the medial geniculate body, and the nucleus of the lateral lemniscus of the opposite side. These nuclei send projection fibres through the posterior segment of the fronto-parietal part of the internal capsule, and thence by the temporal portion of the corona radiata to the cortex of the superior temporal gyrus (auditory area). Probably some of these fibres pass by way of the inferior peduncle of the thalamus. Some of the fibres arising in the nuclei of termination of the vestibular nerve convey impulses which reach the somæsthetic area, but the origin of the terminal portion of this system is uncertain.

(4) *The terminal part of the visual pathway.* The cells of the pulvinar and the lateral geniculate body, serving as nuclei of termination of the optic tract, give off projection fibres which pass by way of the posterior segment of the occipital portion of the internal capsule and the occipito-thalamic radiation to the cortex of the occipital lobe, chiefly the region about the posterior end of the calcarine fissure—the visual area.

(5) *The terminal ascending cerebellar pathway.* The fibres of the brachium conjunctivum, after decussating, terminate both in the red nucleus and in the lateral nucleus of the thalamus. Some fibres from the red nucleus become projection fibres direct, others terminate in the medial and anterior portion of the lateral nucleus of the thalamus. From the thalamus the projection fibres of this system pass in the parietal peduncle of the thalamus to the somæsthetic area.

The descending projection fibres arise as outgrowths of the pyramidal cells of the cerebral cortex. Practically all of them cross to the opposite side in their descent to the structures of the brain stem and spinal cord. The majority of them arise near and within the gyri in which the respective ascending fibres terminate. Those transmitting cortical impulses to the cells giving origin to the motor fibres of the cranial and spinal nerves arise chiefly from the giant pyramidal cells of the precentral (anterior central) gyrus, the paracentral lobule and the posterior ends of the superior, middle, and inferior frontal gyri. These latter occupy nearly three-fourths (the anterior three segments) of the fronto-parietal part of the internal capsule and the middle three-fifths of the basis of the cerebral peduncle, and are usually called *pyramidal* fibres (fig. 700).

The principal descending projection fibres may be grouped as follows:

(1) **The pyramidal fibres to the spinal cord** (cortico-spinal or pyramidal fasciculi proper). These arise from the giant pyramidal cells of the upper two-thirds of the precentral gyrus, the anterior portion of the paracentral lobule and the posterior third of the superior frontal gyrus. Those for the lumbo-sacral region of the spinal cord arise nearest the supero-mesial border of the cerebral hemisphere. The tract descends through the two middle segments of the fronto-parietal part of the internal capsule. Those carrying cortical impulses for the muscles of the arm and shoulder course in the segment anterior to the course of those for the muscles of the leg. Both continue through the cerebral peduncles and the pons and through the pyramids of the medulla, and then decussate, passing down the spinal cord to terminate about the ventral horn cells (the origin of the motor nerve roots) of the opposite side.

(2) **The pyramidal fibres to the nuclei of origin of the motor cranial nerves** arise from the pyramidal cells in the inferior third of the precentral gyrus, the posterior end of the inferior frontal gyrus, the opercular margin of the posterior central gyrus, and probably some (for eye movements) in the posterior end of the middle frontal gyrus. The locality of the origin of the pyramidal fibres terminating in the nuclei of the facial and hypoglossal nerves only has been determined with certainty. The general tract passes in the genu of the internal capsule, through the cerebral peduncle, and, gradually decussating along the brain stem, terminates in the nuclei of the motor cranial nerves of the opposite side.

(3) **The frontal pontile path** (Arnold's bundle) arises in the cortex of the frontal lobe, anterior to the precentral gyrus, descends through the frontal part of the corona radiata and posterior segment of the frontal portion of the internal capsule into the fronto-mesial portion of the cerebral peduncle, and terminates in the nuclei of the pons.

(4) **The temporal pontile path** (Türk's bundle) arises in the cortex of the superior and middle temporal gyri, passes through the posterior segment of the occipital part of the internal capsule, enters the cerebral peduncle postero-lateral to its pyramidal portion, and terminates in the nuclei of the pons. An occipito-pontile path is described as arising in the occipital cortex and joining the temporal pontile path in the internal capsule to pass to the nuclei of the pons.

(5) **The occipito-mesencephalic path** (Flechsig's secondary optic radiation) arises in the cortex of the visual area of the occipital lobe (cuneus and about the calcarine fissure), passes forward through the occipito-thalamic radiation, downward in the posterior segment of the occipital portion of the internal capsule, and terminates in the nucleus of the superior quadrigeminate body and the lateral geniculate body. It is probable that some of its fibres terminate directly in the nuclei of the eye-moving nerves.

(6) Those **fibres of the fornix** which arise in the hippocampus and terminate in the corpus mammillare or pass through it to the anterior nucleus of the thalamus of the same and opposite side (mammillo-thalamic fasciculus) or pass into the mescencephalon and probably to structures lower down.

The commissural system of fibres.—The commissural fibres of the telencephalon serve to connect or associate the functional activities of one hemisphere with those of the other. They consist of three groups:—The corpus callosum, the anterior commissure and the hippocampal commissure.

(1) The **corpus callosum**, the great commissure of the brain. A general description of this with the medial and lateral striæ running over it has already been given. It is a thick band of white substance, about 10 cm. wide, which crosses between the two hemispheres at the bottom of the longitudinal fissure. Its shape is such that in its medial transverse section its parts are given the names *splenium*, *body*, *genu*, and *rostrum* (figs. 667 and 679). Its lower surface is medially joined to the fornix, in part by the septum pellucidum and in part directly. Laterally it is the tapetum of the roof of the lateral ventricle of either side. The majority of its fibres arise from the cortical cells of the two hemispheres, and terminate in the cortex of the side opposite that of their origin. In dissections, its fibres are seen to radiate toward all parts of the cortex—the radiation of the corpus callosum. These radiations may be divided into frontal, parietal, temporal and occipital parts. The occipital parts curve posteriorly in two strong bands from the splenium into the occipital lobes, producing the figure known as the **forceps major.** Anteriorly, the frontal parts are two similar but lesser bands which curve from the genu forward into the frontal lobe, producing the **forceps minor.**

(2) The **anterior commissure** has been described in connection with the rhinencephalon. In addition to the olfactory fibres coursing through it from the olfactory bulb and parolfactory area of one hemisphere to the uncus of the opposite hemisphere, its greater part consists of fibres which arise in the cortex of the temporal lobe, the uncus chiefly, of one side and terminate in that of the opposite side. It crosses in the substance of the anterior boundary of the third ventricle, and through the inferior portions of the lenticular nuclei, and can be seen only in dissections (figs. 684, 693). It is a relatively small, round bundle, and its mid-portion between its terminal radiations presents a somewhat twisted appearance.

(3) The **hippocampal commissure** (*transverse fornix*) belongs wholly to the limbic lobe (rhinencephalon), and has been described there. It connects the hippocampal gyri of the two sides, and crosses the mid-line under and usually adhering to the under surface of the splenium of the corpus callosum. Crossing the body of the fornix, it thins anteriorly and ceases in the posterior angle of the septum pellucidum.

With these three commissures of the telencephalon, the three other commissures of the prosencephalon should be called to mind. **The inferior cerebral commissure** (Gudden's commissure), while occurring in the optic chiasma and allotted by position to the telencephalon, really belongs to the diencephalon since it connects with each other the medial geniculate bodies of the two sides. **The supra-mammillary commissure,** connecting the nuclei of the mammillary bodies of the two sides, is allotted to the diencephalon. **The posterior cerebral commissure,** situated just below the stalk of the epiphysis, belongs to both the diencephalon and mesencephalon. Its superior part, the *habenular commissure*, connecting the two nuclei of the habenulæ, belongs wholly to the diencephalon. In its inferior part, the fibres arising in the thalamus of one side and terminating in that of the other side belong likewise to the diencephalon, but those passing between the superior quadrigeminate bodies of the two sides and between the so-called nuclei of the medial longitudinal fasciculi belong to the mesencephalon.

The association system of the hemisphere.—The possibilities for association bundles connecting the different parts of the same hemisphere with each other are innumerable, and a large number are recognised. They serve for the distribution or diffusion of impulses brought in from the exterior by the ascending projection system, and it is by means of them that the different areas of the cortex may function in harmony and coördination. Most of the association bundles are supposed to contain fibres coursing in both directions. Several of them have already been described in company with the grey masses with which they are concerned. They may be summarised as follows (see figs. 683, 701 and 702):—

(1) Those of short course, the **fibræ propriæ,** which associate contiguous gyri with each other. These arise from the cells of a gyrus and loop around the bottoms of the sulci, continually receiving and losing fibres in the cortex they associate. The stripes of Baillarger within the cortical layer might be included among the short association bundles.

(2) The **cingulum** (girdle) lies in the gyrus cinguli and is shaped correspondingly. It

extends from the anterior perforated substance and the subcallosal gyrus around the genu of the corpus callosum, then, under cover of the gyrus cinguli and around the splenium, and thence downward and forward in the hippocampal gyrus to the uncus. It is chiefly an aggregation of fibres of short course—fibres which associate neighbouring portions of the cortical substance

Fig. 701.—Photograph of "Torn Preparation" of Cerebral Hemisphere showing some of the Association Fasciculi. (After R. B. Bean.)

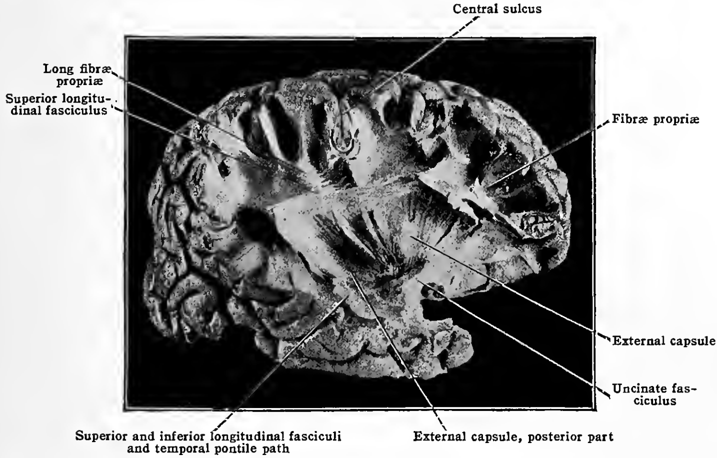


Fig. 702.—Schematic Representation of Certain of the Association Pathways of the Cerebral Hemisphere.

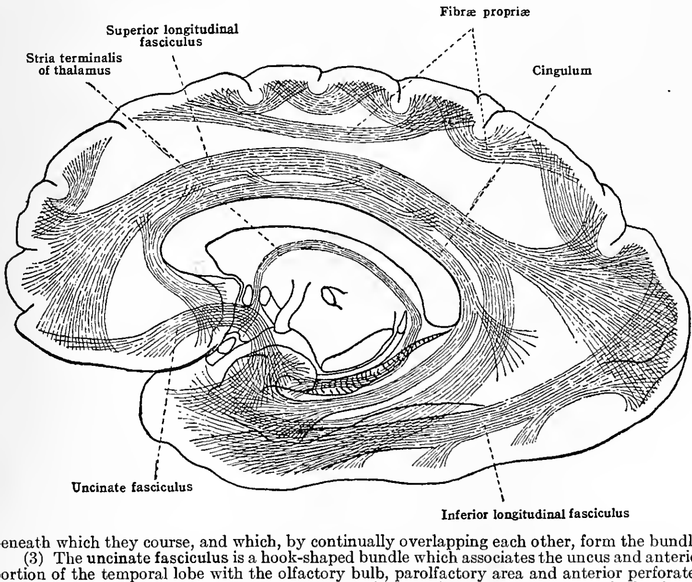


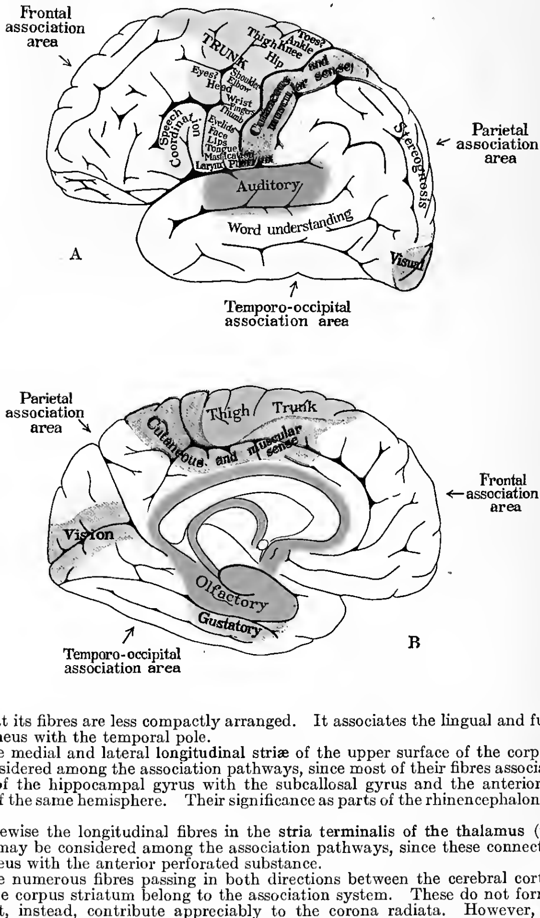
beneath which they course, and which, by continually overlapping each other, form the bundle.

(3) The **uncinate fasciculus** is a hook-shaped bundle which associates the uncus and anterior portion of the temporal lobe with the olfactory bulb, parolfactory area and anterior perforated substance and perhaps the frontal pole with the orbital gyri. Its shape is due to its having to curve medialward around the stem of the lateral cerebral fissure.

(4) The **superior longitudinal fasciculus** is the longest of the association paths, and associates the frontal, occipital, and temporal lobes. From the frontal lobe it passes laterally in the frontal and parietal operculum, transverse to the radiations of the corpus callosum and the lower part of the corona radiata, and above the insula to the region of the posterior end of the lateral fissure, and thence it curves downward and forward to the cortex of the temporal lobe. Some of its fibres extend to the cortex of the temporal pole. The occipital portion consists of a loose bundle given off from the region of the downward curve, which radiates thence to the occipital cortex.

(5) The **inferior longitudinal fasciculus** associates the temporal and occipital lobes and extends along the whole length of these lobes parallel with their tentorial surfaces. Posteriorly it courses lateral to the lower part of the occipito-thalamic radiation, from which it differs by

FIG. 703.—DIAGRAMS SUGGESTING THE GENERAL MOTOR, GENERAL AND SPECIAL SENSORY AND THE ASSOCIATION AREAS OF THE CONVEX AND MESIAL SURFACES OF THE CEREBRAL HEMISPHERE.



the fact that its fibres are less compactly arranged. It associates the lingual and fusiform gyri and the cuneus with the temporal pole.

(6) The medial and lateral **longitudinal striæ** of the upper surface of the corpus callosum may be considered among the association pathways, since most of their fibres associate the grey substance of the hippocampal gyrus with the subcallosal gyrus and the anterior perforated substance of the same hemisphere. Their significance as parts of the rhinencephalon has already been given.

(7) Likewise the longitudinal fibres in the **stria terminalis of the thalamus** (tænia semicircularis) may be considered among the association pathways, since these connect the amygdaloid nucleus with the anterior perforated substance.

(8) The numerous fibres passing in both directions between the cerebral cortex and the nuclei of the corpus striatum belong to the association system. These do not form a definite bundle, but, instead, contribute appreciably to the corona radiata. However, a pathway described as the **occipito-frontal fasciculus** probably consists largely of the more sagittally running fibres of this nature. The existence of this fasciculus has been noted in degenerations and in cases of arrested development of the corpus callosum. Its fibres are described as contributing greatly to the tapetum, and as coursing beneath the corpus callosum immediately

next to the ependyma of the lateral ventricle. As a mass, they appear in intimate connection with the caudate nucleus, and are spread toward both the frontal and the occipital lobes (chiefly the latter), in the mesial part of the corona radiata of those lobes. It is described as also containing fibres in both directions associating the occipital with the temporal lobe. *Vertical association fibres* pass through the caudate and lenticular nuclei between the cortex above and that of the temporal lobe below.

(9) Since the olfactory bulb is a part of the hemisphere proper, the *olfactory tract* may be considered an association pathway connecting the olfactory bulb with the parolfactory area, the subcallosal gyrus, the anterior perforated substance, and the uncus. As already shown, a portion of the fibres of the tract belongs to the commissural system.

THE FUNCTIONAL AREAS OF THE CEREBRAL CORTEX

The definitely known areas of specific function of the human cerebral cortex are relatively small. They comprise but little more than a third of the area of the entire hemisphere. They are—(1) the general sensory-motor or somæsthetic area, and (2) the areas for the organs of special sense. They represent portions of the cortex in which terminate sensory or ascending projection fibres bearing impulses from the given peripheral structures, and in which arise motor or descending projection fibres bearing impulses in response.

Knowledge of the location of the areas has been obtained—(1) by the Flechsig method of investigation, and to a considerable extent by Flechsig himself; (2) from clinico-pathological observations, largely studies of the phenomena resulting from brain tumors and traumatic lesions; (3) by experimental excitation of the cortex of monkeys and apes, the resulting phenomena being correlated with the anatomical findings and compared with the observations upon the human brain. The remaining larger and less known areas of the cortex are referred to as 'association centres' or areas of the 'higher psychic activities.'

In development, the sensory fibres to the specific areas acquire their medullary sheaths first, before birth, and then the respective motor fibres from each become medullated. It is not till a month after birth that the association centres show medullation and therefore acquire active functional connection with the specific areas.

In defining an area it is not claimed that all the fibres bearing a given type of impulse terminate in that area, nor that all the motor fibres leading to the given reaction originate in the area. It can only be said that of the fibres concerned in a given group of reactions, more terminate and arise in the areas cited than in any other areas of the cortex. The corresponding motor fibres arise both in the region of the termination of the sensory fibres (sensory area) and also in a zone (motor area) either partially surrounding or bordering upon a part of the region of termination.

The different areas are as follows:—

(1) **The somæsthetic (sensory-motor) area**, the area of general sensibility, and the area in which arise the larger part of the cerebral motor or pyramidal fibres for the cortical control of the general muscular system. As is to be expected, it is the largest of the specific areas. It includes the anterior central gyrus, posterior central gyrus, the posterior ends of the superior, middle, and inferior frontal gyri, the paracentral lobules, and the immediately adjacent part of the gyrus cinguli. The ascending or sensory fibres are found to terminate most abundantly in the part posterior to the central sulcus (Rolandi), the posterior central gyrus being the special area of cutaneous sensibility, and the adjacent anterior ends of the horizontal parietal gyri have been designated as the area of 'muscular sense.' Both these areas are carried over upon the medial surface to involve the lower part of the paracentral lobule and a part of the gyrus cinguli. The anterior central gyrus gives origin to relatively more motor fibres than the other portions of the somæsthetic area. In distribution, the muscles furthest away from the cortex are innervated from the most superior part of the area, the leg area being in the supero-mesial border of the hemisphere, while that from the head is in the anterior and inferior part of the area (fig. 703). The muscles of mastication and the laryngeal muscles are controlled from the fronto-parietal operculum. Broca's convolution, the opercular portion and part of the triangular portion of the inferior frontal gyrus, of the left hemisphere, constitutes the especial motor area of speech, and Mills has extended this area to include the supero-anterior portion of the insula below. The various authorities differ considerably as to the exact locations of many of the areas for the cortical control of given sets of muscles. Further observations must be skillfully made for localisation of areas of the human cortex in detail and further correlations must be determined between the experiments upon the cortex of anthropoid apes and the functions of that of man. The accompanying diagrams are compiled from several of the diagrams more usually given and must be considered as only approximately correct.

(2) **The visual area.**—The especial sensory portion of this area is that immediately bordering upon either side of the posterior part of the calcarine fissure. The entire area, motor and sensory overlapping each other, includes the whole of the cuneus. The motor visual area proper is described as the more peripheral portion of the entire area. In addition, an area producing eye movements is described as situated in the posterior end of the middle frontal gyrus.

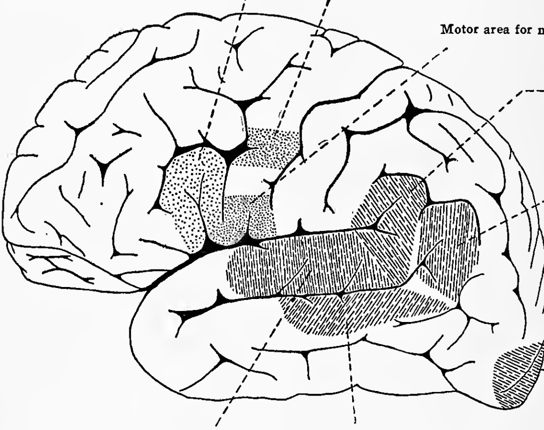
(3) **The auditory (cochlear) area** comprises the middle third of the superior temporal gyrus and the transverse temporal gyri of the temporal operculum. The motor portion of this area lies in its inferior border. The fibres arising in the area course downward in the temporal pontile path to the motor nuclei of the medulla.

(4) **The olfactory area** consists of the olfactory trigone, the parolfactory area, the subcallosal gyrus, part of the anterior perforated substance, the hippocampal gyrus (especially the uncus), and the callosal half of the gyrus cinguli. Its motor or efferent area lies chiefly in the hippocampal gyrus, the fibres from which pass out from the telencephalon by way of the fornix and cingulum.

(5) The gustatory area is supposed to comprise the anterior portion of the fusiform gyrus and the zone (motor portion) about the anterior extremity of the inferior temporal sulcus.

(6) The assocaition areas.—The relatively large areas allotted at present to the so-called higher psychic activities are indicated in fig. 703. The great relative extent of these is one of the characteristics of the human brain. They probably merely represent the portions of the cortex of which little is known, and may eventually be subdivided into more specific areas. They are considered to be connected with the structures below by fewer projection fibres than are the recognised areas named above, while, on the other hand, they are rich in association fibres. By means of the latter they are in intimate connection with the specific areas and have abundant means of correlating and exercising a controlling influence upon the functions of these areas. According to Flechsig, they consist of—(1) a *parietal association area*, comprising that part of the parietal cortex between the somæsthetic area and the visual area; (2) an *occipito-temporal association area*, including the unspecified portions of the temporal lobe and the adjoining portion of the occipital lobe not included in the visual area; (3) a *frontal association area*, including all the frontal lobe anterior to the somesthetic and olfactory area. In the folds of the inferior parietal lobule of the parietal association area such intellectual activities as the optic discrimination of words, letters, numbers, and objects generally are supposed to

Fig. 704.—Convex Surface of left Cerebral Hemisphere with Diagrammatic Presentation of the Areas Suggested as Concerned with Speech.



take place, while the superior parietal lobule continued into the posterior part of the præcuneus is the general region for the perception of form and solidity of objects—the stereognostic centre.

The *insula* is suggested as the area in which auditory, olfactory and gustatory impulses are associated with the motor areas beginning in the operculum dorso-laterally adjacent to it.

Observations of symptoms and the position of lesions accompanying them have made it possible to arrive at some trustworthy conclusions regarding the cortical areas controlling speech. Broca announced in 1861 that the inferior frontal gyrus of the *left* hemisphere was peculiarly concerned with speech. This area was later confined to the posterior end or opercular portion of this gyrus and the name "Broca's Convolution" was given it. It is now known that Broca's convolution and the adjacent portion of the triangular part of the inferior frontal gyrus as well comprise the *motor* area or *emissive speech area*—the area especially devoted to the control of that coordinated action of the muscles concerned which makes possible articulate speech. Patients in whom this area is impaired are unable to give utterance to words though they may understand them both written and spoken, and though they may give utterance to sound. This inability is known as *motor aphasia.* Results of observed lesions have further shown that the area in which the *auditory images* of words are retained (word memories) comprises the posterior end of the superior temporal gyrus and the adjoining portion of the supramarginal gyrus. Injury to this area is accompanied by inability to recognise spoken words although the patient hears them and may recognise and understand written words, a phenomenon known as "word-deafness" or *sensory aphasia.* This area may be considered as continuous with the superior portion of the posterior end of the middle temporal gyrus which has been suggested as the area of "word-understanding," or "*lalognosis.*" On the other hand, the area in which visual images of words are retained is located as the angular gyrus. Injury to this results in an inability to recognise printed or written words although the patient may hear, understand and speak them. This is called *"word-blindness."* This area is nearest the special area of vision on the one hand and on the other hand, is continuous into the area to which word-understanding is attributed. For purposes of writing, it must be associated with the motor area for the muscles of the hand in the precentral gyrus.

While the motor area for speech is most functional in the left hemisphere, the remaining areas concerned are probably equally developed in the two hemispheres.

III. GENERAL SUMMARY OF SOME OF THE PRINCIPAL CONDUCTION PATHS OF THE NERVOUS SYSTEM

In the following summary the arabic numerals indicate paragraphs in which are mentioned the nuclei or ganglia containing the cell-bodies of the neurones interposed in the chains; the small letters indicate the different names given to the different levels of the pathways through which their fibres run. For detailed descriptions of either nuclei or pathways see pages describing them. Only the more common neurone chains are followed here.

I. The Spino-cerebral and Cerebro-spinal Path

A. The ascending system of neurones. (fig. 705)

1. Spinal ganglion—neurone of first order.
   - (a) Terminal corpuscles and peripheral process of T-fibre.
   - (b) Dorsal or afferent root of spinal nerve.
   - (c) Ascending branch of bifurcation of dorsal root fibre in fasciculus gracilis, or fasciculus cuneatus of spinal cord.
2. Nucleus of fasciculus gracilis or nucleus of fasciculus cuneatus in medulla oblongata—neurone of second order.
   - (a) Internal arcuate fibres.
   - (b) Decussation of lemniscus.
   - (c) Interolivary stratum of lemniscus of opposite side.
   - (d) Medial lemniscus.
3. Hypothalamic nucleus and lateral nucleus of thalamus—neurone of third order.
   - (a) Internal capsule, posterior segment of fronto-parietal portion.
   - (b) Corona radiata, fronto-parietal part.
   - (c) Posterior central gyrus of somæsthetic area of cerebral cortex.

B. Descending system of neurones (fig. 706).

1. Giant pyramidal cells of precentral gyrus of somæsthetic area.
   - (a) Corona radiata, fronto-parietal part.
   - (b) Internal capsule, middle segments of fronto-parietal portion.
   - (c) Basis of the cerebral peduncle and the peduncle.
   - (d) Pyramid of medulla oblongata.
   - (e^1) Decussation of pyramids.
   - (f^1) Lateral cerebro-spinal fasciculus (crossed pyramidal tract).
   - (e^2) Ventral cerebro-spinal fasciculus (direct or uncrossed pyramidal tract).
   - (f^2) Gradual decussation of latter in cervical and upper thoracic regions of spinal cord.
2. Cells of ventral horn of spinal cord of opposite side.
   - (a) Ventral or efferent roots of spinal nerves.
   - (b) Peripheral nerve-trunks directly to skeletal muscles or indirectly to smooth muscle or glands by way of sympathetic neurones.

II. Short 'Reflex' Paths of Spinal Cord

1. Spinal ganglia.
   - (a) Terminal corpuscles and peripheral process of T-fibres.
   - (b) Dorsal root of spinal nerve.
   - (c) Collaterals and descending branches of bifurcation of dorsal root fibres in spinal cord
   - (d) Directly to ventral horn cells of same level of spinal cord.
   - (e) Or, more commonly, to same through intermediation of Golgi cell of type II.
   - (f) Or to neurones of fasciculi proprii to ventral horn cells of other levels of spinal cord.
2. Ventral horn cells of same (chiefly) and opposite side and thence by way of ventral roots and peripheral nerve trunks directly to muscles.
3. Dorso-lateral group of ventral horn cells of same (chiefly) and opposite sides and thence by ventral root fibres to cell-bodies in sympathetic ganglia.
4. Sympathetic axones to smooth muscle or glands.

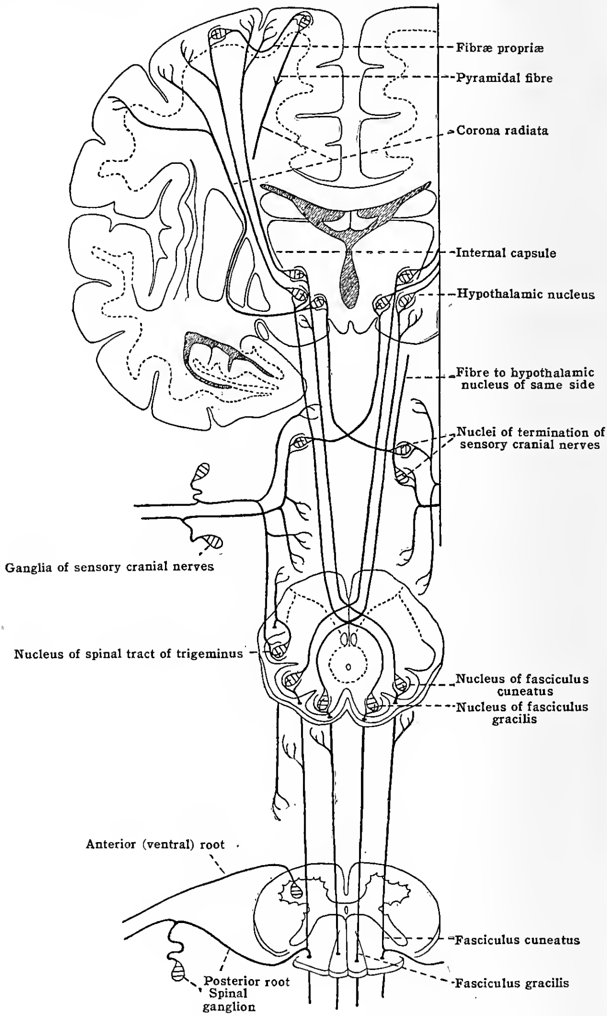
III. Cerebral Path for the Cranial Nerves, Exclusive of Those of Special Sense

A. Ascending system of neurones.

1. Ganglia of origin of sensory components of vagus, glossopharyngeus, glosso-palatine and trigeminus.
   - (a) Peripheral arborisations and afferent peripheral branches of T-fibres of same.
   - (b) Central branches of T-fibres of same (sensory nerve roots).
2. Nuclei of termination of central branches (bifurcated and unbifurcated) in medulla oblongata.
   - (a) Reticular formation, internal arcuate fibres and medial lemniscus of the opposite side.

3. Hypothalamic nucleus and lateral nucleus of thalamus.
   (*a*) Internal capsule, posterior segment of fronto-parietal portion.
   (*b*) Corona radiata, fronto-parietal part.
   (*c*) Cerebral cortex—chiefly lower third of posterior central gyrus.

Fig. 705.—Scheme of Ascending or Spino-cerebral Conduction Pathways.



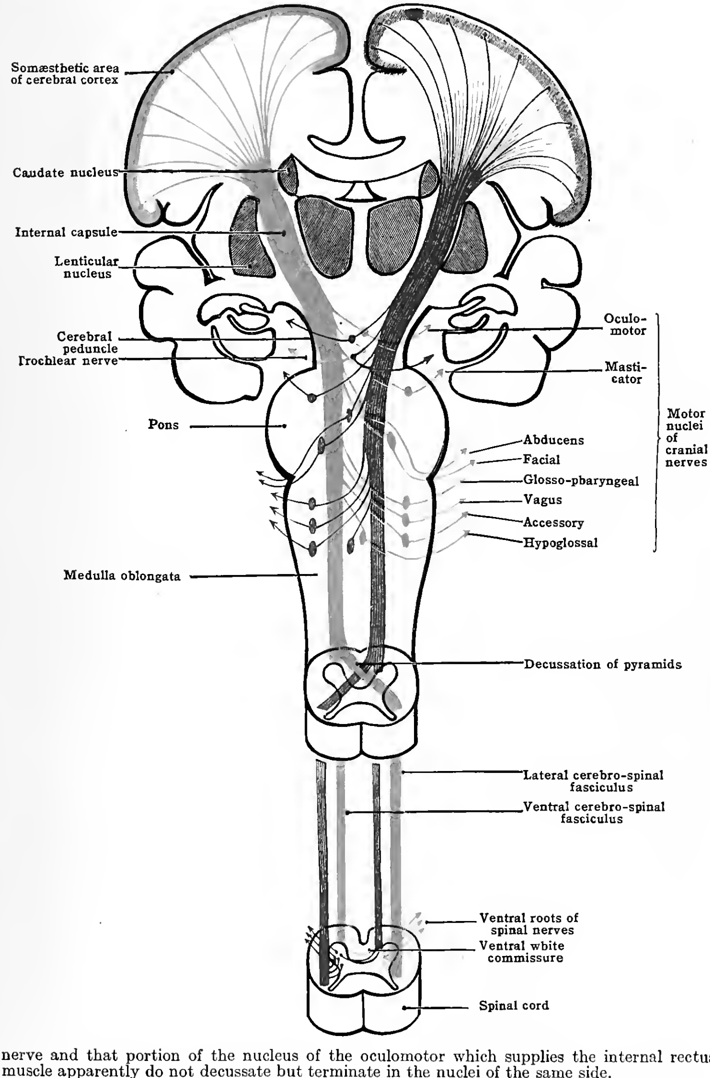
B. Descending system of neurones.

1. Pyramidal cells of opercular region of somæsthetic area.
   (*a*) Corona radiata, fronto-parietal.
   (*b*) Internal capsule, genu chiefly.
   (*c*) Basis of cerebral peduncle and peduncle.
   (*d*) Decussation in brain stem.

2. Nuclei of origin of motor cranial nerves and motor components of mixed cranial nerves, of opposite side chiefly and thence by way of these nerves to the respective muscles supplied.

Notes: (1) Most of the descending cortical fibres to the nucleus of origin of the trochlear

Fig. 706.—Scheme of Descending Cerebro-spinal Conduction Pathways.



nerve and that portion of the nucleus of the oculomotor which supplies the internal rectus muscle apparently do not decussate but terminate in the nuclei of the same side.

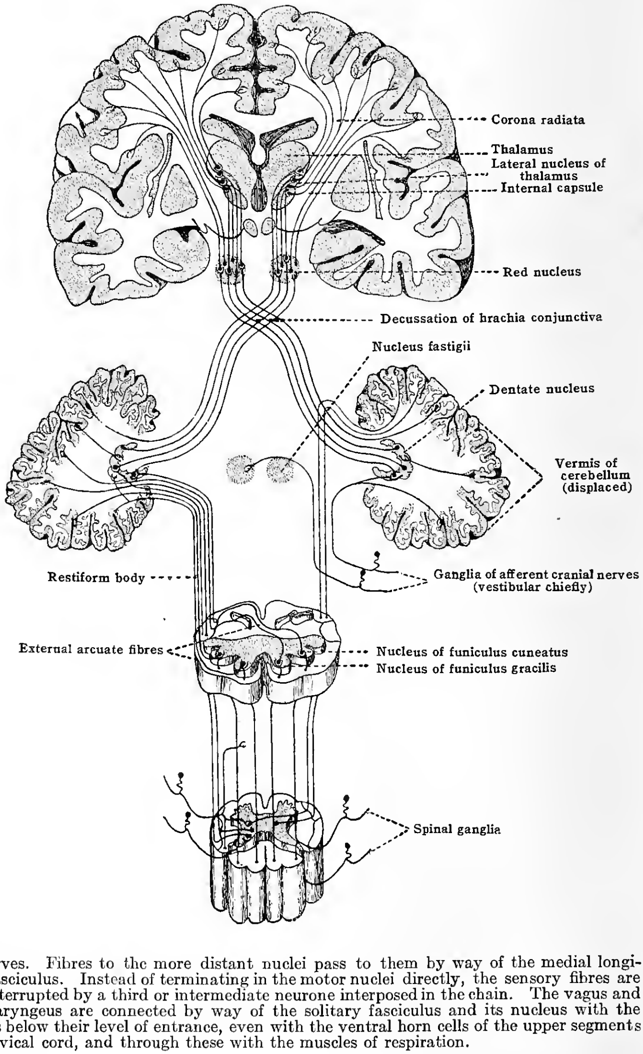
(2) The efferent nucleus of the glosso-palatine (salivatory nucleus) and the dorsal efferent nucleus of the vagus give rise to visceral efferent fibres, i. e., carry impulses destined for smooth muscle and glands by way of sympathetic neurones. The same is true for the supero-median part of the nucleus of the oculomotor.

(3) The nuclei of termination of the cranial nerves, especially those of the vestibular and trigeminus, send fibres also into the cerebellum.

IV. The Short 'Reflex' Paths of the Cranial Nerves

These consist of the central branches of their afferent or sensory fibres, bearing impulses to the nuclei of origin of both their own motor components and to the nuclei of origin of other

Fig. 707.—Scheme of Principal Ascending Cerebellar Conduction Paths.



motor nerves. Fibres to the more distant nuclei pass to them by way of the medial longitudinal fasciculus. Instead of terminating in the motor nuclei directly, the sensory fibres are usually interrupted by a third or intermediate neurone interposed in the chain. The vagus and glosso-pharyngeus are connected by way of the solitary fasciculus and its nucleus with the structures below their level of entrance, even with the ventral horn cells of the upper segments of the cervical cord, and through these with the muscles of respiration.

V. Conduction Paths Involving the Cerebellum

A. Ascending cerebellar pathways.

1. Spinal ganglia.
   (*a*) Dorsal roots of spinal nerves.
   (*b*) Collaterals and descending branches of bifurcation of dorsal root fibres in spinal cord, chiefly those conveying impulses of *muscle-sense*.

2*x*. Dorsal nucleus (Clarke's column).
   (*a*) Dorsal spino-cerebellar fasciculus (direct cerebellar tract).
   (*b*) Restiform body (inferior cerebellar peduncle)—
   (*c*) Joined in medulla by external arcuate fibres (crossed and uncrossed fibres arising in nuclei of funiculus gracilis and cuneatus);
   (*d*) Joined in medulla by fibres arising in nuclei of termination of afferent vagus, glosso-pharyngeal, vestibular, and trigeminal nerves;
   (*e*) Joined by fibres both to and from (ascending and descending) the inferior olivary nucleus of the same and opposite sides (*cerebello-olivary fibres*).

2*y*. Nerve-cells in base of ventral horn of same and opposite side.
   (*a*) Superficial antero-lateral spino-cerebellar fasciculus (Gowers' tract), ascending through spinal cord and reticular formation of medulla and pons.
   (*b*) Anterior medullary velum and brachium conjunctivum to cerebellar cortex (vermis).

3. Cerebellar cortex (vermis), dentate nucleus, nucleus fastigii, nucleus emboliformis, and nucleus globosus.
   (*a*) White substance (corpus medullare) of cerebellum, associating various regions of its cortex and its nuclei with each other.
   (*b*) Brachium conjunctivum (superior cerebellar peduncle) arising chiefly from dentate nucleus.
   (*c*) Decussation of brachium conjunctivum.

4. Red nucleus and ventral portion of lateral nucleus of thalamus. Most fibres of the brachium conjunctivum terminate in the red nucleus; many merely give off collaterals to it in passing to their termination in the thalamus. Most of the ascending fibres arising in the red nucleus also terminate in the ventral part of the thalamus; some ascend to the cerebral cortex direct.
   (*a*) Internal capsule, middle third, and fronto-parietal part of corona radiata.
   (*b*) Somæsthetic area of cerebral cortex and cortex of frontal lobe anterior to it.
   (*c*) Inferior peduncle of thalamus to cortex of temporal lobe.

B. Descending cerebrocerebellar paths.

1. Pyramdial cells of somæsthetic area send fibres through corona radiata, internal capsule, and cerebral peduncle to nuclei of pons and arcuate nucleus of same and opposite side.
2. Cells of cortex of posterior part of frontal lobe give fibres to form frontal pontile path through frontal parts of corona radiata and internal capsule and through medial part of cerebral peduncle to nuclei of pons of opposite side.
3. Cells of cortex of temporal lobe (superior and middle gyri) give fibres to form temporal pontile path which passes under the lenticular nucleus into anterior segment of occipital portion of internal capsule and lateral part of cerebral peduncle to nuclei of pons of opposite side. This path is joined in the internal capsule by a small occipito-pontile path.
4. Cells of nuclei of pons send fibres by way of brachium pontis (middle cerebellar peduncle) to cortex of cerebellar hemisphere, of side opposite to that of the origin of the cerebral fibres making synapses with the cells of the pons.

C. Descending cerebello-spinal paths.

1. From cells of nucleus fastigii of same and opposite sides and probably from other nuclei of cerebellum arise fibres which terminate in the nuclei of termination of the vestibular nerve and these send fibres into the intermediate and anterior marginal fasciculi of spinal cord (fig. 619), and thence to the cells of the anterior horn.
2. Probably connected with the cerebellum is the pathway arising in the red nucleus of the opposite side and descending in the rubro-spinal tract of the lateral funiculus of the spinal cord (fig. 619). The rubro-spinal tract decussates in the ventral portion of the tegmentum of the mesencephalon and is said to pass through the medulla oblongata in the medial longitudinal fasciculus. It must be noted here that some fibres arising in the cortex of the frontal lobe terminate in the red nucleus.

VI. The Vestibular Conduction Paths (Equilibration)

1. Vestibular ganglion gives origin to the peripheral utricular and three ampullar branches and to the combined and centrally directed vestibular nerve.
2. Lateral vestibular nucleus (Deiters'), medial nucleus, superior nucleus, and nucleus of descending or spinal root (nuclei of termination) give origin to fibres as follows:—
   (*a*) From lateral and superior nuclei to nucleus fastigii of opposite side and to cortex of vermis and to dentate nucleus (cerebellar connection).
   (*b*) From medial and superior nuclei to nuclei of origin of eye-muscle nerves of same and opposite sides, by way of medial longitudinal fasciculi.
   (*c*) From lateral nucleus and nucleus of descending root through reticular formation into lateral and ventral vestibulo-spinal tracts of spinal cord.

(*d*) The nuclei receive fibres from the grey substance of the vermis. It is probable that all the nuclei of termination give off fibres bearing ascending impulses which ultimately reach the somæsthetic area, but the course pursued and neurones involved in such a chain are uncertain.

VII. The Auditory Conduction Path (Cochlear Nerve)

1. Spiral ganglion of the cochlea gives origin to short peripheral fibres to organ of Corti, and to the centrally directed cochlear nerve.
2. Dorsal and ventral nuclei of the cochlear nerve (nuclei of termination).
   (*a*) Striæ medullares arise from dorsal nucleus and pass around outer side of restiform body (acoustic tubercle), then medianward under ependyma of floor of fourth ventricle to mid-line, then ventralward into tegmentum, where they decussate and join trapezoid body and lateral lemniscus of opposite side.

Fig. 708.—Diagram Showing Some of the Connections of the Vestibular and Cochlear Nerves.

   (*b*) Fibres arising in ventral nucleus pass ventrally medianward and some terminate in the superior olivary nucleus of same side; others pass by way of trapezoid body and lateral lemniscus to terminate in superior olivary nucleus, nucleus of lateral lemniscus, medial geniculate body and nucleus of inferior quadrigeminate body of the opposite side.
3. Nuclei of superior olives of both sides and nucleus of lateral lemniscus send fibres by way of lateral lemniscus to inferior quadrigeminate body and through inferior brachium to medial geniculate body, and some may pass uninterrupted to the cortex of the temporal lobe.
4. Fibres from medial geniculate body and probably from nucleus of inferior quadrigeminate body pass into internal capsule and through temporal part of corona radiata to middle third of superior temporal gyrus and adjacent portions (auditory area).
5. From striæ medullares and from superior olivary nucleus (peduncle of superior olive) arise fibres which terminate in nucleus of abducens or pass by way of the medial longitudinal fasciculus to other motor nuclei of cranial nerves. It is probable that fibres from the auditory area of the cerebral cortex are also distributed to nuclei of the cranial nerves.

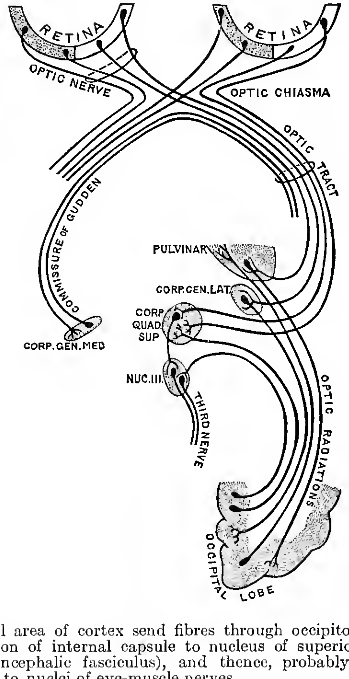
VIII. Conduction Paths of the Optic Apparatus

A. Optic impulses.

1. 'Bipolar' cells of retina with short (peripheral) processes to layer of rods and cones (neuro-epithelium) and short centrally directed processes to ganglion-cell layer of retina (nucleus of termination).

2. Ganglion-cells of retina give origin to—
   (*a*) Optic stratum of retina.
   (*b*) Optic nerve.
   (*c*) Optic chiasma; fibres from nasal side of retina cross in chiasma to opposite side; fibres from lateral side of retina continue on same side in—
   (*d*) Optic tract to—
3. Pulvinar of thalamus, lateral geniculate body, and nucleus of superior quadrigeminate body.
   (*a*) Fibres from nucleus of superior quadrigeminate body pass ventrally, to nuclei of origin of oculomotor and trochlear nerves and to medial longitudinal fasciculus of same and opposite sides, and from it are distributed to nucleus of origin of abducens.
   (*b*) Fibres from lateral geniculate body and pulvinar pass through occipital portion of internal capsule and occipito-thalamic radiation (optic radiation) to cortex of occipital lobe (visual area).

FIG. 709.—DIAGRAM OF PRINCIPAL PATHWAYS OF OPTIC APPARATUS. (After Cunningham.)



4. Cells of visual area of cortex send fibres through occipito-thalamic radiation and occipital portion of internal capsule to nucleus of superior quadrigeminate body (occipito-mesencephalic fasciculus), and thence, probably interrupted by cells of this nucleus, to nuclei of eye-muscle nerves.
5. Cells of nucleus of superior quadrigeminate body and pulvinar send fibres by way of medial longitudinal fasciculus into lateral and ventral funiculi of spinal cord (see fig. 619), chiefly of the opposite side. Fibres from the quadrigeminate body cross mid-line chiefly in decussation of 'optic-acoustic reflex path' (fig. 662).
6. The smaller cells of the supero-mesial group of the nucleus of the oculomotor nerve (nucleus of Edinger and Westphal) send axones, by way of the trunk of the nerve and the short root of the ciliary ganglion, which terminate about cells in—
7. The ciliary ganglion, whose cells send axones to enter the ocular bulb and terminate upon the smooth muscle fibres of the ciliary body and iris.

B. Skin-pupillary reflexes.

1. Peripheral processes of spinal ganglion cells terminating in the skin and central processes of same entering by way of dorsal roots of cervical nerves to bifurcate in spinal cord and give terminal twigs about—
2. Cells of the dorso-lateral group of the ventral horn of the same and opposite sides. These cells send (visceral efferent) axones to terminate about cells in—

3. The superior cervical sympathetic ganglion, which cells send axones chiefly by way of the carotid plexus and the sympathetic roots of the ciliary ganglion to terminat about cells in—
4. The ciliary ganglion. Such cells send axones into the ocular bulb to terminate in the ciliary body and radial muscle fibres of the iris, producing dilation of the pupil.

C. *Auditory-eye reflexes.*
1. Cells of the nuclei of termination of the cochlear nerve and superior olive send fibres by way of the medial longitudinal fasciculus (some to this by way of the peduncle of the superior olive) to the nuclei of origin of the eye-moving nerves.
2. The same nuclei of the cochlear nerve send axones by way of the lateral lemniscus to terminate in the superior quadrigeminate body and thence may be sent impulses which are distributed to the nuclei of the eye-moving nerves.

IX. Principal Conduction Paths of Olfactory Apparatus

1. Bipolar cells of olfactory region of nasal epithelium send short (peripheral) processes toward surface of nasal cavity and centrally directed processes, the olfactory nerve, through lamina cribrosa of ethmoid bone into olfactory bulb (glomerular layer).
2. 'Mitral cells' of olfactory bulb give fibres which form—
   (*a*) The olfactory tract which divides into—

Fig. 710.—Diagram Showing Some of the Principal Tracts and Synapses of the Olfactory Apparatus.

   (*b*) Medial olfactory stria through which fibres pass—(1) into parolfactory area (Broca's area); (2) into subcallosal gyrus; and (3) by way of anterior cerebral commissure to olfactory bulb and uncus of hippocampal gyrus of opposite side.
   (*c*) Intermediate olfactory stria to anterior perforated substance.
   (*d*) Lateral olfactory stria, which terminates to some extent in anterior perforated substance, but chiefly in uncus, hippocampal gyrus, and gyrus cinguli (olfactory area) of same side.
3. Cells of uncus and hippocampal gyrus give fibres which form—
   (*a*) The cingulum (in part), by which they are associated with the cortex of the gyrus cinguli and other areas of the cerebral cortex.
   (*b*) The hippocampal commissure (in part), by which they are connected with the grey substance of the opposite side.
   (*c*) The fornix, which, interrupted in part in the nuclei of the corpus mammillare, conveys impulses—(1) to the anterior nucleus of thalamus of the same (chiefly) and opposite sides (mammillo-thalamic fasciculus), and (2) into the mesencephalon and substantia nigra (mammillo-mesencephalic fasciculus), and by way of this tract probably to the nuclei of the mesencephalon and medulla oblongata.
4. The parolfactory area, anterior perforated substance, anterior portion of thalamus and fornix give fibres which form the medullary stria of the thalamus and which terminate in the habenular nucleus.
5. Habenular nucleus sends fibres in fasciculus retroflexus to terminate in interpeduncular nucleus.
6. Interpeduncular nucleus sends fibres to nuclei of mesencephalon and probably to structures below it.

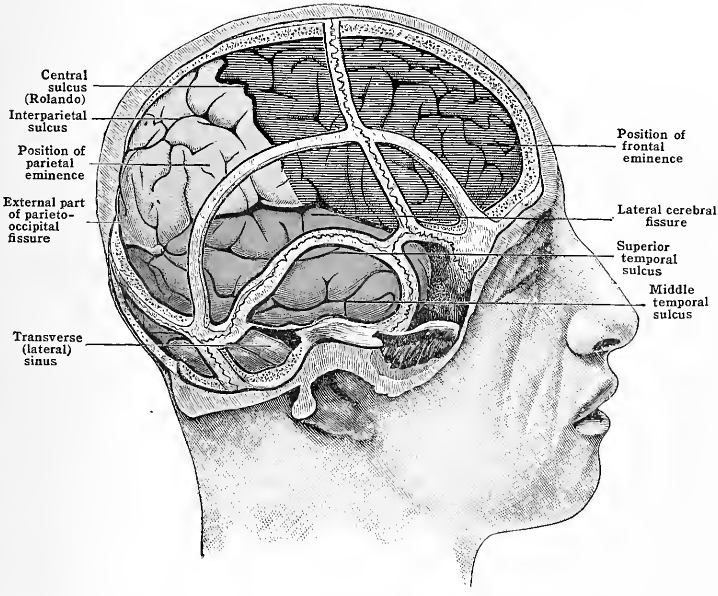
The Relations of the Brain to the Walls of the Cranial Cavity

The precise methods by which the exact positions of the most important fissures, sulci, gyri, and areas can be ascertained and mapped out on the surface of the head in the living subject are fully described in Section XIII. Here, only a very general survey of the relations of the brain to the cranial bones is given and from a purely anatomical standpoint.

The parts of the brain which lie in closest relation with the walls of the cranial cavity are the olfactory bulb and tract, the basal and lateral surfaces of the cerebral hemispheres, the inferior surfaces of the lateral lobes of the cerebellum, the ventral surfaces of the medulla and pons, and the hypophysis.

Certain of these portions of the brain lie in relation with the basi-cranial axis, that is, with the basi-occipital, the basi-sphenoid, and the ethmoid bones, while others are associated with the sides and vault of the cranial cavity. Considering the former portions first, the ventral surface of the medulla oblongata, which is formed by the pyramids, lies upon the upper surface of the basi-occipital bone. More superiorly the ventral surface of the pons rests upon the basi-

Fig. 711.—Drawing of a Cast of the Head of an Adult Male. (Prepared by Professor Cunningham to illustrate cranio-cerebral topography.)



sphenoid, from which it is partly separated by the basilar artery and the pair of abducens nerves. In front of the dorsum sellæ the hypophysis (pituitary body) is lodged in the hypophyseal fossa. Still further forward the olfactory tracts lie in grooves on the upper surface of the pre-sphenoid section of the sphenoid bone; and in front of the sphenoid the olfactory bulbs rest upon the cribriform plates of the ethmoid.

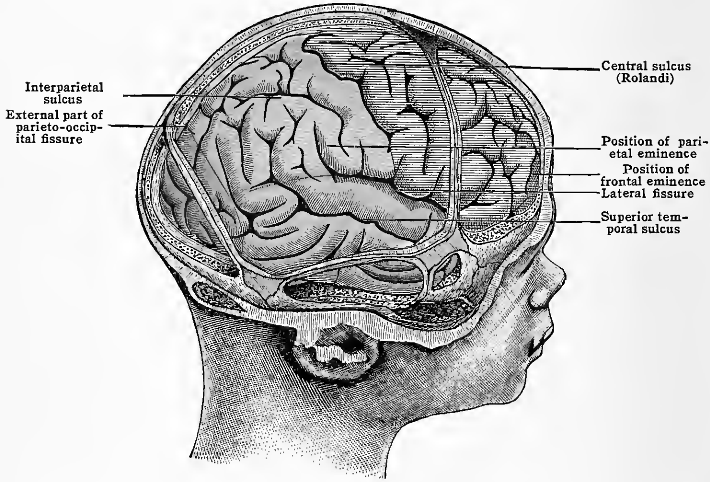
Posterior and lateral to the posterior part of the foramen magnum the lateral lobes of the cerebellum are in relation with the cranial wall, resting upon the lower parts of the supra-occipital and the posterior parts of the ex-occipital portions of the occipital bone, while anteriorly each lobe is in relation with the inner surface of the mastoid process and the posterior surface of the petrous portion of the temporal bone. The area of the skull wall which is in close relationship with the cerebellar hemispheres may be indicated, on the external surface of the skull, by a line which commences at the inferior part of the external occipital protuberance and thence runs upward and lateralward. It crosses the superior nuchal line a little beyond its centre, and, continuing in the same direction, crosses the inferior part of the lambdoid suture and reaches a point directly above the asterion (the meeting-point of the occipital, temporal, and parietal bones); thence it descends, just in front of the occipito-mastoid suture, to the tip of the mastoid process, and there turns medialward to its termination at the margin of the foramen magnum, immediately behind the posterior end of the occipital condyle.

The basal surface of each cerebral hemisphere may be said to consist of two parts, an anterior and a posterior, separated by the stem of the lateral cerebral fissure. The anterior part, formed by the orbital surface of the frontal lobe, rests upon the upper surfaces of the orbital plate of the frontal bone and the lesser wing of the sphenoid. It is, therefore, in close relation with the upper wall of the orbital cavity. The posterior part, behind the stem of the lateral fissure, begins with the anterior portion of the temporal lobe, including its pole. The pole itself projects against the orbital plate of the great wing of the sphenoid bone, and it is in relationship with the posterior part of the lateral wall of the orbit. The basal surface of the hemisphere, behind the pole of the temporal lobe is in contact with the upper surfaces of the great wing of the sphenoid and the petrous part of the temporal bone.

The convex surfaces of the cerebral hemispheres have the most extensive relationships with the cranial wall, and it is more especially to these surfaces that the surgeon turns his attention. The general area in which the convex surface of each cerebral hemisphere is in relation with the skull bones is readily indicated by a series of lines which correspond with the positions of its superciliary, infero-lateral, and supero-mesial borders.

The line marking the superciliary margin of the hemisphere commences at the nasion (the mid-point of the fronto-nasal suture); it passes lateralward above the superciliary ridge, crosses the temporal ridge, then, turning posteriorly in the temporal fossa, it reaches the parieto-sphenoidal suture, and continues backward along it to its posterior extremity.

FIG. 712.—DRAWING OF A CAST OF THE HEAD OF A NEWLY BORN MALE INFANT. (Prepared by Professor Cunningham to illustrate cranio-cerebral topography.)



The line marking out the infero-lateral border commences at the posterior end of the parieto-sphenoidal suture, whence it passes downward, in front of the spheno-squamous suture, to the infra-temporal crest (pterygoid ridge); there it turns posteriorly and, running parallel with and mesial to the zygomatic arch, it crosses the root of the zygoma, and, ascending slightly, it passes above the external auditory meatus. Continuing backward with an inclination upward it reaches a point immediately above the asterion; thence it descends, and, crossing the inferior part of the lambdoid suture and the superior nuchal line, it passes medialward to the inferior part of the external occipital protuberance.

The supero-mesial border of the hemisphere is defined by a line which runs from the nasion to the inion. This line should be drawn about 5 mm. lateral to the sagittal suture, because the mesial area is occupied by the superior sagittal sinus, and it should be further away from the middle line on the right than on the left side, because the sinus tends to lie more to the right side.

The area of the skull wall enclosed by the three lines which mark the positions of the superciliary, infero-lateral, and the supero-mesial borders of the cerebral hemisphere is formed by the vertical plate of the frontal bone, the parietal bone, the great wing of the sphenoid, the squamous part of the temporal, and the upper section of the supra-occipital segment of the occipital bone. It covers the outer surfaces of the frontal, parietal, temporal, and occipital lobes of the cerebrum and the fissures and sulci which bound and mark them.

In every consideration of the topographical relations of the cerebral gyri to the walls of the cranial cavity it must be borne in mind that the conditions are not constant, and that, therefore, the relations are variable. The three main factors upon which this variability depends are age, sex, and the shape of the skull. As examples of the variations which occur it may be mentioned that the lateral cerebral fissure is relatively higher in the child than in the adult (compare figs. 711 and 712). The supero-mesial end of the central sulcus is further away from the coronal suture in the female and in the child than in the adult male, and in dolichocephalic than in brachycephalic heads. The angle formed between the line of the central fissure and the mid-sagittal plane, which averages about 68° in the adult, is more acute in dolichocephalic heads, and the external part of the parieto-occipital fissure is further forward in the child, and possibly in the female, than it is in the adult male.

The position of the posterior horizontal limb of the lateral fissure varies even in the adult. Its posterior part is always under cover of the parietal bone, and it terminates either in front of or inferior to the parietal eminence, but the anterior part may be above, parallel with, or inferior to the squamo-parietal suture. In the adult the anterior part of the fissure runs upward and backward from the posterior end of the spheno-parietal suture along the anterior part of the squamo-parietal suture to its highest point; thence it continues in the same direction beneath the parietal bone toward the lambda, terminating either in front of or below the parietal eminence. In the child, however, the fissure is considerably above the line of the squamo-parietal suture (fig. 712), which it gradually approaches, attaining its adult position about the ninth year. This change of position, which occurs during the first nine years, is due partly to the ascent of the sutural line and partly to the descent of the fissure on the surface of the brain.

The frontal bone always covers the superior, middle, and inferior frontal gyri, except their posterior extremities, which are beneath the parietal bone (fig. 711). The ascending limb (ramus anterior ascendens) of the lateral fissure, which cuts into the posterior part of the inferior frontal gyrus, runs parallel with and under cover of the lower part of the coronal suture, or immediately in front of it, and the anterior horizontal limb is parallel with and beneath the upper margin of the great wing of the sphenoid.

The parietal bone is in relation with the convex surfaces of four lobes of the brain. Speaking very generally, it may be said that the anterior third covers the posterior part of the frontal lobe, including the anterior central gyrus, and the posterior ends of the superior, middle, and inferior frontal gyri and the precentral sulcus. The posterior two-thirds of the bone are superficial to the perietal lobe, the posterior part of the temporal lobe, the anterior part of the occipital lobe, the posterior part of the horizontal limb of the lateral fissure, the superior and inferior parts of the post-central sulcus, the interparietal sulcus, the posterior sections of the superior and middle temporal sulci, and the external part of the parieto-occipital fissure. The central sulcus is beneath the parietal bone at the junction of its middle and anterior thirds (fig. 711).

In the adult, the upper end of the central sulcus is situated at about 55 per cent. of the whole length of the naso-inionic line posterior to the nasion. It is about 4 or 5 cm. from the coronal suture. The inferior end of the sulcus, which extends to near the posterior horizontal limb of the lateral fissure, lies beneath the point of intersection of the auriculo-bregmatic line with a line drawn from the stephanion (the point where the temporal ridge cuts the coronal suture) to the asterion. This point is about 46 per cent. of the horizontal arc measured from the glabella to the inion.

The superior end of the parieto-occipital fissure usually lies about 5 mm. in front of the lambda, and the course of the fissure may be indicated by a line drawn from 5 mm. in front of the lambda to a point immediately above the asterion, and, as the latter point corresponds with the pre-occipital notch on the infero-lateral border of the hemisphere, the line in question will indicate the adjacent margins of the parietal, temporal, and occipital lobes.

The occipital bone is in close relation with the cerebellum, as already pointed out, but it also covers the posterior part of the lateral surface of the occipital lobe of the cerebral hemisphere. The great wing of the sphenoid covers the outer surface of the pole of the temporal lobe, and the squamous part of the temporal bone covers the anterior parts of the superior, middle, and inferior temporal gyri and the sulci which separate them.

The Blood Supply of the Encephalon

The double origin of the continuous arterial system of the brain given by the confluence of the two vertebral arteries and the two internal carotid arteries, together with the description of the general distribution of the different cerebral, mesencephalic, and cerebellar arteries into which the system is divided, and the origin and course of the corresponding veins, are fully dealt with in Section V. Here attention may be called briefly to the abundant and systematic internal distribution of the terminal branches of the system and their intimate arrangement for the actual nourishment of the nervous tissues within.

The general plan of the blood supply for the entire encephalon may be summarised as follows:—(1) At their origin the different arteries are so connected, directly or indirectly, on the base of the encephalon, that the blood approaching the brain by way of the vertebral and internal carotid arteries is practically a common supply for all the arteries of the encephalon, and a given part of it may possibly pass into any one of them. (2) In the pia mater of each gross division of the encephalon the different arteries again become connected with each other in a superficial, freely anastomosing plexus, continuous throughout. (3) From this plexus of the surface, naturally composed in part of the trunks of the different arteries themselves, arise branches which enter directly into the nervous substance and which break up into twigs that are *terminal;* i. e., twigs that *do not* anastomose with each other. (4) The arterial capillary system arising from the terminal twigs passes over into venous capillaries which converge to form corresponding venous twigs which in their turn pass to the surface and join in forming a peripheral, anastomosing venous plexus superimposed upon the similar arterial plexus. (5) From this venous plexus arise the different veins of the encephalon which may or may not accompany the arteries for a short distance, and which finally empty into the sinuses in the cranial dura mater. These, likewise confluent, empty into the internal jugular veins. The chorioid plexuses of the ventricles of the brain are modifications of the general anastomosing peripheral plexuses. The chorioid plexuses of the lateral and third ventricles are derived largely from branches of the chorioid arteries, which arises separately from the internal carotid artery.

The **blood supply of the cerebrum** may best be taken as an illustration of the general plan of the blood-vascular system of the encephalon. The terminal or internal branches of the surface plexus, derived from the posterior, middle, and anterior cerebral arteries, are arranged into two groups, a **central** or **ganglionic** and a **cortical group.** The central branches themselves form four groups in each hemisphere:—

(1) The *antero-mesial group* consists of terminal branches from the plexus of the domain of the anterior cerebral artery, which pass through the medial part of the anterior perforated substance and supply the head of the caudate nucleus, the septum pellucidum, the columns of the fornix, and the lamina terminalis.

(2) The *antero-lateral group* consists of terminal branches from the domain of the middle cerebral artery. These pierce the anterior perforated substance in two sub-groups—(*a*) the internal and (*b*) the external striate arteries (fig. 713). The **internal striate arteries** pass through the segments of the globus pallidus of the lenticular nucleus and through the internal capsule, to both of which they give branches, and they terminate in the caudate nucleus and thalamus. The **external striate arteries** are larger and more numerous. They pass upward between the external capsule and the putamen, and then through or around the upper part of the putamen into the internal capsule, where they form two groups, the *lenticulo-thalamic* and the *lenticulo-caudate groups.* The former terminate in the thalamus and the latter in the caudate nucleus. On account of its larger size at its origin and its direct linear continuation with the internal carotid, emboli (*thrombi*) pass more frequently into the middle cerebral artery

Fig. 713.—Diagram Showing the Manner of Distribution of the Cortical and Central Branches of the Cerebral Arteries.

than into the anterior cerebral artery. One of the lenticulo-caudate arteries which is larger and longer than the others and which is a direct branch from the middle cerebral artery has been called the **'artery of cerebral hemorrhage'** (Charcot), on account of the greater frequency with which it is ruptured.

(3) The *postero-medial central* arteries are terminal branches of the posterior cerebral artery. They also enter the anterior perforated substance, but supply the floor of the third ventricle, the posterior part of the thalamus, and the hypothalamic region.

(4) The *postero-lateral group* are also terminal branches of the posterior cerebral artery. They supply the posterior part of the internal capsule, the pulvinar of the thalamus, the geniculate bodies, the corpora quadrigemina and their brachia, the epiphysis, and the cerebral peduncles.

The *cortical group* of the cerebral arteries arise from the anastomosing plexus in the pia mater of the cortical surfaces of the hemisphere. They pass into the cortical substance both from the summits of the gyri and from the walls of the sulci. They consist of short, medium, and long branches, and pass at right angles into the gyri. The short branches terminate in the cortical substance; the medium branches supply the more adjacent white substance, and the longer branches pass more deeply into the general medullary centre of the hemisphere.

All of both the central or ganglionic and the cortical arteries are terminal in the sense that they do not anastomose in the substance of the cerebrum.

The blood-vascular system of the other divisions of the encephalon is in accordance with the same general plan of that of the cerebrum. Slight individual modifications of the general plan are to be expected.

The **blood-vessels of the mesencephalon,** in addition to the supply derived from the postero-lateral group of central arteries, include the vessels of the quadrigeminate bodies and those of the cerebral peduncles. The arteries of the quadrigeminate bodies are usually six in number, three for each side—the **superior, middle,** and **inferior quadrigeminate arteries.** The superior and middle are branches of the posterior cerebral arteries, and the inferior are branches of the superior cerebellar arteries. The superior supply the superior quadrigeminate bodies and the epiphysis; the middle supply both the superior and inferior quadrigeminate bodies, and the inferior the inferior quadrigeminate bodies. They all anastomose in the pia on the surface of the stratum zonale, forming a fine-meshed plexus, and from this superficial plexus the terminal branches pass into the substance of the bodies. The **veins** terminate in the vein of Galen (v. cerebri magna.)

The **arteries of the cerebral peduncles** form two groups, mesial and lateral. The **mesial peduncular arteries** are branches of the basilar and the posterior cerebral arteries. They pass to the medial sides of the penduncles and supply the superior and medial part of the tegmentum. The vessels of this group which accompany the fibres of the oculomotor nerves are known as the radicular arteries; they supply the root-fibres and the nuclei of the nerves, which receive no other branches. The **lateral peduncular arteries** are branches of the posterior cerebral and

Fig. 714.—Showing the Capillary Supply of the Cerebellar Cortex. (After Aby, "Journal of Comparative Neurology," Vol. IX.)

superior cerebellar arteries. They supply the lateral portions of the peduncles and the lateral part of the tegmentum. The veins of the mid-brain terminate in the basilar veins and the vein of Galen.

The blood-vessels of the cerebellum.—Six arteries supply the cerebellum; two, the **posterior inferior cerebellar,** are derived from the vertebral arteries, and the remaining four, two **anterior inferior** and two **superior cerebellar,** from the basilar artery. The course and general distribution of the arteries are described in Section V, but here it must be noted that the branches of these six vessels form a rich network in the pia mater on the surfaces of the cerebellar lobes, and that extensions of the plexus pass with the folds of the pia mater into the sulci and fissures. From the superficial plexus terminal branches pass into the interior of the cerebellum and their collaterals form capillary plexuses in the white and grey substance. The extensions of the surface plexus are of three lengths:—(1) a longer set, which pass through the cortex of the cerebellum and supply the white substance of the corpus medullare; (2) a set of shorter arterioles which pass through the molecular layer of the cortex and break up in its granular layer; (3) the shortest set pass into the cortex and immediately break up in its molecular layer. The meshes of the capillary plexuses in the grey susbtance are ovoidal and their axes run radially. The meshes of the plexuses in the white substance are parallel with the nerve-fibres. In addition to the vessels mentioned, a distinct branch is distributed to each dentate nucleus. This springs either from the superior cerebellar or from the anterior inferior cerebellar artery of the corresponding side.

The efferent veins of the cerebellum do not accompany the arteries; they spring from a plexus in the pia mater which receives tributaries from the interior, and they form three groups on each cerebellar surface, the vermian veins and the lateral veins. The **superior vermian vein** runs forward on the superior surface of the vermis and terminates in the vein of Galen. The **inferior vermian vein** runs posteriorly and ends in one of the transverse sinuses. The **superior lateral veins** open into the superior petrosal or transverse sinuses, and the **inferior lateral veins** into the inferior petrosal and transverse sinuses. The vein from the dentate nucleus usually joins the inferior lateral veins.

The blood-vessels of the pons.—The arteries to the pons are branches of the basilar artery, and of its anterior inferior and superior cerebellar branches. The plexus in the pia mater is comparatively unimportant, and the branches which enter the substance of the pons form two main groups, the central and the peripheral. The **central arteries** spring directly from the basilar. They pass backward along the raphe, giving branches to the adjacent parts, and they terminate in the nuclei of the pons and those in the floor of the fourth ventricle. The **peripheral arteries** are radicular and intermediate. The *radicular branches* spring from the peripheral plexus and from the anterior inferior cerebellar arteries; they accompany the roots of the trigeminus, abducens, facial, vestibular, and cochlear nerves, supply their fibres and the adjacent parts, and they end in the grey nuclei with which the nerve-fibres are connected. The *intermediate arteries* enter the surfaces of the pons irregularly and break up into capillaries in its substance. **The veins** form a plexus on the surface. The dorsal and lateral part of this plexu- is drained into the basilar vein on each side, and the inferior part is connected by efferent channels with the inferior petrosal sinus and the cerebellar veins.

The blood-vessels of the medulla oblongata.—The **arteries of the medulla** are derived directly from the vertebral arteries, from their anterior and posterior spinal and posterior inferior cerebellar branches, and from the basilar artery. The branches of these vessels form a plexus in the pia mater from which, and from the arteries themselves, three main groups of vessels pass into the medulla—the chorioidal, the central, and the peripheral. The **chorioidal arteries** are derived chiefly from the posterior inferior cerebellar arteries. They supply the chorioid plexus of the fourth ventricle. The **anterior central arteries** rise from the anterior spinal artery, from the basilar artery, and from the peripheral plexus; they pass caudalward along the raphe, supplying the adjacent parts of the ventral funiculi and the olivary bodies, and they break up into fine terminals in the grey substance of the floor of the fourth ventricle around the nuclei of the cranial nerves. The **posterior central arteries** spring from the posterior spinal arteries; they pass down the median septum of the inferior part of the medulla and supply the adjacent nervous substance. The **peripheral arteries**, like those of the spinal cord, are separable into radicular and intermediate groups. The *radicular arteries* pass from the anterior and posterior spinal branches and from the trunks of the vertebral arteries and accompany the fibres of the last six cranial nerves into the substance of the medulla. They supply the nerve-roots and adjacent white substance and they terminate in capillaries in the grey substance of the lateral part of the floor of the ventricle. The *intermediate peripheral arteries* spring from the arteries previously named and from the peripheral plexus, and they pass directly into the funiculi of the medulla, where they terminate in a capillary plexus which supplies the white substance and the grey nuclei; some of these arteries, more especially those derived from the posterior inferior cerebellar and the posterior spinal arteries, extend inward to the lateral part of the floor of the fourth ventricle.

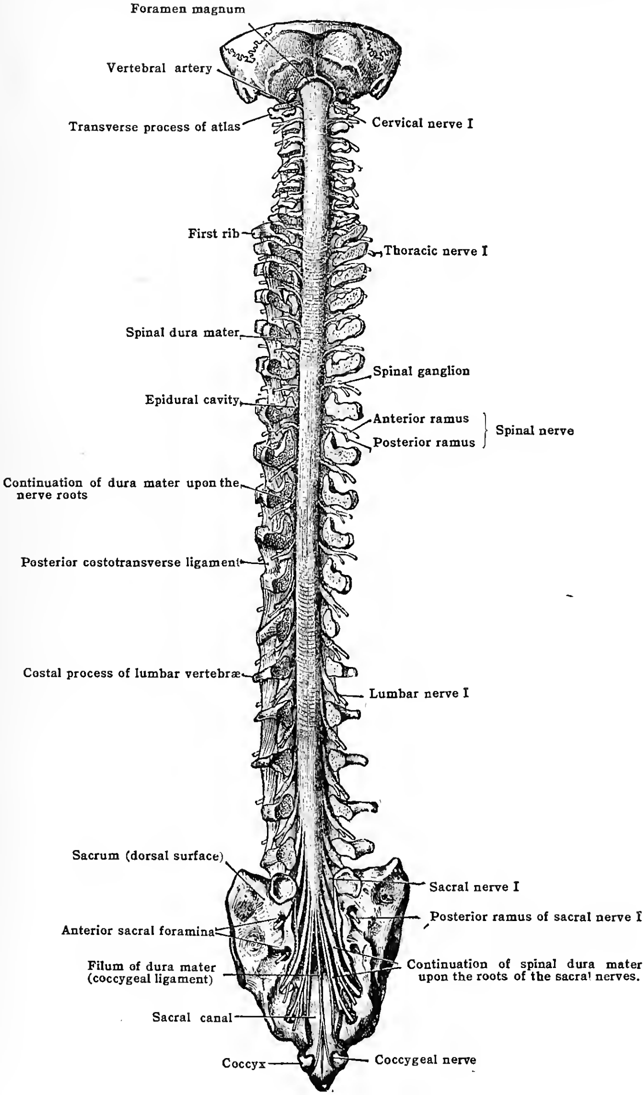
The veins which issue from the medulla form a peripheral plexus in the pia mater in which there are two main longitudinal channels, an **anterior median** and a **posterior median vein.** The former communicates posteriorly with the anterior median vein of the cord, and anteriorly with the veins of the pons and with the veins which accompany the hypoglossal nerves. The latter veins empty into the internal jugular veins. The posterior median vein is continuous caudally with the corresponding vein of the cord, and anteriorly, in the region of the calamus scriptorius, it divides into branches which join the radicular veins. The blood is carried away from the peripheral plexus mainly by the **radicular veins,** which pass along the roots of the last six cranial nerves. Those which accompany the hypoglossal nerves have already been referred to. The others end in the terminal parts of the transverse sinuses, the inferior petrosal sinuses, or the inferior part of the occipital sinuses.

The **nerve supply of the blood-vessels** of the brain consists of a perivascular plexus of sympathetic nerve-fibres upon the walls of the vessels and medullated fibres which accompany the vessels and apparently terminate, for the most part, in the connective tissue about them. The former are thought to be vaso-motor in function; the latter probably sensory fibres of the cranio-spinal type. Nerves have been described only for the larger vessels.

IV. THE MENINGES

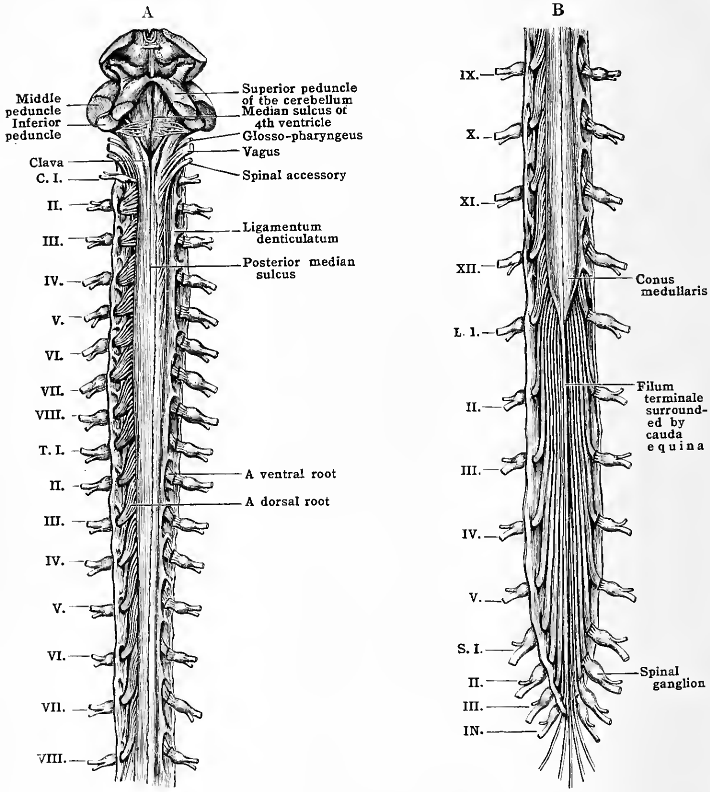
Three membranes, collectively called the **meninges,** envelope the entire central nervous system, separate it from the walls of the bony cavities in which it lies, and aid in its protection and support. They consist of feltworks in which white fibrous connective tissue predominates, and through them pass the blood-vessels which supply the central nerve-axis and the nerves by which the axis is connected with the periphery. Though there are definite spaces or cavities between them, the membranes are not wholly separated from each other, and they are both continuous with and contribute to the walls of the blood-vessels and the sheaths (epineurium) of the nerves passing through them. Beginning with the outermost, they are—(1) the *dura mater,* the thickest, most dense and resistant of the mem-

Fig. 715.—Showing the Spinal Dura Mater Exposed *in situ*. (Dorsal aspect.) (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



branes; (2) the *arachnoid*, the much less dense, web-like middle membrane; and (3) the *pia mater*, a thin, compact membrane, closely adapted to the surface of the central system, into which it sends numerous connective-tissue processes. It is highly vascular in that it contains the rich superficial plexuses of blood-vessels from which the intrinsic blood supply of the central system is derived. The space between the dura mater and the arachnoid is known as the *sub-dural*

Fig. 716.—Dorsal Aspect of the Medulla Oblongata and Spinal Cord with the Dura Mater Partially Removed. (Hirschfeld and Leveillé.)



cavity, and that between the arachnoid and the pia mater is the *sub-arachnoid cavity*.

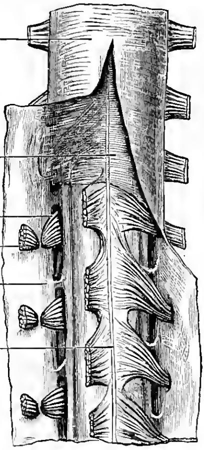
The Dura Mater

In the fresh condition the dura mater appears as a bluish-white, exceedingly resistant membrane, forming the outermost envelope of the entire central nervous system. Its external surface or that next to the bony wall is rough, while its internal surface appears smooth, due to the fact that the subdural cavity partakes of the nature and has the lining of a lymph-space. The cranial dura mater consists of two distinct, closely associated layers, the outermost of which serves as the internal periosteum of the cranial bones. The spinal dura mater is described as consisting of but one layer. The internal periosteum of the spinal canal, though continuous at the foramen magnum with the outer layer of the cranial dura mater, is not considered a part of the spinal dura mater, from the fact that it is so widely separated from the layer actually investing the spinal cord. Thus, since the cranial and spinal portions of the dura mater differ, they are described separately.

The spinal dura mater is a fibrous tube with funnel-shaped caudal end which encloses and forms the outermost support of the spinal cord. It consists of but one layer and this corresponds to the inner layer of the cranial dura mater. It begins at the foramen magnum and terminates in the spinal canal at about the level of the second piece of the os sacrum. It is firmly attached to the periosteum of the surrounding bones only in certain localities:—

(1) The upper end of the tube blends intimately with the periosteum of the margin of the foramen magnum, and thus in this locality it becomes continuous with the outer layer of the cranial dura mater. Also in this locality it is attached firmly, though less intimately, to the periosteum of the posterior surfaces of the second and third cervical vertebræ. This locality may be considered the upper fixation-point of the spinal dura mater. (2) It extends laterally and contributes to the connective tissue investments of each pair of spinal nerves, and as such it passes into the intervertebral foramina and becomes continuous with the periosteum lining each. (3) Along its ventral aspect the spinal dura mater is attached by numerous proc-

Fig. 717.—View of Membranes of Spinal Cord from Ventral Aspect. (Ellis.)



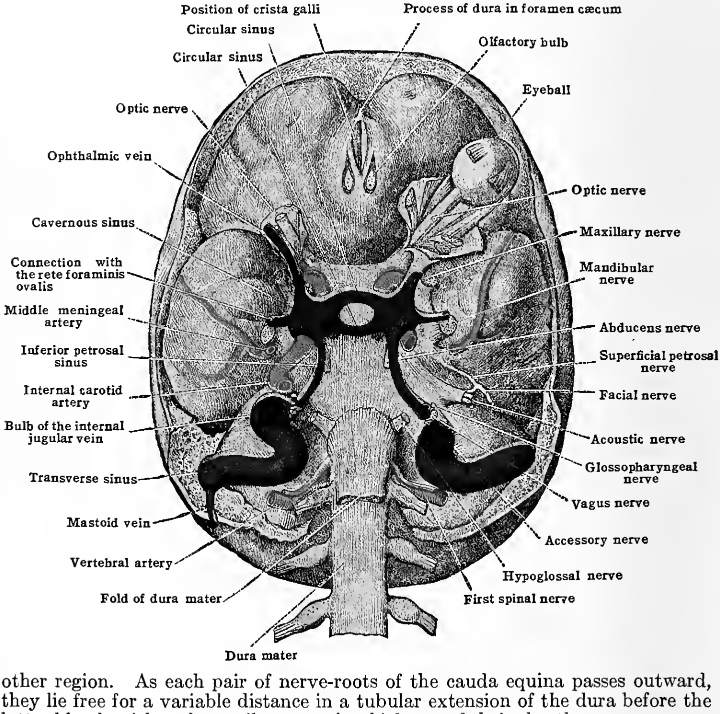
esses to the posterior longitudinal ligament of the vertebral canal. These attachments are more or less delicate, loose, and irregular, and are easily torn or cut in removing the specimen. They are stronger and more numerous in the cervical and lumbar regions than in the thoracic. (4) In the space between the dura and the walls of the vertebral canal (*epidural cavity*) lies the rich internal vertebral venous plexus, and along the lateral aspect the dura is occasionally connected with the periosteum through the tissue of the walls of the vessels of this plexus, especially in case of the vessels which penetrate the dura. Along its dorsal aspect the spinal dura mater is practically free from the wall of the vertebral canal. (5) At its lower and funnel-shaped extremity, opposite the second sacral vertebra, the tube suddenly contracts into a filament extending into the coccyx and breaking up into a number of processes which become continuous with the periosteum of the dorsal surface of the coccyx. This filament is the **coccygeal ligament** or *filum* of the dura mater, and its attachment may be considered the lower fixation-point of the spinal dura mater. (See figs. 613 and 715). The extent of the tube is maintained chiefly by means of the two fixation-points, for all the other attachments are sufficiently loose to permit of the movements of the vertebral column.

The *inner surface* of the spinal dura mater appears smooth, but upon closer examination it is found to be connected with the arachnoid by a few delicate subdural trabeculæ—occasional fine strands of connective tissue bridging the subdural space (fig. 725). Along its lateral aspects the inner surface is at intervals quite firmly attached to the pia mater by the dentations of the **ligamenta denticulata**, which are prolonged through the arachnoid.

Further, it is continuous at intervals with both the pia mater and arachnoid by way of the connective-tissue sheaths of the nerve-roots which are prolonged from the pia and blend with the dura mater in the passage of the nerve-roots through it. The dura is also pierced by the spinal rami of the vertebral arteries, and the connective tissue of the outer walls of these vessels blends with all three of the meninges. The filum terminale of the pia mater extends below the termination of the spinal cord into the point of the funnel-shaped end of the dura mater, and there blends with it in line with the coccygeal ligament of the outer surface.

The tube of the spinal dura mater varies in calibre with the variations in the diameter of the spinal cord. However, the termination of its cavity occurs about seven segments below the termination of the spinal cord. This extension contains the long intra-dural nerve-roots forming the cauda equina, and the calibre of this part, before its sudden contraction, is about as great as that found in any

Fig. 718.—The Dura Mater Encephali of the Base of the Cranium. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



other region. As each pair of nerve-roots of the cauda equina passes outward, they lie free for a variable distance in a tubular extension of the dura before the latter blends with and contributes to the thickness of their sheath.

The **subdural cavity,** the space between the dura mater and the arachnoid, is the thinnest of the meningeal spaces. Along the ventral aspect especially, the spinal arachnoid is quite closely applied to the inner surface of the dura mater. It contains a small amount of cerebro-spinal fluid (lymph) which prevents friction between the opposing surfaces, and is continuous with the fluid in the like space of the cranial meninges.

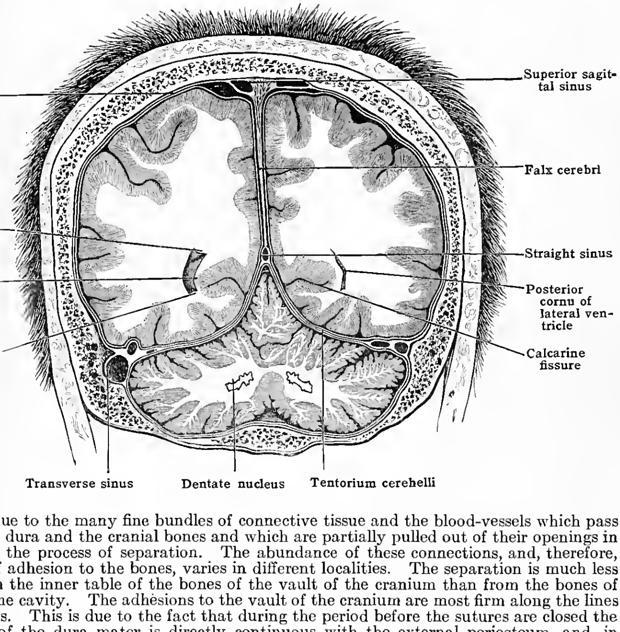
The space communicates with the venous sinuses of the cranium in the region of the Pacchionian bodies, and its fluid is likewise in contact with the blood-vessels passing through it. It is probably continuous with the lymph-spaces of the nerve-roots passing through it, for colored fluids injected into it pass into the nerve-roots. The arachnoid is so thin and gauze-like that a ready interchange of fluids between this space and the subarachnoid space is possible by simple filtration.

The cranial dura mater [dura mater encephali].—The dura mater investing the brain performs a double function—it serves as an internal periosteum for the cranial bones and gives support and protection to the brain. In conformity with its double function it consists of two layers, easily separable in the child, but closely adhering to each other in the adult, except in occasional localities, where there exist small clefts lined with endothelium. The large blood sinuses and venous lacunæ, corresponding to the internal vertebral venous plexus of the vertebral canal, are placed between the two layers and the semilunar ganglia of the trigemini also lie between them. The cranial dura begins with the adhesion of the spinal dura mater to the periosteum at the foramen magnum, and it forms a sac-like envelope about the entire encephalon. Consisting of two layers, it is a much thicker membrane than that of the spinal cord.

The *outer surface* of the cranial dura mater when torn away from the cranial bones appears very uneven, and when placed in water presents a flocculent appearance.

Fig. 719.—Coronal Section of the Head, Passing through the Posterior Horns of the Lateral Ventricles.

From a mounted specimen in the Anatomical Department of Trinity College, Dublin.



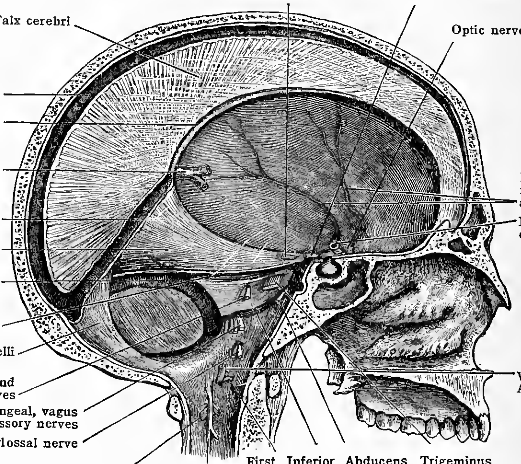
This is due to the many fine bundles of connective tissue and the blood-vessels which pass between the dura and the cranial bones and which are partially pulled out of their openings in the latter in the process of separation. The abundance of these connections, and, therefore, the degree of adhesion to the bones, varies in different localities. The separation is much less difficult from the inner table of the bones of the vault of the cranium than from the bones of the base of the cavity. The adhesions to the vault of the cranium are most firm along the lines of the sutures. This is due to the fact that during the period before the sutures are closed the outer layer of the dura mater is directly continuous with the external periosteum, and, in consequence of this condition during development, the connective-tissue connection is more abundant along these lines and some is even caught in the closure of the sutures. Along the vault there are occasionally noticed small lymph-spaces between the bone and the dura mater. The stronger adherence to the base of the cranial cavity is due to the numerous foramina in the floor, through which all the larger cranial blood-vessels and the cranial nerves pass, and the dura mater is continuous with the connective-tissue investments of these as well as with the periosteum lining the foramina. Also the floor of the cavity is more uneven than the vault, and the projections of the bones here tend to increase the firmness of attachment. The weight of the brain upon the floor probably contributes to the result.

The *inner surface* of the inner layer of the cranial dura mater forms the outer boundary of the subdural cavity. Except for the occasional delicate subdural trabeculæ and the passage of blood-vessels and nerve-roots, this surface appears smooth and glistening, being lined by a layer of endothelium and containing a small amount of the cerebro-spinal lymph.

The subdural cavity of the base of the brain is prolonged a short distance outward along the roots of the various cranial nerves before it is obliterated by the blending of the dura mater with the sheaths of the nerves. This outward extension of the space is most marked about the optic and auditory nerves. In the optic especially, the dura mater remains separate from the nerve throughout its length, only fusing with its sheath upon the posterior surface of the ocular bulb (fig. 718).

One of the most striking differences between the cranial dura mater and that of the spinal cord is that the inner layer of the former undergoes striking septa-like duplications or folds, forming exceedingly strong partitions which project between the larger subdivisions of the encephalon. These are four in number, two large and two small—the falx cerebri and the tentorium cerebelli; the falx cerebelli and the diaphragma sellæ. The larger enclose within their folds the great venous sinuses, into which most of the spent blood of the encephalon collects to pass outward by way of the internal jugular veins (figs. 720, 721).

Fig. 720.—The Cranium with Encephalon Removed to show the Falx Cerebri, the Tentorium Cerebelli, and the Places where the Cranial Nerves pierce the Dura Mater. (Sappey.)

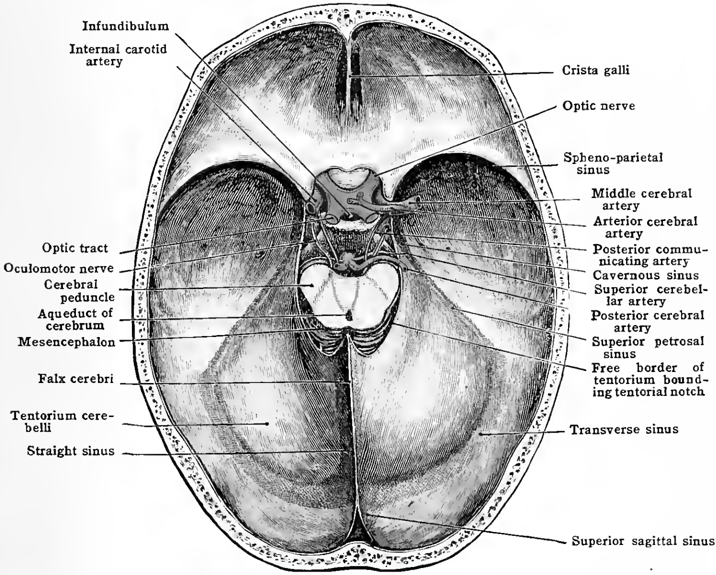


The **falx cerebri** is the most striking of these partitions. It is a sickle-shaped fold which projects vertically from the vault into the longitudinal fissure between the cerebral hemispheres. It begins attached to the crista galli in front, and arches to terminate by blending with the superior surface of the hirozontally placed tentorium cerebelli. Its convex, superior border joins the outer layer of the dura along the medial plane of the vault, and encloses the superior sagittal sinus. Its concave border is free and contains in its posterior two-thirds the smaller inferior sagittal sinus. The anterior and narrower end is often perforated and occasionally so much so as to appear as a coarse, fibrous reticulum. The posterior part of the concave border touches the upper surface of the corpus callosum, but the anterior part, which does not descend so low, is separated from the corpus callosum by a part of the subarachnoid space. The base of the fold which slopes downward and blends with the upper surface of the tentorium cerebelli, contains the straight sinus running along the line of junction.

The **tentorium cerebelli** is a large transverse, semilunar fold, concave forward. It descends from its central part which is elevated, and consequently it forms a tent-shaped covering. Its superior surface is in relation with the tentorial surfaces of the hemispheres, and its inferior surface conforms accurately to the superior surface of the cerebellum. The outer or convex border of the fold is attached on each side to the posterior clinoid process, the superior border of the petrous portion of the temporal bone, the mastoid portion of the temporal bone, the posterior inferior angle of the parietal bone, and the horizontal ridge of the occipital bone. The transverse sinus lies in this border. From the internal occipital protuberance to the mastoid portion of the temporal bone and along the petrous part of the temporal bone it encloses the superior petrosal sinus.

The greater part of the inner or anterior border of the tentorium is free, and it forms the superior and lateral boundaries of an arched cavity, the **tentorial notch** or foramen ovale of Pacchioni, which encloses the mesencephalon, and through which ascend the cerebral peduncles and the posterior cerebral arteries. The anterior extremities of the inner border cross the outer border, and they are attached to the anterior clinoid processes. A depressed angle is formed between

Fig. 721.—Showing the Upper Surface of the Tentorium Cerebelli and the Tentorial Notch through which the Mid-brain and Posterior Cerebral Arteries enter the Middle Fossa of the Cranium.



the inner and outer borders of the tentorium in the middle fossa of the skull at the lateral portion of the posterior clinoid process, and in this angle the root of the oculo-motor nerve pierces the inner layer of the dura mater.

The **falx cerebelli** is a small, sickle-shaped, triangular fold which projects forward into the small groove (*posterior cerebellar notch*), between the hemispheres of the cerebellum. Its base is attached to the tentorium; its postero-inferior border, along which runs the occipital sinus, is attached to the internal occipital crest. Its anterior border is free, and its apex, which lies immediately above the foramen magnum, usually bifurcates as it disappears anteriorly, grasping the foramen magnum from behind. Bifurcation is always the case when the internal occipital crest splits below to enclose a vermiform fossa.

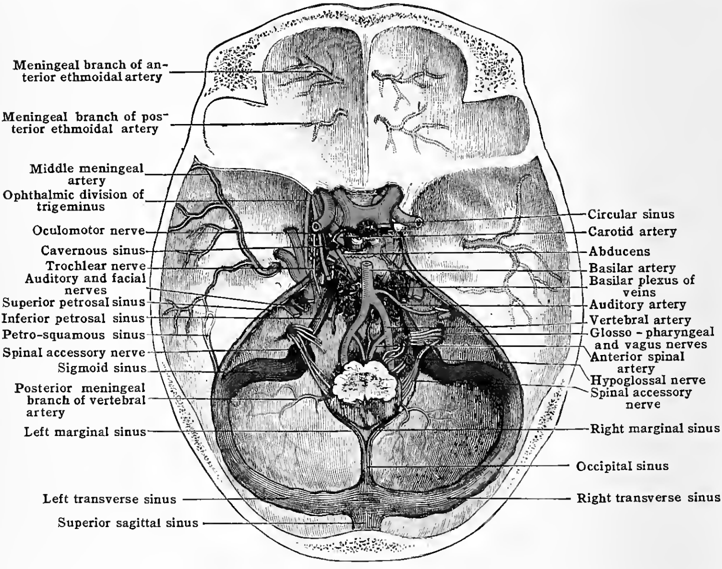
The **diaphragma sellæ** is a small circular fold, deficient in the centre, which projects horizontally from the margins of the hypophyseal fossa or sella turcica. Its lateral border is attached to the clinoid processes and the limbus of the sphenoid, and its medial border forms the boundary of the *foramen of the diaphragma sellæ* and surrounds the infundibulum. Its superior surface is in relation with the base of the brain, and its inferior surface is in relation with the hypophysis, which it binds down in the hypophyseal fossa.

The spaces which lie between the layers of the cranial dura mater are Meckel's caves, the spaces which lodge the endolymphatic sacs, and the blood sinuses and lacunæ.

Meckel's caves are two cleft-like spaces or niches which lie, one on each side, in the trigeminal impression on the apex of the petrous portion of the temporal bone. Each space lodges the semilunar (Gasserian) ganglion and the trigeminus and masticator nerves of the corresponding side, and it communicates with the subdural space in the posterior fossa of the cranium by an oval opening, which lies above the superior border of the petrous portion of the temporal bone and inferior to the superior petrosal sinus.

FIG. 722.—SHOWING BLOOD-VESSELS OF CRANIAL DURA MATER AND CRANIAL NERVES IN THE BASE OF THE SKULL.

(On the left side the dura mater has been removed from the middle fossa.)



The space which contains the endolymphatic sac on each side lies behind the petrous portion of the temporal bone and communicates with the aquæductus vestibuli.

The venous sinuses and lacunæ.—The cranial blood sinuses have already been fully described in the account of the vascular system, and it is sufficient to note here that they are continuous, on the one hand, with the meningeal veins, and, on the other, with the veins outside the cranial walls. The vessels which establish communication between the blood sinuses and the extracranial veins are referred to collectively as **emissary veins.** They possibly help to maintain the regularity of the cranial circulation, and they have therefore a certain amount of practical importance.

The sinuses which are connected with the extracranial veins by emissary veins are the superior sagittal, the transverse (lateral), and the cavernous. Three or four emissary veins pass from the superior sagittal sinus:—one passes through the foramen cæcum and communicates with the veins of the roof of the nose, or, through the nasal bones, with the angular veins. Two pass through the parietal foramina and establish communications with the occipital veins, and a fourth, which is very inconstant, pierces the occipital protuberance and joins the tributaries of the occipital veins. Connecting each lateral sinus with the extracranial veins there are, as a rule, two emissary veins:— one, the mastoid emissary vein, which passes through the mastoid foramen to the occipital or posterior auricular vein; and the other, the post-condyloid vein, which traverses the condyloid (posterior condyloid) foramen and joins the suboccipital plexus. The cavernous sinus is in communication anteriorly with the superior ophthalmic vein, and through the latter with the angular vein; it is connected with the pterygoid plexus by emissary veins which pass either through the foramen ovale or the foramen Vesalii, and with the pharyngeal plexus by small venous channels which accompany the internal carotid artery through the carotid canal.

The **venous lacunæ** or spaces are small clefts lined by endothelium which communicate with the meningeal veins and with the blood sinuses. They also have communications with the emissary veins and the diploic veins. They lie between the outer and inner layers of the dura mater, the majority of them at the sides of the superior sagittal sinus, but others are found in the tentorium associated with the transverse sinuses and the straight sinus.

Blood-vessels.—The blood supply of the cranial dura mater is derived from the **meningeal arteries,** which ramify in its outer layer. The more important of these arteries have already been described in the account of the vascular system, and it is only necessary here to recall the fact that the greater part of the dura mater above the tentorium cerebelli is supplied by branches of the middle meningeal arteries. These are reinforced—(1) at the vertex by branches of the occipital arteries which enter through the parietal foramina; (2) in the middle fossa by the small meningeal arteries and by meningeal branches of the internal carotid, lacrimal, and ascending pharyngeal arteries; and (3) in the anterior fossa by meningeal branches of the anterior and posterior ethmoidal arteries.

The dura mater in the posterior fossa of the skull, below the tentorium cerebelli, also receives branches from the middle meningeal arteries, but its blood supply is derived mainly—(1) from the meningeal branches of the vertebral arteries which enter the fossa through the foramen magnum, (2) from meningeal branches of the occipital arteries which enter through the mastoid and hypoglossal foramina, and (3) from meningeal branches of the occipital and ascending pharyngeal arteries which enter through the jugular and hypoglossal (anterior condyloid) foramina.

The **meningeal veins** accompany the arteries as *venæ comitantes,* usually one vein with each artery. The middle meningeal artery usually has two venæ comitantes. The meningeal veins communicate with the venous sinuses and with the diploic veins, and, unlike ordinary veins, they do not increase much in calibre as they approach their terminations.

The **nerves** of the dura mater are partly derived from the sympathetic filaments which accompany the arteries and partly from the cranial nerves. The nerves, other than sympathetic filaments, which supply the cranial dura mater are sensory fibres derived from the trigeminus and vagus nerves, and possibly from the first cervical nerves. The branches from the trigeminus are derived from the three divisions of that nerve on each side, and it has been stated that branches are given from the nasal branch of the ophthalmic division to the dura mater in the anterior fossa.

The meningeal branch of the ophthalmic division of the trigeminus supplies the tentorium; that from the maxillary division accompanies the branches of the middle meningeal artery. The meningeal branch of the mandibular division (nervus spinosus) passes into the skull through the foramen spinosum and is distributed to the dura mater over the great wing of the sphenoid and to the mastoid cells. The "*recurrent branch of the hypoglossal nerve*" passes to the dura mater of the posterior fossa of the cranium. This recurrent or meningeal branch of the hypoglossal nerve really consists of fibres derived from the superior cervical ganglion of the sympathetic, and contains sensory fibres from the first and second cervical nerves. The meningeal branch of the vagus springs from the ganglion of the root of that nerve, and is distributed in the posterior cranial fossa. The sympathetic filaments are distributed to the smooth muscle of the walls of the blood-vessels.

The cranial **subdural cavity** is not of uniform thickness throughout, being thinner along the basal aspect of the encephalon. The lymph contained in it is usually but little more than is sufficient to keep moist its bounding surfaces. It is continuous with the lymph capillaries of the nerves and those of all the tissues it bathes, and it is continuous with the similar cavity of the spinal canal. Its lymph is in free contact with the blood-vessels passing through it and with those in the tissues it bathes, and it is replenished by filtration through their walls. Though extensive, the subdural space is thin at best, for the dura mater is quite closely applied to the second of the three meninges.

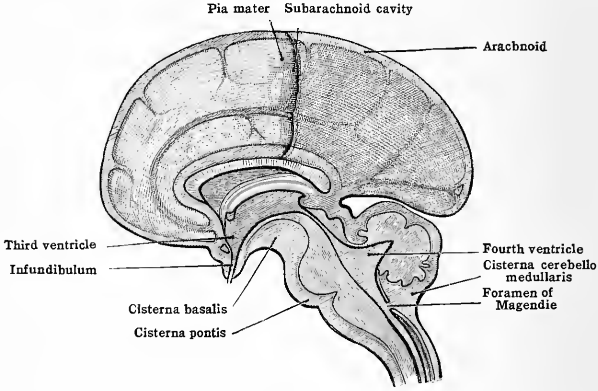
The Arachnoid

The arachnoid or 'serous' membrane is the middle of the three meninges of the central nervous system. As in the case of the other two, an attempt is made to give this membrane a name descriptive of its texture. It is a gauzy reticulum of almost web-like delicacy, which in reality pervades the space it occupies.

Its *outer surface,* or that closely related to the dura mater and bounding the subdural cavity alone shows a sufficiently organized structure to merit the name of membrane. This surface is covered by a layer of endothelium which is identical with that lining the inner surface of the dura mater and is continuous with it by way of the endothelial cells covering the blood-vessels, the nerve-roots, the ligamenta denticulata of the spinal cord, and the occasional delicate trabeculæ passing between the dura mater and the arachnoid. Immediately under the endothelium, the connective-tissue fibres of the arachnoid are woven into a very thin, more or less compact web. This, however, quickly grades into a loose, spongy reticulum which pervades the thick subarachnoid cavity throughout, and the strands of which are directly continuous into the more compact tissue of the pia mater. Thus an *inner surface* can hardly be claimed. This loose, sponge-like arachnoid tissue holds the cerebro-spinal fluid of the subarachnoid cavity, the meshes of the sponge constituting a reticular web of intercommunicating spaces lined by endothelioidal cells covering the strands of the web. The cranial subarachnoid cavity is larger, and the strands of the web are relatively more abundant than in that of the spinal canal. In addition, the cavity is traversed by the spinal and cranial nerves, by the blood-vessels passing to and from the pia, and, in the spinal canal distinctively, it is traversed by the ligamenta denticulata and the filum terminale. Through these the arachnoid is further continuous with the pia mater.

The cranial arachnoid is directly continuous into that of the spinal cord, and in the two localities does not differ as much as does the dura mater. Within the cranium, the arachnoid does not closely follow the surface of the encephalon. It is folded in between the cerebellum and cerebral hemispheres, following the contour of the tentorium cerebelli, but it does not dip into the fissures and sulci except the anterior part of the longitudinal fissure and slightly into the lateral (Sylvian) fissure. Otherwise it fills in the inequalities of surface of the encephalon, its outer surface forming a sheet enveloping the whole and bridging over the sulci and the deeper grooves between the gross divisions. Upon the summits of the gyri it is more closely applied to the pia mater, and there its reticulum becomes so dense

Fig. 723.—Diagram showing the Relations of the Pia Mater, the Arachnoid, and the Subarachnoid Cavity to the Brain.



that the two membranes almost appear as one. The sulci, occupied by looser reticulum, form a continuous system of channels filled more abundantly by the cerebro-spinal fluid.

The arachnoid folds in between the cerebellum and medulla oblongata, and at the base of the brain it ensheathes the olfactory bulbs and tracts, and its outer surface forms a continuous sheet stretching from one temporal lobe to the other and bridging over the interpeduncular fossa and the inequalities of surface in the region of the optic chiasma and the stems of the lateral fissures. Obviously, therefore, the subarachnoid cavity between its outer surface and the pia mater is of considerable depth in certain localities. These localities comprise the *subarachnoid cisternæ.* These occur where the cavity at the base of the brain is especially large, and make possible a 'water-bed' which serves to protect the brain from injurious contact with the bones.

The following cisternæ are distinguished (fig. 723):—

(1) **The cisterna basalis** lies at the base of the cerebrum and is divided by the optic chiasma into two parts—(*a*) the *cisterna chiasmatis* and (*b*) the *cisterna interpeduncularis.*

(2) **The cisterna pontis** is situated about the pons, especially in its basilar sulcus and the

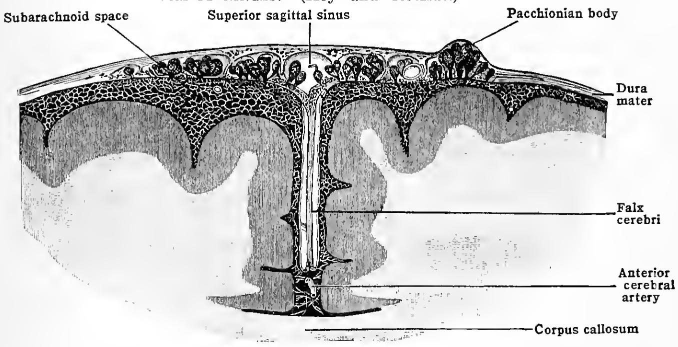
transverse fissures of either border, and is continuous anteriorly with the cisterna basalis and posteriorly with the subarachnoid cavity about the medulla.

(3) **The cisterna superior** lies in the angle between the splenium of the corpus callosum and the superior surfaces of the cerebellum and the mesencephalon, and is connected ventrally, around the cerebral peduncles, with the cisterna basalis.

(4) **The cisterna cerebello-medullaris** (cisterna magna) is the cavity between the inferior surface of the cerebellum and the dorsal surface of the medulla oblongata. It is continuous below into the spinal subarachnoid space. The fluid in this cavity is directly continuous with that in the fourth ventricle by way of the foramen of Magendie (median aperture of the fourth ventricle).

Pacchionian bodies [granulationes arachnoideales] (fig. 724.)—In certain situations, more particularly along the margins of the longitudinal fissure, particularly in the frontal region, and to a much less extent upon the superior surface of the vermis of the cerebellum, the subarachnoid tissue elaborates numerous small, ovoid or spherical nodules, the Pacchionian bodies. Each body or arachnoid villus consists of a retiform network of subarachnoid substance and its meshes are filled with cerebro-spinal fluid. The Pacchionian bodies on the vertex of the brain project through the inner layer of the dura mater, both into the superior sagittal sinus and into the venous spaces or **parasinoidal sinuses** which lie at the sides of that sinus, and, as they become larger, they press against the outer layer of the dura mater and produce ovoid depressions in the inner plate of the cranium.

Fig. 724.—Coronal Section transverse to the Great Longitudinal Fissure, Showing the Meninges. (Key and Retzius.)



They probably facilitate the passage of lymph from the subarachnoid cavity into the blood sinuses, and thus may aid in relieving pressure within. On the other hand, through them the cerebro-spinal fluid is replenished at need from the blood plasma. They are not present at birth, but they appear at the tenth year and increase in number and size with advancing age. They are less marked in the female than in the male.

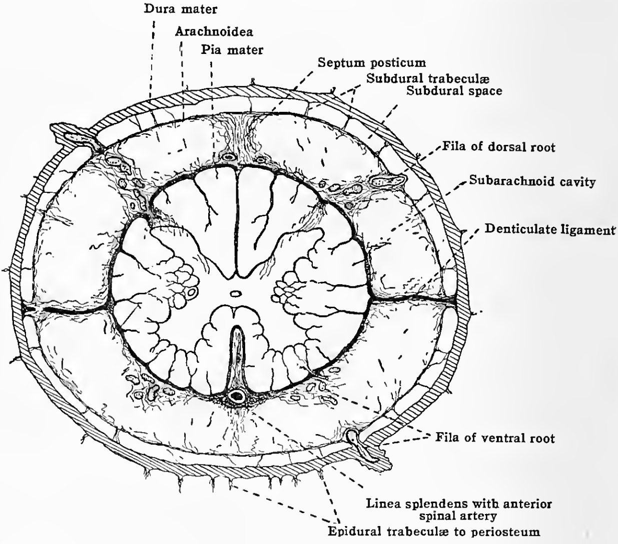
The spinal arachnoid (figs. 725, 726) is a loose, reticular sac which is most capacious about the lumbar enlargement of the spinal cord and about the cauda equina. Like that of the encephalon, the portion next to the dura mater alone resembles a membrane, being a loosely organized feltwork, covered on the side of the subdural cavity by a layer of endothelium common to that cavity. Throughout its length the spinal subarachnoid cavity is relatively wide, and, as in the cranium, contains a fine, spongy, web-like reticulum, numerous threads of which are continuous with the pia mater. This spongy tissue is the inner modification of the arachnoid, and its meshes are occupied by the cerebro-spinal fluid. It is not so abundant as in the cranial subarachnoid cavity.

In addition to the delicate threads, the arachnoid is more firmly attached to the pia mater by three incomplete partitions. The most continuous of these is arranged along the dorsal mid-line and is known as the **septum posticum of Schwalbe** (subarachnoid septum). This may be described as a linear accumulation of the spongy tissue which pervades the subarachnoid space. It is most incomplete in the upper cervical region, where it becomes merely a line of threads connecting with the pia. It is most complete as a septum in the lower cervical and in the thoracic region, but at best it maintains a spongy character. The other two partitions are formed by the **denticulate ligaments**, which extend laterally from either side of the spinal cord, connecting the pia and dura mater and involving the arachnoid in passing through it. Within the subarachnoid cavity these form more or less complete septa, though outside the arachnoid they are attached to the dura only at the intervals of their pointed dentations. They belong to the pia mater and will be described with it. The arachnoid is further continuous with the pia by way of the connective-tissue sheaths of the roots of the spinal nerves and the blood-vessels passing through the subarachnoid cavity.

Vessels and nerves.—The arachnoid has no special blood supply and probably no special nerves other than those supplying the walls of the blood-vessels passing through it.

The cerebro-spinal fluid.—The subarachnoid cavity is the great lymph-space of the central nervous system. That of the spinal region is directly continuous into that of the cranium, and the fluid contained communicates freely with that in the ventricles of the brain and the central canal of the medulla and spinal cord by way of the foramen of Magendie or medial aperture into the fourth ventricle. In addition, there are the lateral apertures into the fourth ventricle and there is possible an interchange of fluid between the lateral ventricle and the subarachnoid cavity of the base of the brain by diffusion through the thin floor of the chorioid fissure. The arachnoid throughout is not a membrane sufficiently compact to seriously oppose diffusion between the fluid contained in its cavity and that contained in the subdural cavity, and the endothelium covering it probably even facilitates such activities. The cerebro-spinal fluid occupying the cavities is a transparent fluid of a slight yellow tinge, characteristic of the

FIG. 725.—DIAGRAM OF TRANSVERSE SECTION OF UPPER THORACIC REGION OF THE SPINAL CORD SHOWING THE RELATIONS OF THE SPINAL MENINGES AND THEIR CAVITIES.



lymph in other lymph-spaces of the body. It is not very great in amount, probably never exceeding 200 c.c. in normal conditions. It is greatest in amount in old age, when the cavities are larger, due to atrophy and shrinkage of the nervous tissues. It collects from the lymph spaces in the meninges, and from exudation through the walls of the vascular chorioid plexuses and sinuses of the system it bathes. Its amount may be temporarily increased by a period of increased blood-pressure in the cranial vessels. Pressure due to its abundance may be relieved by diffusion through the membranes containing it, and especially through the villi of the Pacchionian bodies into the venous sinuses and lacunæ and thence into the venous system through the internal jugular veins.

THE PIA MATER

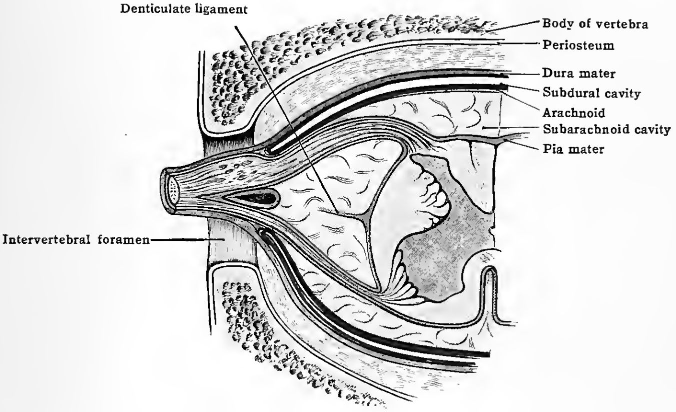
The **pia mater,** the third of the meninges, is a thin membrane which envelopes and closely adheres to the entire central nervous system and sends numerous processes into its substance. It likewise contributes the most proximal and compact portion of the sheaths worn by the nerve-roots in their passage through the meningeal spaces. It is very vascular in that the superficial plexuses of blood-vessels of both the brain and spinal cord ramify in it as they give off the central branches into the nervous substance. The structure and arrangement of the membrane vary somewhat in the cranial and spinal regions.

The spinal pia mater consists of two layers, an inner and an outer. It is thicker and more compact than that of the encephalon, due to the extra development of its outer layer, which is in the form of a strong, fibrous layer with the fibres arranged for the most part longitudinally.

The spinal pia mater also appears less vascular than the cranial from the fact that the blood-vessels composing the plexus lying in it are obviously much smaller than those of the encephalon. Its inner layer is a thin feltwork of fibres which is closely adherent to the surface of the spinal cord throughout, sending numerous connective-tissue processes into it which contributes to the support of the nervous tissues. The larger of these processes carry with them the numerous intrinsic blood-vessels from the superficial plexus. The two layers are closely connected with each other, and are distinguished by the difference in the arrangement of their fibres.

The membrane dips into the anterior median fissure and bridges it over by forming an extra thickening along it. This thickening appears as a band along the mid-line of the ventral surface of the cord, the **linea splendens** (fig. 717). It carries, or ensheathes, the anterior spinal artery, the largest of the arterial trunks of the superficial plexus (fig. 725).

Fig. 726.—Diagram showing Relations of Meninges to Spinal Nerve-roots.



The pia mater contributes the innermost and most compact portion of the epineurium of each of the nerve-roots, and thus, upon the roots, it is prolonged laterally into the intervertebral foramina, where the dura mater blends with it in producing the increased thickness of the epineurium.

From each side of the cord the pia mater gives off a leaf-like fold, the **denticulate ligament,** which spreads laterally toward the dura mater midway between the lines of attachment of the dorsal and ventral nerve-roots. The outer border of this fold is dentate or scalloped into about twenty-one pointed processes, which extend through the arachnoid and are attached to the inner surface of the dura mater. The dentations are usually inserted between the levels of exit of the roots of the spinal nerves, the uppermost one a little cephalad to the first cervical nerve and the region where the vertebral artery perforates the dura mater; the most caudal one between the last thoracic and first lumbar nerves, or, between the last two thoracic nerves. The ligaments, aided slightly by the septum posticum, serve to hold the spinal cord more or less suspended in the subarachnoid cavity.

Below, at the sudden, conical termination of the spinal cord in the lumbar portion of the spinal canal, the pia mater is spun out into a thin, tubular filament, the **filum terminale,** which continues caudalward into the sac formed by the dura mater about the cauda equina, and at the end fuses with the dura mater in line with the filum of the spinal dura mater (coccygeal ligament) of the outside (figs. 613, 715).

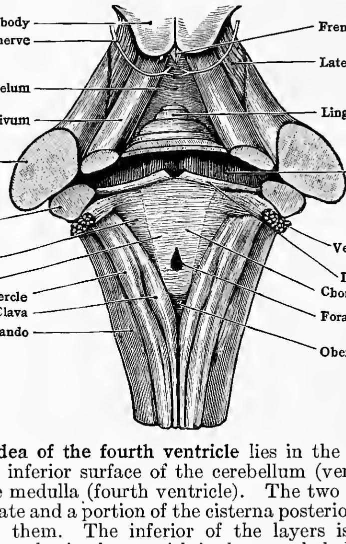
The cranial pia mater is closely applied to the external surface of the brain, dipping into all the fissures, furrows, and sulci. It is connected with the arachnoid by numerous filaments of the spongy subarachnoid tissue and by the blood-vessels traversing the subarachnoid cavity. It is also pierced by the cranial nerves, and furnishes them their sheaths, which become continuous with the arachnoid and dura mater.

Its *outer surface* bounds the subarachnoid cavity. It is with difficulty separable into two layers of mixed white fibrous and elastic connective tissue, with slightly pigmented connective-tissue cells enmeshed between them. Its *inner surface* sends a large number of fibrous processes into the nervous substance, which blend with the neuroglia and aid in the support of the nervous elements. The larger of these processes accompany the central arterial and venous branches of the rich superficial plexuses of blood-vessels contained in the pia on the surface of the brain. Pieces of the pia when pulled off and placed in water present a flocculent appearance as to their inner surfaces, due to these processes having been pulled out.

The cranial pia mater sends strong, vascular duplications into two of the great fissures of the encephalon; viz., the *transverse cerebellar fissure*, between the cerebellum and the medulla oblongata, and the *transverse* cerebral fissure, between the cerebellum, mesencephalon, and thalamencephalon, and the overhanging cerebral hemispheres. These duplications are spread over the cavities of the fourth and third ventricles, and are known as the *chorioid telæ* of these ventricles respectively.

Fig. 727.—Diagram showing Chorioid Tela of Fourth Ventricle after Removal of Cerebellum.

(The trochlear nerve should be shown emerging from the frenulum veli.)



The tela chorioidea of the fourth ventricle lies in the transverse cerebellar fissure, between the inferior surface of the cerebellum (vermis chiefly) and the dorsal surface of the medulla (fourth ventricle). The two layers of this fold of the pia remain separate and a portion of the cisterna posterior of the subarachnoid cavity lies between them. The inferior of the layers is the tela chorioidea (fig. 727.) It is triangular in shape, with its base cephalad at the nodule of the vermis and its apex below at the level of the tuber vermis. The superior layer of the fold is the pia mater of the vermis. The tela chorioidea is strengthened by the epithelial roof (ependyma) of the fourth ventricle and is continuous with the pia mater of the medulla oblongata and spinal cord. In roofing over the fourth ventricle the tela chorioidea of the fourth ventricle constitutes the ligula and the obex. A little above the calamus scriptorius it is pierced by the foramen of Magendie and the two lateral apertures into the fourth ventricle.

In front of the foramen of Magendie the vessels of the chorioid tela, which are derived from the posterior inferior cerebellar arteries, form two longitudinal, lobulated strands which invaginate the epithelial roof of the ventricle, one on either side of the mid-line, and project into its cavity. These form the **chorioid**

plexus of the fourth ventricle. At the base of the tela the two chorioid plexuses join each other and then turn transversely lateralward into the lateral recesses of the ventricle, where they pass behind the restiform bodies and form the '*cornucopiæ.*'

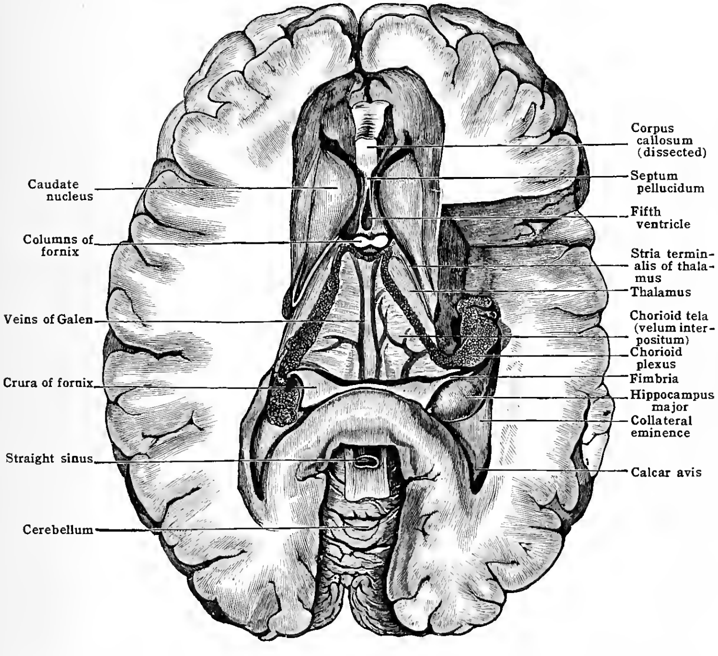
The chorioid tela of the third ventricle, or **velum interpositum,** is a triangular duplication of the pia mater which extends between the fornix above and the thalami and third ventricle below, and in front fuses with the brain substance at the interventricular foramina.

In the transverse cerebral fissure the layers of pia forming this tela are separate, the upper being the pia of the under surface of the corpus callosum and continuous with that of the tentorial surfaces of the occipital lobes; the lower being continuous into the pia enfolding the epiphysis, and covering the mesencephalon, anterior medullary velum, and cerebellum. The layers forming the portion of the duplication which roofs over the third ventricle are loosely adherent to each other and form the tela chorioidea proper of that ventricle. The upper surface of this portion is in relation with the fornix and its lower surface, covered by the epithelial chorioid lamina, lies laterally over the superior surfaces of both thalami, and mesially forms the roof of the third ventricle between them. The epithelium or ependyma is continuous with that covering the thalami and lining the ventricles. Between the two layers of this portion, and embedded in a small amount of the spongy subarachnoid tissue retained between them, are the two veins of Galen, the internal cerebral veins. Posteriorly these veins unite in the region of the epiphysis to form the single great cerebral vein (*vena cerebri magna*) which empties into the straight sinus. Anteriorly the veins of Galen receive the veins of the septum pellucidum from each lamina of the septum pellucidum above, and also the terminal vein (vein of corpus striatum), lying in the stria terminalis of the thalamus, empties into them from each side.

Fig. 728.—Horizontal Dissection of the Cerebrum showing the Tela Chorioidea of the Third Ventricle.

(From a mounted specimen in the Anatomical Department of Trinity College, Dublin.)

The fornix has been removed to show the chorioid tela of the third ventricle.

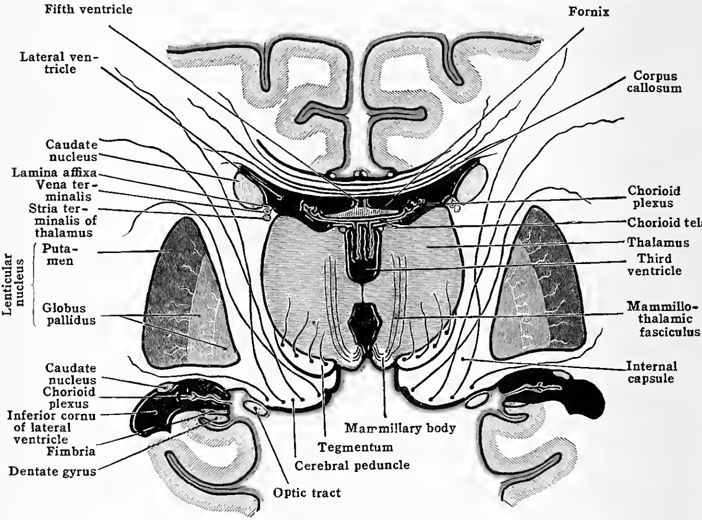


The chorioid tela of the third ventricle or velum interpositum extends laterally between the fornix and fimbria above and the stria terminalis of the thalamus below into each lateral ventricle. The blood-vessels of the border projecting into the lateral ventricle are amplified into a plexus which appears as a strip of reddish, lobulated, villus-like processes known as the **chorioid plexus of the lateral ventricle.** The plexus, being in the border of the tela, begins at the interventricular foramen, extends through the body or central portion of the ventricle, and downward into its inferior cornu. It is most developed at the junction of the body with the inferior cornu, and is there known as the **glomus chorioideum.**

From the under surface of the chorioid tela of the third ventricle, hanging down on either side of the mid-line into the cavity of the ventricle, are two other longitudinal, lobulated strands of blood-vessels which are the **chorioid plexuses of the third ventricle.** At the anterior end of the third ventricle these two plexuses join with each other and also with the plexus of the lateral ventricle of each side through the interventricular foramina.

The chorioid plexuses of both the ventricles are covered by a layer of ependyma, *epithelial chorioid lamina,* which is but a reflexion of the ependyma lining the cavities throughout and represents the remains of the germinal layer of the embryonic brain vesicles. The blood-vessels

FIG. 729.—DIAGRAM OF CORONAL SECTION OF CEREBRUM THROUGH MIDDLE OF THALAMENCEPHALON SHOWING RELATIONS OF PIA MATER ENCEPHALI AND CHORIOID PLEXUSES OF THIRD AND LATERAL VENTRICLES.



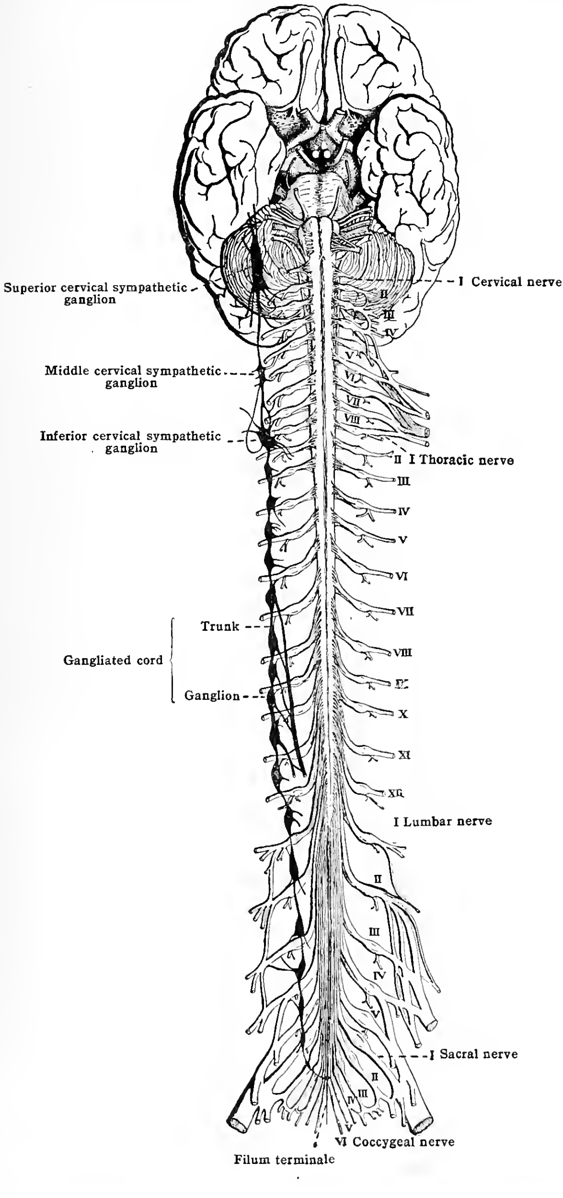
of the chorioid plexus of the lateral ventricle receive blood by the chorioid artery (a direct branch of the internal carotid), which enters the plexus through the chorioid fissure immediately mesial to the uncus, and also by the chorioidal branches of the posterior cerebral artery, which supply the plexus of the body of the ventricle. The chorioid plexuses of the third ventricle receive blood chiefly by branches from the superior cerebellar arteries. The greater part of the blood of both plexuses passes out by way of the tortuous chorioid veins, which, at the interventricular foramen, empty into the venæ terminales (veins of the corpus striatum), which, in their turn, go to form the greater part of the veins of Galen. Thence the blood passes by way of the vena cerebri magna into the straight sinus. It is probable that a large part of the cerebro-spinal fluid of the third and lateral ventricles is derived by diffusion through the walls of the vessels of the chorioid plexuses.

THE PERIPHERAL NERVOUS SYSTEM

The intimate connection and consequent control exercised by the central nervous system over all the tissues and organs of the body is attained through the

FIG. 730.—SHOWING THE RELATION BETWEEN THE CENTRAL AND THE PERIPHERAL NERVOUS SYSTEMS.

(Combination drawing, spinal part after Allen Thompson, from Rauber.)



peripheral nervous system. This system, abundantly attached to the central system, consists of numerous bundles of nerve-fibres which divide and ramify throughout the body, anastomosing with each other and forming various plexuses, large and small. The terminal rami divide and subdivide until the divisions attain the individual nerve-fibres of which they are composed, and finally the nerve-fibres themselves divide and terminate in relations with their allotted peripheral elements. It is by means of this system that stimuli arising in the peripheral tissues are conveyed to the central system, and that impulses in response are borne from the central system to the peripheral organs. For purposes of description, as well as upon the basis of certain differences in structure, arrangement, and distribution, the peripheral nervous system is separated into two main divisions:—(1) **the cranio-spinal** and (2) **the sympathetic system.**

Both of these divisions include numerous ganglia or peripheral groups of nerve-cells from which arise a considerable proportion of the fibres forming their nerve-trunks, but neither of the divisions may be considered wholly apart from the central system nor are they independent or separate from each other. The sensory or afferent fibres of the cranio-spinal nerves pass by way of the afferent nerve-roots into the central system and contribute appreciably to its bulk, and the motor or efferent fibres of these nerves have their cells of origin (nuclei) situated within the confines of the central system. The sympathetic system is intimately associated with the cranio-spinal, and consequently with the central system—(1) by means of fibres which enter and terminate in the cranio-spinal ganglia and transfer impulses which enter the central system; (2) by efferent fibres of central origin which course in the nerve-trunks and terminate in the ganglia of the sympathetic system; (3) also, the sympathetic trunks usually contain numerous afferent cranio-spinal fibres which thus course to their peripheral termination, usually in the so-called 'splanchnic area,' or domain of the sympathetic, in company with the sympathetic fibres. Likewise the peripheral branches of the cranio-spinal nerves often carry for varying distances numerous sympathetic fibres which are on their way to terminate either in other sympathetic ganglia or upon their allotted peripheral tissue-elements.

The following differences between the cranio-spinal and sympathetic systems of nerves may be cited:—(1) The cranio-spinal nerves are anatomically continuous with the brain and spinal-cord; probably no fibres arising in the sympathetic ganglia actually enter the central system other than for the innervation of its blood-vessels. (2) The ganglia of the cranio-spinal nerves all lie quite near the central axis, in line on either side of it, and at more or less regular intervals; the sympathetic ganglia are scattered throughout the body tissues, are far more numerous and more variable in size, and probably only the larger of them are symmetrical for the two sides of the body. (3) The cranio-spinal nerves are paired throughout, and the nerves of each pair are symmetrical as to their origin and also, with certain exceptions (notably the vagus), in their course and distribution; most of the larger and more proximal of the sympathetic nerve-trunks are symmetrical for the two sides of the body; many of them are not, and many of the smaller and most of the more peripheral nerves and ganglia, large and small, are not paired at all. (4) Even in their finer twigs, the cranio-spinal nerves of the two sides probably do not anastomose with each other across the mid-line of the body; the sympathetic nerves do so abundantly, especially within the body cavity. (5) The cranio-spinal nerves are distributed to the ordinary sensory surfaces of the body and the organs of special sense and to the somatic, striated or 'voluntary' muscles of the body; the sympathetic fibres are devoted chiefly to the supply of the so-called involuntary muscles of the body, including the smooth muscle in the walls of the viscera and in the walls of the blood and lymph vascular-systems, while others serve as secretory fibres to the glands. (6) Cranio-spinal nerve-fibres are characterized in general by well-developed medullary sheaths, making the nerves appear as white strands; most of the sympathetic fibres are non-medullated, some are completely and some partially medullated, but none possess as thick medullary sheaths as those of the cranio-spinal nerves. Thus sympathetic nerves appear as grey strands.

The cranio-spinal nerves.—There are forty-six pairs of cranio-spinal nerves, of which thirty-one pairs are attached to the spinal cord (spinal nerves) and fifteen pairs to the encephalon (cranial nerves). The spinal nerves are the more primitive and retain the typical character, i. e., each is attached to the spinal cord by two roots, a dorsal or sensory ganglionated root, and a ventral, which is motor, and thus not ganglionated. Most of the cranial nerves have only one root, which in come cases corresponds to a dorsal root and therefore has a ganglion, and in other cases corresponds, physiologically at least, to a ventral root of a spinal nerve. Among other differences, the fibres of the first cranial nerve, for example, do not collect to form a distinct nerve-trunk.

I. THE CRANIAL NERVES

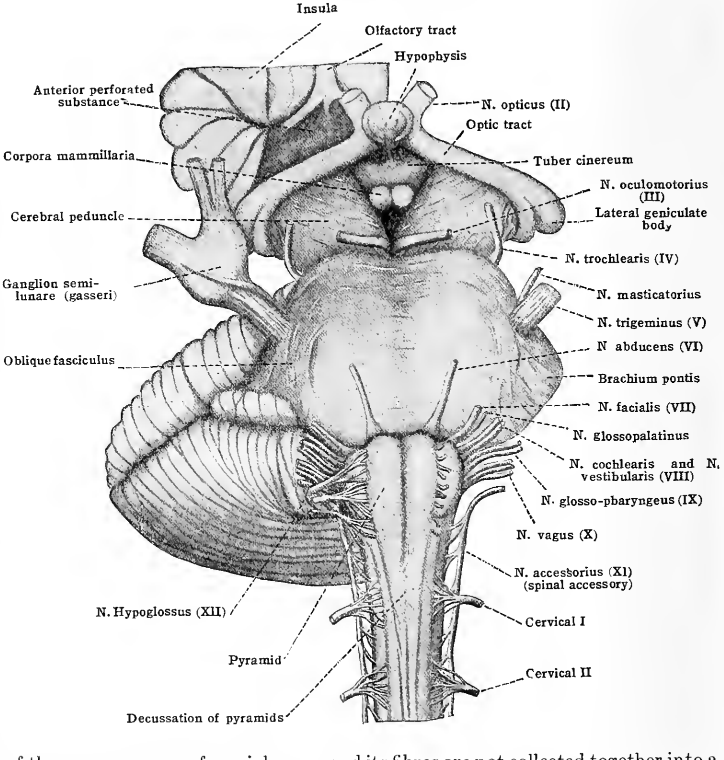
Customarily, the cranial nerves are described as comprising twelve pairs and each is referred to by number. However, present knowledge of their origin, central connections and peripheral distribution suggests that those enumerated as the fifth, seventh, and eighth pairs under the old nomenclature are better each separated into its two component nerves, each of which merits a separate description and a separate name. None of the cranial nerves corresponds closely to a typical spinal nerve with its motor and sensory root. The so-called motor portion of the fifth is no more its motor root than is the seventh nerve. The sensory portion of the seventh is not wholly sensory and rather resembles the ninth pair in distribution, and it has long been commonly referred to as a separate nerve. The two parts of the eighth nerve, both sensory, are known to be wholly different in functional character and are so named. Further, the names of the nerves, descriptive of their function, are pedagogically much more efficient than the use of numbers in referring to them.

Separating the three pairs mentioned, each into its two nerves, gives fifteen pairs instead of twelve. Their names and functional nature are given in the following table. The Roman numerals given in parentheses correspond to the serial numbers given when twelve pairs only are considered. It is also customary to enumerate the cranial nerves from in front backward and caudalward, and this custom is followed here, but again it would be pedagogically better to take them in the reverse order. Then each in its turn could be directly considered as in continuous series with the spinal nerves below and the similarities to and progressive modifications from the spinal type could be better realized. It will be remembered that *somatic motor* or *efferent* fibres are those which terminate directly upon the fibres of skeletal muscle while *visceral* motor fibres transfer their impulses to sympathetic neurones, and the axones of the latter terminate upon gland cells and upon the fibres of cardiac and smooth muscle.

Name	Nature	General Distribution
Olfactory (I)	Sensory	Olfactory region, nasal epithelium.
Optic (II)	Sensory	Retina.
Oculomotor (III)	Motor: Somatic	Eye-moving muscles.
	Motor: Visceral	Ciliary body, iris.
Trochlear (IV)	Motor-somatic	Eye-moving muscles.
Abducens (VI)	Motor-somatic	Eye-moving muscles.
Trigeminus (V)	Sensory	Face, mouth, and scalp.
Masticator (*minor part or motor root of trigeminus*).	Motor-somatic	Muscles of mastication.
Facial (VII)	Motor: Somatic	Facial muscles.
	Motor: Visceral (?)	Salivary glands, vessels(?).
Glossopalatine. (*Intermediate part of facial*).	Sensory	Tongue, palate.
	Motor-visceral	Salivary glands.
Cochlear (*auditory*) (VIII)	Sensory	Internal ear.
Vestibular (*equilibrator*) (VIII).	Sensory	Semicircular canals, utriculus, sacculus.
Glossopharyngeal (IX)	Sensory	Tongue, palate, pharynx.
	Motor: Somatic	Pharynx.
	Motor: Visceral	Glands and vessels.
Vagus (X)	Sensory	Alimentary canal, lung, heart.
	Motor: Somatic	Larynx, pharynx.
	Motor: Visceral	Alimentary canal, heart, larynx, trachea, lung.
Hypoglossal (XII)	Motor-somatic	Tongue-moving muscles.
Spinal acessory (XI)	Motor: Somatic	Neck and shoulder muscles.
	Motor: Visceral	Pharynx, larynx, heart.

The cranial nerves, like the spinal nerves, are developed from cells of the primitive neural tube and, beginning with the fifth pair downward, all the sensory nerves are developed from the cells corresponding to those of the ganglion crest which give origin to the spinal ganglia with the sensory components or dorsal roots of the spinal nerves. Otherwise between the cranial nerves and the spinal nerves there are many important differences. Each spinal nerve has a dorsal or sensory root, which springs from the cells of a spinal ganglion; a ventral or motor root, whose fibres are processes of the nerve-cells which are situated in the walls of the central system, and at their attachment to the surface of the cord the two roots are some distance apart. Only one of the (usually considered) twelve pairs of cranial nerves corresponds at all closely with typical spinal nerves. This one is the trigeminus which possesses a sensory ganglionated root and near its attachment is accompanied by a small motor nerve, the masticator, which serves in very small part as a corresponding motor root of the trigeminus. But even in this case where the similarity between the cranial and spinal nerves is greatest, there are still points of anatomical difference, which if not essential are very obvious, for the so-called motor root joins not the whole but only with one branch of the sensory portion. The two are only slightly separated from each other at their attachment to the surface of the brain. All the other cranial nerves differ in a still more marked manner from typical spinal nerves. The first nerve is an afferent nerve whose cells of origin (olfactory ganglion) are scattered in the mucous membrane

Fig. 731.—Surface Attachment of the Cranial Nerves. (After Allen Thomson, modified.)



of the nose, an organ of special sense, and its fibres are not collected together into a nerve-trunk, but pass, as a number of small bundles, through the lamina cribrosa of the ethmoid bone directly into the olfactory bulb. The optic nerve is also a nerve of special sense. Its fibres form a very distinct bundle, similar in appearance to an ordinary nerve, from which, however, it differs essentially, both with regard to structure and development; for, unlike an ordinary nerve, its connective tissue consists to a large extent of neuroglia instead of ordinary connective tissue, and its component nerve-fibres are of much smaller calibre than those of an ordinary nerve. It represents the location of the original optic stalk, a diverticulum from the neural tube and it associates the retina (optic cup), a bit of modified cortex, with the encephalon. The optic nerve, therefore, corresponds more closely with an association tract of the central system than with an ordinary nerve.

The oculomotor, trochlear, abducens and hypoglossal nerves are purely motor nerves, and thus correspond only with the ventral roots of spinal nerves. The spinal accessory is also purely motor. Its fibres arise from the cells of the anterior horn of the spinal cord and from a nucleus of the medulla which represents a displaced portion of that horn, but they do not leave the surface of the spinal cord and brain in the usual situation of ventral roots. On the contrary, they emerge in a series of rootlets from the lateral funiculus of the cord on the dorsal side of the ligamentum denticulatum, and from the upward prolongation of this funiculus.

The cochlear and vestibular are nerves of special sense, and in some respects both correspond closely with the dorsal root of a typical spinal nerve, and the ganglia of both represent spinal ganglia, but their distribution is limited to the membranous labyrinth.

The vagus and glosso-pharyngeal nerves contain both motor and sensory fibres, but they differ from typical spinal nerves in that the motor fibres, in company with the sensory, issue from the postero-lateral sulcus of the medulla, and they are intimately intermingled, from their origin, with the sensory fibres, which latter arise from ganglia interposed in the trunks of the nerves and otherwise correspond with the fibres of the dorsal root of a typical spinal nerve.

Superficial attachments and origins.—It is customary to speak of the area where the nerve-fibres leave or enter the brain substance as the superficial attachments of the cranial nerves, and the groups of cells from which the fibres spring, and about which they terminate, as their nuclei of origin or termination, respectively.

THE OLFACTORY NERVES

The **olfactory nerve-fibres** are the central processes of the bipolar olfactory nerve cell-bodies situated in the olfactory region of the nasal mucous membrane. In man, the olfactory region comprises the epithelium upon the superior third of the nasal septum and that upon practically the whole of the superior nasal concha. The area is relatively small as compared with that of other mammals and, as in other mammals, is characterized by an increased thickness of the epithelium and a yellowish brown colour in the fresh. The peripheral processes of the olfactory cell-bodies (the olfactory ganglion) are short and extend only to the surface of the olfactory epithelium. As the central processes pass upward from their cells of origin they form plexuses in the mucous membrane, and from the upper parts of these plexuses, immediately below the lamina cribrosa of the ethmoid, about twenty filaments issue on each side. These filaments comprise the **olfactory nerve.** They are non-medullated. They pass upward, through the foramina in the lamina cribrosa, into the anterior fossa of the cranium in two rows, and after piercing the dura mater, the arachnoid, and the pia mater, they enter the inferior surface of the olfactory bulb. They contribute to the superficial stratum of nerve-fibres on the inferior surface of the olfactory bulb and end in the **glomeruli,** which are formed by the terminal ramifications of the olfactory nerve-fibres intermingled with the similar ramifications of the main dendrites of the large mitral cells which lie in the deeper part of the grey substance of the olfactory bulb.

The olfactory nerve-fibres are grey fibres, since they do not possess medullary sheaths, and they are bound together into nerves by connective-tissue sheaths derived from the pia mater, from the subarachnoid tissue, and from the dura mater. Prolongations of the subarachnoid space pass outward along the nerves for a short distance.

Central connections.—The olfactory impulses are transmitted by way of the peripheral processes of the olfactory neurones through the cell-bodies and the olfactory nerve-fibres and through the glomeruli to the mitral cells. Thence they are carried by the central processes (axones) of the mitral cells, which pass backward along each olfactory tract and its three olfactory striæ (see Rhinencephalon, p. 864).

THE TERMINAL NERVE (*Nervus Terminalis*)

In lower vertebrates and recently in those mammals whose sense of smell is relatively much more developed than in man, three nerves have been found concerned with the olfactory apparatus:—(1) The olfactory nerve proper whose fibres, as noted above, are the central processes of the nerve cell-bodies situated in the epithelium of the olfactory region of the nasal mucosa, and which terminate in the olfactory bulb; (2) The vomero-nasal nerve, whose fibres are the central processes of nerve cell-bodies situated in the epithelium of the vomero-nasal (Jacobson's) organ and which pass caudalward in the submucosa and upward to join the filaments of the olfactory nerve proper and which, in the dog, cat, rabbit, rat, etc., terminate in the accessory olfactory bulb—a small protuberance possessed by these animals on the postero-median aspect of the olfactory bulb proper; (3) The terminal nerve, a small plexiform nerve, which unlike the other two, is ganglionated.

In man, the vomero-nasal (Jacobson's) organ is rudimentary after birth and, therefore, the vomero-nasal nerve is not present, the only fibres for the vomero-nasal region being those of general sensibility from the trigeminus and sympathetic fibres common to the epithelium of the entire nasal fossa.

The terminal nerve has been recently described as present in the human fœtus and it is mentioned here because of the expressed belief that it is present in the adult. From the observations recorded for human and rabbit fœtuses and the adult dog and cat, the following description may be given: It is variably plexiform throughout its course. Its peripheral twigs are distributed to the mucosa of the nasal septum, some to the mucosa joining the olfactory region while other and larger twigs extend further forward and are distributed to mucosa of the vomero-nasal organ, accompanying and sharing in the distribution of the vomero-nasal nerve when this is present. Its central connections are in the form of two or three small roots which pass through the cribriform plate of the ethmoid bone in company with and mesial to the vomero-nasal nerve and then, still plexiform, extend caudalward over the infero-mesial aspect of the olfactory bulb and upon the olfactory peduncle or stalk (olfactory tract) beyond, a root often extending to near the lamina terminalis and optic chiasma. The roots disappear in the mesial and infero-mesial aspect of the frontal portion of the brain at different localities caudal to the olfactory bulb and usually near the olfactory peduncle, but often one may disappear in the region corresponding to the anterior perforated substance of the adult human brain.

Numerous small groups of ganglion cells are found interposed along both the peripheral and intracranial course of the terminal nerve. A group, larger in size than the others and situated in the intracranial course of the nerve, is called the *ganglion terminale*. The fibres of the nerve are non-medullated. Both the ganglion cells and the fibres of the nerve are described as having more the appearances characteristic of sympathetic neurones than of cranio-spinal. On the other hand, our conceptions of sympathetic neurones do not permit of their terminating within the central system except for the innervation of its blood vessels. It may result that, instead of being an independent nerve as now claimed, the nervus terminalis is a part of the forward extension of the cephalic sympathetic, the larger ganglia and plexuses of which latter are well known, and that its neurones receive and convey impulses to the gland cells of the nasal mucosa and to the muscle of the blood-vessels of the mucosa and those supplying the infero-mesial part of the frontal end of the cerebrum.

THE OPTIC NERVES

The **fibres of the optic nerve** are the central processes of the ganglion cells of the retina. Within the ocular bulb they converge to the optic papilla, where they are accumulated into a rounded bundle, the **optic nerve.** The nerve thus formed pierces the chorioid and the sclerotic coats, and, at the back of the bulb, enters the orbital fat, in which it passes backward and medialward to the optic foramen. After traversing the foramen it enters the middle fossa of the cranium, and anastomoses with its fellow from the opposite side, forming the optic chiasma. It may, therefore, for descriptive purposes, be divided into four portions—the intra-ocular, the intra-orbital, the intra-osseous, and the intra-cranial. The total length of the nerve varies from forty-five to fifty millimetres.

The **intra-ocular part** is rather less than one millimetre in length. It passes backward from the optic papilla through the chorioid and through the sclerotic coats of the bulb. As it passes through the latter coat of the bulb in many separate bundles, the area it traverses has a cribriform appearance when the nerve is removed, and consequently is known as the *lamina cribrosa scleræ.*

The **intra-orbital part** of the nerve emerges from the sclerotic about three millimetres below and to the median side of the posterior pole of the bulbus, and it is about thirty millimetres long. It passes backward and medialward, surrounded by the posterior part of the fascia bulbi (Tenon's capsule) and by the orbital fat, to the optic foramen.

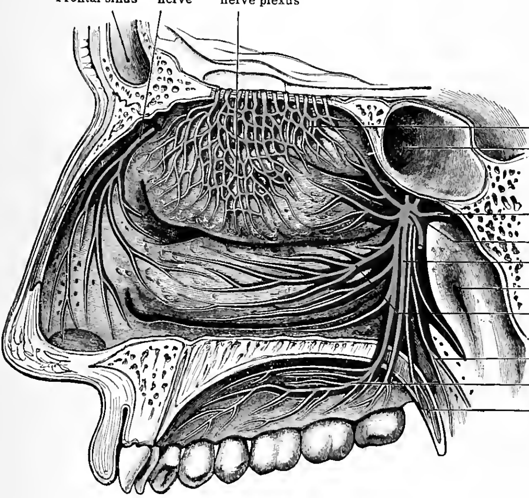
As it runs backward in the orbit it is in relation above with the naso-ciliary (nasal) nerve and the ophthalmic artery which pass obliquely from behind and laterally, forward and medialward across the junction of its posterior and middle thirds, and also in relation with the superior ophthalmic vein, the superior rectus muscle, and the upper branch of the oculo-motor nerve. Below it are the inferior rectus muscle, and the inferior division of the oculo-motor nerve. To its lateral side, near the posterior part of the orbit, are the ophthalmic artery, the ciliary ganglion, the abducens nerve, and the external rectus muscle. The anterior two-thirds of this portion of the optic nerve are surrounded by the ciliary arteries and the ciliary nerves and it is penetrated on its medial and lower aspect by the central artery of the retina. As it enters the optic foramen to become continuous with the intra-osseous part, it is in close relation with the ligaments of Lockwood and Zinn (annulus tendineus communis) and with the four recti muscles which arise from them.

The **intra-osseous portion** is from six to seven millimetres long. It lies between the roots of the small wing of the sphenoid and the body of that bone, and it is in relation below and laterally with the ophthalmic artery.

The **intra-cranial portion,** which is from ten to twelve millimetres long, runs backward and medialward, beneath the posterior end of the olfactory tract, and above the ophthalmic artery, the medial border of the internal carotid artery and the diaphragma sellæ to the chiasma. From the chiasma to the central connections of the nerve, the path is known as the optic tract.

Central connections.—The central connections of the fibres of the optic nerve have been considered with the optic chiasma and the optic tract (see p. 849).

Fig. 732.—Nerves of the Nasal Cavity.



The sheaths of the optic nerve.—The optic nerve receives a sheath from each of the membranes of the brain, and prolongations of the subdural and subarachnoid cavities also pass outward along it to the posterior part of the sclera.

THE OCULO-MOTOR NERVES

The oculo-motor or third cranial nerve is a purely motor nerve. Each supplies seven muscles connected with the eye, two of which, the sphincter of the iris and ciliary muscle, are within the ocular bulb. The remaining five are in the orbital cavity, and four of them—the superior, inferior, and medial recti and the inferior oblique—are attached to the bulb, while the fifth, the levator palpebræ superioris, is inserted into the upper eyelid.

The fibres of the oculo-motor nerve spring from their nucleus of origin situated in the grey substance of the floor of the cerebral aquæduct in the region of the superior quadrigeminate body (fig. 662). The cells of this nucleus are divided into two main groups, a superior and an inferior (fig. 663). The **superior group** includes two nuclei, a medial and a lateral. The latter, besides being lateral, is also somewhat dorsal to the former. The **inferior group** has been divided into five secondary nuclei, according to the eye-muscles the cells of each group innervate. Three of the five lie lateral to the others and somewhat dorsally, and of the remaining two, which are placed more medially, one encroaches upon the mid-line (*nucleus medialis*) and is continuous with the corresponding group of the opposite side and is common to the oculo-motor nerves of both sides.

It has been found, by the study of diseased conditions and by experiments with animals, that the centres of innervation of the eye-muscles supplied by the nerve correspond to the above divisions of both the superior and inferior group of cells into a medial and lateral series. The relative position of the divisions of each group and the muscles they are thought to innervate are shown in the following diagram devised by Starr:—

Mesial Plane.

SUPERIOR GROUP.	Sphincter of Iris.	Ciliary Muscle.	Ciliary Muscle.	Sphincter of Iris.
INFERIOR GROUP.	Levator Palpebræ Superioris.	Medial Rectus.	Medial Rectus.	Levator Palpebræ Superioris.
	Superior Rectus.	Inferior Rectus.	Inferior Rectus.	Superior Rectus.
	Inferior Oblique.			Inferior Oblique.

As they leave their nucleus of origin in the mid-brain, the fibres of the oculo-motor nerve form a series of fasciculi, which curve ventrally around and through the red nucleus and the medial part of the substantia nigra, to the oculo-motor sulcus on the medial surface of the cerebral peduncle, where they emerge in from six to fifteen small bundles which pierce the pia mater and collect into the trunk of the nerve. Immediately after its formation along the oculo-motor sulcus, the trunk of the nerve passes between the posterior cerebral and the superior cerebellar arteries, and, running downward, forward, and laterally in the posterior part of the cisterna basalis, it crosses the anterior part of the attached border of the tentorium cerebelli at the side of the dorsum sellæ, and, piercing the arachnoid and the inner layer of the dura mater, it enters the wall of the cavernous sinus about midway between the anterior and posterior clinoid processes. Immediately after its entry into the wall of the sinus it lies at a higher level than the trochlear nerve, but the latter soon crosses on its lateral side and gets above it, and directly afterward the oculo-motor nerve divides into a smaller superior and a larger inferior branch (fig. 734). Before its division **communications** join it from the cavernous plexus of the sympathetic about the internal carotid artery, and from the ophthalmic division of the trigeminus. Both branches proceed forward, and the nasal branch of the trigeminus, which has passed upward, on the lateral side of the inferior branch of the oculomotor lies between them. At the anterior end of the cavernous sinus the two branches pass through the superior orbital (sphenoidal) fissure, between the heads of the lateral rectus muscle, and enter the orbital cavity. In the orbit, the **superior branch** lies between the superior rectus and the optic nerve; it supplies the superior rectus and then turns round the medial border of that muscle and terminates in the levator palpebræ superioris. The **inferior branch** runs forward, beneath the optic nerve, and divides into three branches which supply the inferior and medial recti and the inferior oblique.

The branch to the inferior oblique muscle is connected with the ciliary ganglion by a short thick offset, the **short root of the ciliary ganglion,** by mediation of the sympathetic neurones of which the oculo-motor nerve sends impulses to the ciliary muscle and the sphincter muscle of the iris. The inferior branch also gives some small twigs to the inferior rectus. The branches of the oculo-motor nerve, which supply the recti muscles, enter the muscles on their ocular surfaces, but the branch to the inferior oblique muscle enters the posterior border of that muscle.

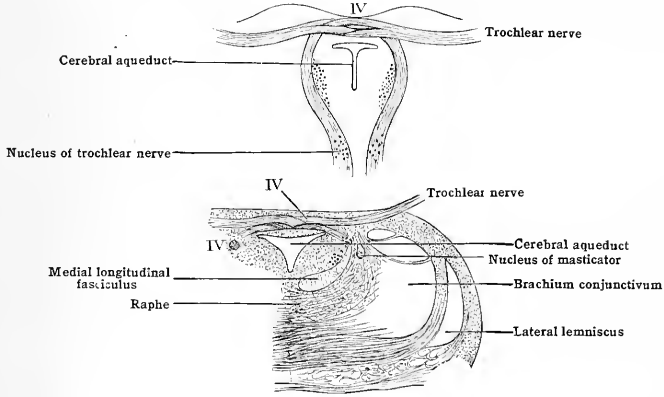
Some of the fibres which spring from the medial portion of the oculo-motor nucleus do not pass into the nerve of the same side, but into that of the opposite side, and it is believed that they are distributed to the opposite medial rectus muscle. Other fibres which arise from the nucleus descend in the medial longitudinal fasciculus and either terminate about the cells of the nucleus of the facial or join the facial nerve, in which they pass to the upper part of the orbicularis palpebrarum. The eye is opened by the oculo-motor and closed by the facial nerve.

Central connections.—The nucleus of the oculo-motor is associated with the middle portion of the anterior central gyrus, the posterior end of the middle frontal gyrus and with the cortex about the visual area of the occipital lobe of the opposite side of the brain by the pyramidal fibres. It is probably associated with the cerebellum by the fibres in the superior cerebellar peduncles, with the superior calliculus, and with the sensory nuclei of the other cranial nerves by the medial longitudinal fasciculus. To produce the coördinated activities of the eye-moving muscles, it must be associated with the nuclei of the trochlear and abducens.

THE TROCHLEAR NERVES

The fibres of each trochlear or fourth nerve (or patheticus) spring from the cells of a nucleus which lies in the grey substance of the floor of the cerebral aquæduct in line with the oculo-motor nucleus, but in the region of the inferior quadrigeminate bodies. As the fibres pass from their origins they run ventrally and laterally in the substance of the tegmentum for a short distance, then they curve medianward and dorsalward, and, in passing through the anterior end of the superior medullary velum they decussate totally with the fibres of the trochlear nerve

Fig. 733.—Diagrams of Sections through the Origin of the Trochlear Nerve. (Stilling.) (The upper figure is an oblique section, the lower is a coronal section.)



of the opposite side. After the decussation the fibres emerge from the surface of the superior medullary velum, at the side of the frenulum veli, usually in two small bundles, which pierce the pia mater and join together to form the slender trunk of the nerve. This trunk curves forward and ventralward to the base of the brain around the sides of the superior peduncle of the cerebellum and cerebral peduncle of the side opposite to that in which the nerve originates, running parallel with and between the superior cerebellar and posterior cerebral arteries. As it reaches the base of the brain behind the optic tract the nerve enters the cisterna basalis, in which it runs forward, immediately beneath or piercing the free border of the tentorium cerebelli, to the superior border of the petrous portion of the temporal bone, where it pierces the arachnoid and the dura mater and enters the posterior end of the lateral wall of the cavernous sinus. In the wall of the cavernous sinus it receives **communications** from the cavernous plexus of the sympathetic and by a small filament from the ophthalmic division of the trigeminus. It gradually ascends, as it passes forward in the lateral wall of the sinus, and, beyond the middle of the sinus, it crosses the lateral side of the trunk of the oculo-motor nerve and gains a higher position. At the anterior end of the sinus the nerve enters the orbit above the lateral rectus and immediately turns medialward between the periosteum of the roof of the orbit and the levator palpebræ superioris. At the medial border of the roof it turns forward to its termination, and enters the orbital or superior surface of the superior oblique muscle to which its fibres are distributed.

The central connections of the nucleus of the trochlear nerve are similar to those of the oculo-motor save that its cells probably do not send fibres which connect with the facial nerve.

The trochlear is peculiar in that—(1) it is the smallest of the cranial nerves; (2) it is the only nerve having its superficial attachment upon the dorsal aspect of the encephalon; (3) it is the only cranial nerve whose fibres undergo a total decussation, and (4) in that it terminates in a muscle of the side of the body opposite that in which it has its origin. Gaskell has suggested that this latter condition has probably been brought about, phylogenetically, by the transference of the muscles which have carried their nerves with them. It should be remembered that most of the fibres arising from the medial group of the cells of the nucleus of the oculo-motor, cross the opposite side. This is thought to be especially true for those supplying the medial rectus muscle.

THE ABDUCENS

The abducens (or sixth nerve) on each side arises from the cells of a nucleus which lies in the grey substance of the floor of the fourth ventricle in the region of the inferior part of the pons. The nucleus is situated close to the middle line, ventral to the acoustic medullary striæ and beneath the colliculus facialis and it is in direct linear series with the nuclei of the oculo-motor, trochlear and hypoglossal nerves. It is the third of the eye-moving nerves. The fibres which pass from the nucleus into the nerve run inferiorly and ventralward through the reticular formation, the trapezium, and the pyramidal fasciculi, and they emerge from the ventral surface of the medulla in the sulcus at the inferior border of the pons and the upper end of the pyramid of the medulla. From this superficial attachment the nerve runs upward and forward in the subarachnoid space between the pons and the basisphenoid and at the side of the basilar artery. A little below the level of the upper border of the petrous portion of the temporal bone it pierces the dura mater, passes beneath the petro-sphenoidal ligament, at the side of the dorsum sellæ, and enters the cavernous sinus, in which it runs forward along the lateral side of the internal carotid artery. At the anterior end of the sinus it passes through the superior orbital (sphenoidal) fissure between the heads of the rectus lateralis, below the inferior branch of the oculo-motor nerve, and above the ophthalmic vein. In the orbit it runs forward on the inner or ocular surface of the rectus lateralis, and finally it pierces this muscle and terminates upon its fibres.

While it is in the cavernous sinus it receives communications from the carotid plexus of the sympathetic and from the ophthalmic nerve.

All the fibres arising in the nucleus of the sixth nerve do not pass into the sixth nerve. Some of them ascend in the medial longitudinal fasciculus of the same and opposite sides, and terminate about cells of the medial group of the nucleus of the oculo-motor nerve, by which the impulses are conveyed to the opposite medial rectus muscle. Thus impulses reaching the abducens nucleus can throw into simultaneous action the lateral rectus of the same side and the medial rectus of the opposite side, and thus turn both eyes in the same direction.

Central connections.—The nucleus of the abducens receives impulses from the anterior central gyrus of the opposite side by the pyramidal fibres, and it is associated with the sensory nuclei of other nerves by way of the medial longitudinal fasciculus, and that of the trigeminus especially through the reticular formation.

THE TRIGEMINUS

The trigeminus is the largest of the cranial nerves with the exception of the optic. It is usually described as the fifth cranial nerve and as possessing both a sensory and a motor root. For reasons already given, the "motor root" is here described separately and given the separate name, *masticator nerve.* The fibres of the trigeminus, which are all sensory, spring from the cells of the semilunar (Gasserian) ganglion, which corresponds with the ganglion of the dorsal root of a spinal nerve, and they enter the brain stem through the side of the anterior third of the pons.

The **semilunar (Gasserian) ganglion** is a semilunar mass which lies in Meckel's cave, a cleft in the dura mater above a depression in the medial part of the upper surface of the petrous portion of the temporal bone. The convexity of the ganglion is turned forward, and from it three large nerves, the *ophthalmic*, the *maxillary*, and the *mandibular*, are given off. From the concavity, which is directed backward, springs the root of the nerve. The medial end of the ganglion is in close relation with the cavernous sinus and the internal carotid artery at the foramen lacerum, and the lateral end lies to the medial side of the foramen ovale. The surfaces of the ganglion are striated, due to bundles of fibres traversing them. The upper surface is separated by the dura mater from the temporal lobe of the brain, and the lower rests upon the masticator nerve and the outer layer of dura mater upon the petrous portion of the temporal bone.

The fibres of the trigeminus root as they leave the semilunar (Gasserian) ganglion, form from thirty to forty fasciculi which are bound together into a flat band, from six to seven millimetres broad, which passes backward over the upper border of the petrous portion of the temporal bone and below the superior petrosal sinus into the posterior fossa of the cranium. In the posterior fossa it runs backward, medialward, and downward, and passes into the pons through its continuation into the middle peduncle of the cerebellum. In the tegmentum of the pons region, the fibres bifurcate into ascending and descending branches which terminate about the cells of the nucleus of termination of the trigeminus. This nucleus, large at the level of the entrance of the root, has tapering superior and inferior extremities. The inferior extremity of the nucleus, which is much the longer, descends as low as the upper portion of the spinal cord and the fibres of the root terminating about the cells of this extremity are known as the spinal tract of the trigeminus.

Central connections.—The nuclei of termination of the trigeminus send impulses to the somæsthetic area of the cortex of the opposite side by the fibres of the medial lemniscus (fillet) and, for reflex actions, to the motor nuclei of other cranial nerves by the medial longitudinal fasciculus and by fasciculi propri in the reticular formation of the same, and opposite sides.

THE BRANCHES OF THE TRIGEMINUS

The main branches of the trigeminus, given off by the front side of the semilunar ganglion, are three in number (ophthalmic, maxillary, and mandibular), each of which is referred to as a nerve and each of which is purely sensory, though the third branch, or mandibular nerve, is joined by the fibres of the masticator nerve which is motor.

(1) The Ophthalmic Nerve or First Division

The ophthalmic nerve, the first division of the trigeminus, is the smallest of the three branches which arise from the semilunar (Gasserian) ganglion. It springs from the medial part of the front of the ganglion and passes forward, in the lateral wall of the cavernous sinus, where it lies below the trochlear nerve and lateral to the abducens nerve and the internal carotid artery (fig. 734). A short distance behind the superior orbital (sphenoidal) fissure the nerve divides into three terminal branches—the frontal, lacrimal, and naso-ciliary (nasal) nerves. They pierce the dura mater, which closes the fissure, and pass forward into the orbit. Before its division the ophthalmic nerve receives filaments from the cavernous plexus of the sympathetic and it gives off, soon after its origin, a **tentorial (recurrent meningeal) branch** which runs backward, in close association with the trochlear nerve, and ramifies between the layers of the tentorium cerebelli. Further forward three branches spring from the ophthalmic nerve which contribute sensory fibres to the oculo-motor, trochlear, and abducens nerves.

The terminal branches.—(*a*) The **frontal nerve** is the largest terminal branch. It pierces the dura mater and passes into the orbit through the superior orbital (sphenoidal) fissure, above the rectus lateralis and a little below and to the lateral side of the trochlear nerve. In the orbit it runs forward, between the levator palpebræ superioris and the periosteum, and breaks up into three branches, the supra-orbital, frontal proper, and supratrochlear.

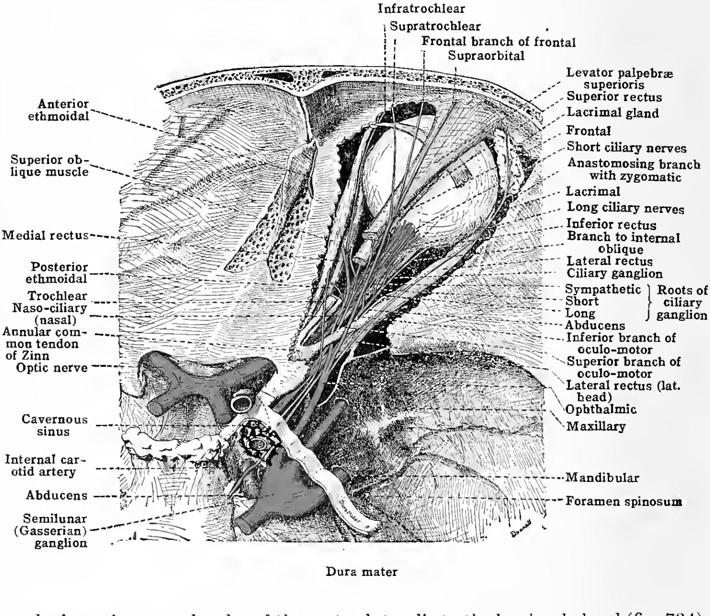
The **supra-orbital nerve,** the largest of the three branches, leaves the orbit at the supra-orbital notch (fig. 734). As it passes through the notch it gives off a small branch which enters the bone and supplies the diploë and the mucous membrane of the frontal sinus. Its terminal branches give twigs to the pericranium and to the skin of the scalp, the upper eyelid, the frontal region, and the parietal region almost as far as the lambdoid suture (fig. 740). One branch running at the upper margin of the orbital cavity unites with a branch of the facial nerve.

The **frontal branch**, given off at a variable point, lies medial to the supra-orbital, passes through the frontal foramen, and is distributed to the skin of the forehead and upper eyelid (fig. 734).

The **supratrochlear branch** runs forward and medialward toward the upper and medial angle of the orbit, where it passes above the pulley of the superior oblique muscle, pierces the palpebral fascia, and ascends to the lower and middle part of the forehead, accompanied by the frontal artery (fig. 734). Before it leaves the orbit it sends a branch downward behind or in front of the pulley of the obliquus superior which joins with the infratrochlear nerve, and as it leaves the orbit it gives off filaments to supply the skin and conjunctiva of the medial third of the upper eyelid. Its terminal branches pierce the orbicularis and frontalis, and, as they pass to the skin of the forehead, they communicate with branches of the facial nerve.

(*b*) The **lacrimal nerve** [n. lacrimalis] is the smallest of the three branches of the ophthalmic division. It passes through the superior orbital (sphenoidal) fissure lateral to and slightly below the frontal nerve, and is directed forward and lateral-

Fig. 734.—Nerves of the Orbit from Above and Behind. (Schematic.)



ward, along the upper border of the rectus lateralis to the lacrimal gland (fig. 734). On the lateral wall of the orbit it receives a small branch from the zygomatic nerve (the orbital branch of the maxillary nerve). This branch brings to the lacrimal nerve secretory fibres for the lacrimal gland. A small twig passes beyond the gland, pierces the palpebral fascia, supplies filaments to the conjunctiva, and is then distributed to the integument at the lateral angle of the eye and to the skin over the zygomatic process of the frontal bone.

(*c*) The **naso-ciliary (nasal) nerve** enters the orbit between the two heads of the rectus lateralis and between the superior and inferior branches of the oculo-motor nerve. In the orbit it lies at first lateral to the optic nerve, but, as it runs obliquely forward and medialward to the medial wall of the orbital cavity, it crosses above the optic nerve and between it and the rectus superior, and near the border of the rectus medialis it divides into its terminal branches, the chief of which are the *infratrochlear* and *anterior ethmoidal* nerves (fig. 734). In addition to those received from the cavernous plexus before the division of the ophthalmic nerve, the naso-ciliary nerve itself receives numerous sympathetic (secretory and vaso-motor) fibres.

Its several **branches** are: (i) The **long root of the ciliary ganglion** which is given off at the superior orbital (sphenoidal) fissure. It is a slender filament which runs forward on the lateral side of the optic nerve to the superior and posterior part of the ciliary ganglion (fig. 734).

(ii) The **long ciliary nerves,** usually two in number, which arise from the naso-ciliary nerve as the latter is crossing above the optic nerve. They run forward, on the medial side of the optic nerve, pierce the sclerotic, and are distributed with the lower set of short ciliary nerves (fig. 734). The long root of the ciliary ganglion and the long ciliary nerves carry sensory fibres which belong to the naso-ciliary nerve proper, most of which merely pass through the ganglion, and it carries sympathetic fibres, added to it, most of which may terminate about the cell-bodies of the ganglion.

(iii) The **posterior ethmoidal (spheno-ethmoidal) branch** springs from the posterior border of the naso-ciliary nerve near the upper border of the rectus medialis. It passes through the posterior ethmoidal canal and is distributed to the mucous membrane of the posterior ethmoidal cells and the sphenoidal sinus.

(iv) The **infratrochlear nerve** passes forward between the obliquus superior and the rectus medialis, and under the pulley of the former muscle divides into two branches:—The **superior palpebral branch** helps to supply the eyelids with sensory fibres and usually anastomoses with the supratrochlear nerve. The **inferior palpebral branch** is distributed to the lacrimal sac, the conjunctiva and skin of the medial part of the upper eyelid, the caruncle, and the skin of the upper part of the side of the nose.

(v) The **anterior ethmoidal** (distal part of the nasal) **nerve,** passing forward and medial-ward between the obliquus superior and the rectus medialis, leaves the orbit through the anterior ethmoidal foramen, accompanied by the anterior ethmoidal vessels, and enters into the anterior fossa of the cranium (fig. 734). It then crosses the lamina cribrosa of the ethmoid, lying outside the dura mater, which separates it from the olfactory bulb, and descends into the nasal fossa through the ethmoidal fissure, a slit-like aperture at the side of the crista galli. In the sub-mucosa of the nasal fossa it terminates by dividing into two sets of *anterior nasal branches*: the internal nasal branches and the external nasal branch (fig. 732).

The **internal nasal branches** divide into the **medial nasal branches** (the septal branches of the nasal nerve), which run downward and forward on the upper and front part of the septum, and the **lateral nasal branches** (the external terminal branch of the nasal nerve), which give twigs to the anterior extremities of the superior and middle nasal conchæ (turbinated bones), and to the mucous membrane of the lateral wall of the nose (fig. 732).

The **external nasal branch** (the anterior terminal branch of the nasal nerve) runs downward in a groove on the inner surface of the nasal bone. It pierces the wall of the nose between the nasal bone and the upper lateral cartilage, and supplies the integument of the lower part of the dorsum of the nose as far as the tip.

(2) The Maxillary Nerve or Second Division of the Trigeminus

The maxillary nerve is entirely sensory in function and it is intermediate in size between the ophthalmic and mandibular nerves.

It springs from the middle of the anterior border of the semilunar (Gasserian) ganglion and runs forward in the lower and outer part of the lateral wall of the cavernous sinus (fig. 735). Leaving the middle fossa of the cranium, by passing through the foramen rotundum, it enters the pterygo-palatine (spheno-maxillary) fossa (fig. 734), where it is joined by twigs with the spheno-palatine ganglion; then, changing its name, it passes forward, as the **infra-orbital nerve,** through the inferior orbital (spheno-maxillary) fissure into the infra-orbital sulcus in the floor of the orbit; continuing forward it traverses the infra-orbital canal accompanied by the infra-orbital artery, and appears in the face, beneath the levator labii superioris (quadratus) and above the levator anguli oris (caninus) where it divides into four sets of terminal branches which anastomose more or less freely with branches of the facial nerve to form the **infra-orbital plexus.**

Branches.—The branches of the maxillary nerve are—(*a*) branches given off in the middle fossa of the cranium; (*b*) branches given off in the pterygo-palatine (spheno-maxillary) fossa; (*c*) branches given off in the infra-orbital sulcus and canal; and (*d*) terminal branches.

(*a*) The **middle (recurrent) meningeal branch,** given off in the middle fossa of the cranium, breaks up into numerous branches which supply the dura mater with sensory fibres, reinforce the sympathetic plexus on the middle meningeal artery, and anastomose with the spinous nerve (the recurrent branch of the mandibular nerve).

(*b*) The branches given off in the pterygo-palatine (spheno-maxillary) fossa are the spheno-palatine nerves, the zygomatic branch of the maxillary nerve, and the posterior superior alveolar nerves.

The **spheno-palatine nerve** has two or three branches which descend in the pterygo-palatine fossa and give a small part of their fibres to the spheno-palatine (Meckel's) ganglion (fig. 735), the larger part of their fibres passing through the ganglion into its orbital, nasal, and palatine branches. (See SPHENO-PALATINE GANGLION, p. 962.)

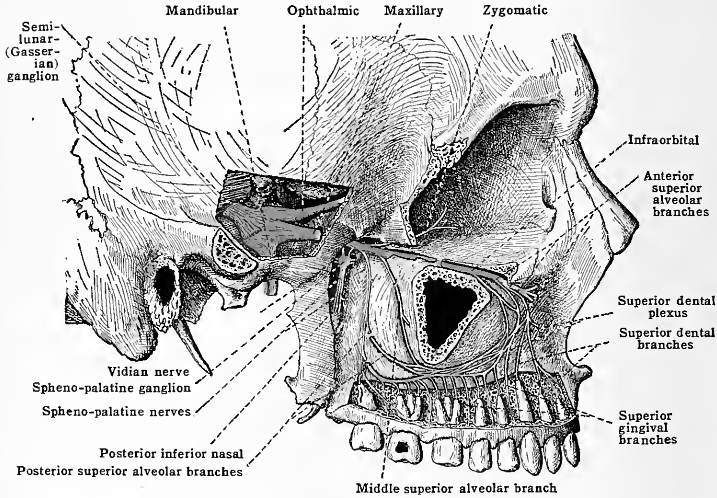
The **zygomatic (orbital or temporo-malar) branch,** given off from the upper surface of the maxillary nerve, passes forward and lateralward, and, at the end of the inferior orbital (spheno-maxillary) fissure, passes through it into the orbit and divides into two branches, facial and temporal.

The **zygomatico-facial (malar) branch** runs forward, passes through a zygomatico-orbital foramen, then through the zygomatico-facial (malar) foramen, pierces the orbicularis palpebrarum, communicates with the zygomatic (malar) branch of the facial nerve, and supplies the skin of the prominence of the cheek. The **zygomatico-temporal (temporal) branch** runs upward in a groove in the lateral wall of the orbit, passes through a zygomatico-orbital foramen, then through the zygomatico-temporal (spheno-malar) foramen, and enters the temporal fossa. It turns around the anterior border of the temporal muscle, pierces the deep layer of the temporal fascia, and runs backward for a short distance in the fat between the superficial and deep lamellæ, then, turning lateralward, it pierces the superficial lamellæ about an inch above the zygoma, anastomoses with the temporal branch of the facial nerve, and supplies the skin of the anterior part of the temporal region.

The **infra-orbital nerve,** that part of the maxillary nerve lying distal to the spheno-palatine ganglion, enters the orbit through the inferior orbital (spheno-maxillary) fissure, accompanied by the infra-orbital artery, and with it passes through the infra-orbital canal (fig. 735) to the face, where it divides into four sets of terminal branches, some of which, by anastomoses with the branches of the facial nerve, form the **infra-orbital plexus.**

Three sets of **superior alveolar nerves** arise from the maxillary and the infra-orbital nerves, namely, the posterior superior alveolar branches, the middle superior alveolar branch, and the anterior superior alveolar branches.

FIG. 735.—LATERAL VIEW OF THE MAXILLARY NERVE.



The **posterior superior alveolar (dental) nerves** are usually two in number, but sometimes arise by a single trunk. They pass downward and lateralward through the pterygo-maxillary fissure into the zygomatic fossa, where they give branches to the mucous membrane of the gums and the posterior part of the mouth; then they enter the posterior alveolar (dental) canals and unite with the other alveolar branches to form the **superior dental plexus,** through which they give branches to the roots and pulp cavities of the molar teeth and to the mucous membrane of the maxillary sinus (fig. 735).

(*c*) The branches given off in the infra-orbital sulcus and canal are the middle and anterior superior alveolar (dental) nerves.

(i) The **middle superior alveolar (dental) nerve** leaves the infra-orbital nerve in the posterior part of the infra-orbital sulcus, and, passing downward and forward in a canal in the maxilla, it divides into terminal branches that anastomose with the other alveolar branches to form the *superior dental plexus.* Through the plexus it supplies the bicuspid teeth and gives branches to the mucous membrane of the maxillary sinus and also to the gums (fig. 735).

(ii) The **anterior superior alveolar (dental) nerve** is the largest of the superior alveolar nerves. It is given off by the infra-orbital nerve in the anterior part of the infra-orbital canal, and passes downward in a bony canal in the anterior wall of the maxilla. After uniting with the other alveolar nerves to form the superior dental plexus, it supplies the canines and the incisors and gives branches to the mucous membrane of the maxillary sinus and the gums (fig. 735). It also gives off a **nasal branch** which enters the nasal fossa through a small foramen, and supplies the mucous membrane of the anterior part of the inferior meatus and the adjacent part of the floor of the nasal cavity.

(iii) The **superior dental plexus** is formed in the bony alveolar canals by the three superior alveolar nerves. It is convex downward and anastomoses across the mid-line with the corresponding plexus of the other side (fig. 735). From it arise the **superior dental branches** supplying the superior canines and incisors, **superior gingival branches** supplying the gums, and also branches to the mucous membrane of the maxillary sinus and to the bone. On the plexus are two gangliform enlargements, one, called the *ganglion of Valentine,* situated at the junction of the middle and the posterior branches, and the other, called the *ganglion of Bochdalek,* at the junction of the middle and anterior branches.

(*d*) The terminal branches of the maxillary nerve are the inferior palpebral, the external and internal nasal (nasal), and the superior labial.

The **inferior palpebral branches,** usually two, pass upward and supply sensory fibres to all the skin and conjunctiva of the lower eyelid (fig. 740).

The **external nasal branches** pass medialward under cover of the levator labii superioris (quadratus), and supply the skin of the posterior part of the lateral aspect of the nose.

The **internal nasal branches** pass downward and medialward under the lateral wall of the nose, and then turn upward to supply the skin of the vestibule of the nose.

The **superior labial branches,** three or four in number, as a rule are larger than the palpebral and nasal branches. They pass downward to supply the skin and mucous membrane of the upper lip and the neighbouring part of the cheek.

(3) The Mandibular Nerve or Third Division of the Trigeminus

The **mandibular division** is the largest of the three divisions of the trigeminus (figs. 736 and 740). As a nerve, it is usually described as formed by the union of two distinct nerves, namely, the entire masticator nerve and the large bundle of sensory fibres derived from the semilunar (Gasserian) ganglion which pass peripherally as the third division of the trigeminus. These two nerves remain separate until they pass through the foramen ovale and then unite immediately outside the skull to form a large trunk which almost directly after its formation divides into a small *anterior* and a larger *posterior portion.* The trunk is situated between the pterygoideus externus, laterally, and the otic ganglion and the tensor palati medially. In front of it is the posterior border of the pterygoideus internus, and behind it, the middle meningeal artery. Two branches arise from the trunk of the nerve before its division, namely, the spinous (recurrent) nerve and the nerve to the pterygoideus internus.

The **spinous (recurrent) nerve,** after receiving a vasomotor filament from the otic ganglion, enters the cranium through the foramen spinosum, accompanying the middle meningeal artery, and divides into an anterior and a posterior branch. The anterior branch communicates with the meningeal branch of the maxillary division of the trigeminus, furnishes filaments to the dura mater, and ends in the osseous substance of the great wing of the sphenoid. The posterior branch traverses the petrosquamous suture and ends in the lining membrane of the mastoid cells.

The fibres going to form the *nerve to the internal pterygoid muscle* are almost wholly motor fibres and therefore comprise a branch of the masticator nerve and are described as such under the description of the masticator (fig. 737).

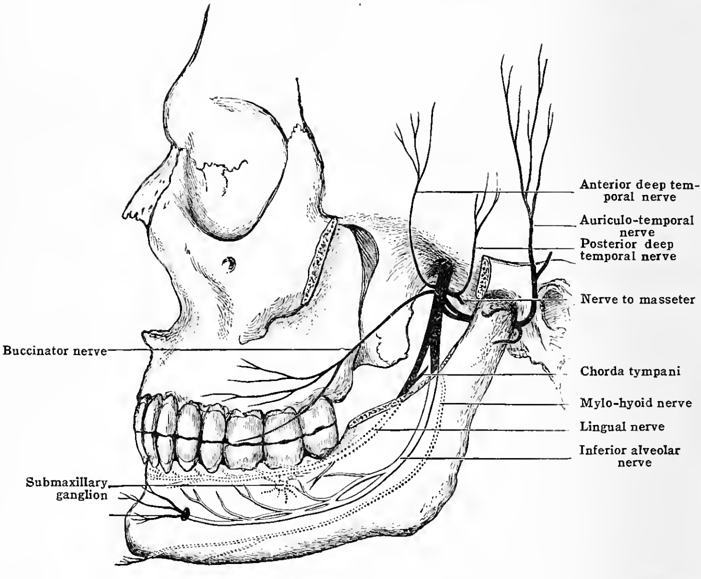
The **anterior portion** of the mendibular nerve is smaller than the posterior and is chiefly composed of motor fibres which form branches of the masticator nerve and supply the muscles of mastication, the temporalis, masseter, and pterygoideus externus. Practically all of the sensory fibres of the anterior portion (fibres of the mandibular nerve proper) form the buccinator (long buccal) nerve. The latter is accompanied, in the first part of its course, by a small strand of motor or masticator fibres which leaves it to end in the anterior part of the temporal muscle.

The **buccinator (long buccal) nerve,** entirely sensory, passes between the two heads of the external pterygoid muscle and runs downward and forward under cover of or through the anterior fibres of the temporalis to the cheek (fig. 736). As it passes forward it emerges from under cover of the anterior border of the masseter and lies on the superficial surface of the buccinator, where it interlaces with the buccal branches of the facial nerve and gives off filaments to supply the superjacent skin; finally it pierces the buccinator and supplies the mucous membrane on its inner surface as far forward as the angle of the mouth. The fibres of the anterior deep temporal nerve, a branch of the masticator, are frequently associated with the buccinator until the latter has passed between the heads of the external pterygoid; then the anterior deep temporal nerve separates from the buccinator and passes upward on the lateral surface of the upper head of the external pterygoid.

The **posterior portion** of the mandibular nerve divides into three large branches. Two of these, the lingual and the auriculo-temporal nerves, are exclusively sensory; the third, the inferior alveolar (dental) nerve, contains a strand of motor fibres, the mylo-hyoid nerve, which comprise a branch of the masticator nerve.

The **lingual nerve** is the most anterior branch of the mandibular nerve (figs. 736, 743). It lies in front and to the medial side of the inferior alveolar (dental) nerve and descends at first on the medial side of the pterygoideus externus, then between the pterygoideus internus and the ramus of the mandible to the posterior part of the mylohyoid ridge, where it passes off the anterior border of the pterygoideus internus; at this point it is situated a short distance behind the last

Fig. 736.—Distribution of the Mandibular Division of the Trigeminus combined with Branches of the Masticator Nerve. (Henle.)



molar tooth and is covered in front by the mucous membrane of the posterior part of the mouth cavity. After leaving the pterygoideus internus it crosses the fibres of the superior constrictor, which are attached to the mandible, and turns forward toward the tip of the tongue, crossing the lateral surfaces of the stylo-glossus, hyoglossus, and genioglossus. In its course across the hyoglossus it lies first above, then to the lateral side of, and finally below Wharton's duct, and as it ascends on the genioglossus it lies on the medial side of the duct.

Communications and branches.—While it is on the medial side of the pterygoideus externus the lingual nerve is joined, at an acute angle, by the chorda tympani (figs. 736, 743), a branch of the glosso-palatine nerve, and as it lies between the ramus of the mandible and the pterygoideus internus it is connected by a branch with the inferior alveolar (dental) nerve, and gives off one or two small branches, the **rami isthmi faucium,** which are ditributed as sensory fibres to the tonsil and the mucous membrane of the posterior part of the mouth (fig. 743).

While it is above the duct it gives a branch, which contains many sensory and visceral motor chorda tympani fibres, to the submaxillary ganglion (see p. 963), and it receives branches, chiefly sympathetic, from that ganglion. A little further forward it is connected by one or two branches, which run along the anterior border of the hyoglossus, with the hypoglossal nerve (fig. 743). It then gives off the **sublingual nerve**, which runs forward to supply the sublingual gland and the neighbouring mucous membrane (fig. 743). Its terminal (**lingual**) branches are derived chiefly from the glosso-palatine nerve. They pierce the muscular substance of the tongue and are distributed to the mucous membrane of its anterior two-thirds. They interlace with similar branches of the other side and with branches of the glosso-pharyngeal nerve.

The **inferior alveolar (dental) nerve** is the largest branch of the posterior portion of the mandibular nerve. It commences on the medial side of the external pterygoid muscle and descends to the interval between the spheno-mandibular ligament and the ramus of the mandible, where it receives one or two communicating branches from the lingual nerve. Opposite the middle of the medial surface of the ramus it enters the mandibular (inferior dental) canal, accompanied by the inferior alveolar (dental) artery, which lies in front of the nerve, and it runs downward and forward through the ramus and the body of the mandible (fig. 736). At the mental foramen it divides into two parts, one of which, the *mental nerve*, passes out through the mental foramen, the other, commonly called the *incisive branch*, continues forward in the canal, and supplies, through the inferior dental plexus, the inferior canine and incisor teeth and the corresponding regions of the gums.

Branches.—The branches of the inferior alveolar (dental) nerve are branches forming the inferior dental plexus, and the mental branch. A bundle of motor fibres, the *mylohyoid nerve*, a branch of the masticator nerve, is given off just before the inferior alevolar nerve enters the mandibular canal.

The **inferior dental plexus** is formed by a series of branches which communicate with one another within the bone, giving rise to a fine network. From this plexus two sets of branches are given off:—the **inferior dental branches**, corresponding in number to the roots of the teeth, enter the minute foramina of the apices of the roots and end in the pulp; the second set, the **inferior gingival branches**, supply the gums.

The **mental nerve** is a nerve of considerable size which emerges through the mental foramen (fig. 736). It communicates, near its exit from the bone, with branches of the facial nerve, and then divides into three branches. The smallest branch, turning downward, divides into several twigs, the *mental branches*, which supply the integument of the chin. The other two, *inferior labial branches*, pass upward, diverging as they ascend, and divide into a number of twigs. The stoutest twigs ramify to the mucous membrane which lines the lower lip. Other twigs are distributed to the integument and fascia of the lip and chin.

The **auriculo-temporal nerve** usually arises from the posterior portion of the mandibular nerve by two roots which embrace the middle meningeal artery and unite behind it to form the trunk of the nerve. The trunk passes backward on the medial aspect of the pterygoideus externus, and between the spheno-mandibular ligament and the temporo-mandibular articulation, lying in close relation with the capsule of the joint. Behind the joint it enters the upper part of the parotid gland, through which it turns upward and lateralward. It emerges from the upper end of the gland, crosses the root of the zygoma close to the posterior border of the superficial temporal artery, and divides into auricular and temporal terminal branches at the level of the tragus of the pinna (fig. 736).

Communications.—(*a*) Each of the two roots of the nerve receives a communication from the otic ganglion containing fibres derived from the glosso-pharyngeal nerve. These fibres have passed from the glosso-pharyngeal through the tympanic plexus and the small superficial petrosal nerve and through the otic ganglion.

(*b*) Sensory filaments pass from the auriculo-temporal nerve to the temporo-facial branch of the facial nerve.

(*c*) Filaments of connection with the sympathetic plexus on the internal maxillary artery.

(*d*) A communication to the inferior alveolar (dental) nerve.

Branches of the auriculo-temporal nerve.—(*a*) An **articular branch** to the temporo-mandibular joint, given off as the nerve lies on the medial side of the capsule.

(*b*) **Branches to the external auditory meatus.** Two branches, as a rule, are given off in the parotid gland. They enter the meatus by passing between the cartilage and the bone and supply the upper part of the meatus, the membrana tympani by a fine branch, and occasionally the lower branch gives twigs to the skin of the lobule of the pinna.

(*c*) **Parotid branches** are distributed to the substance of the parotid gland. Sensory or trigeminal fibres for the gland spring either directly from the nerve or from the communicating branches previously given by it to the glosso-palatine nerve. The parotid branches also contain fibres derived from the glosso-pharyngeal nerve which pass successively through its tympanic branch, the tympanic plexus, the small superficial petrosal nerve, the otic ganglion, and the communicating twigs from the otic ganglion to the roots of the auriculo-temporal nerve. The parotid branches are later again mentioned as concerned chiefly with the *gangliated cephalic plexus*.

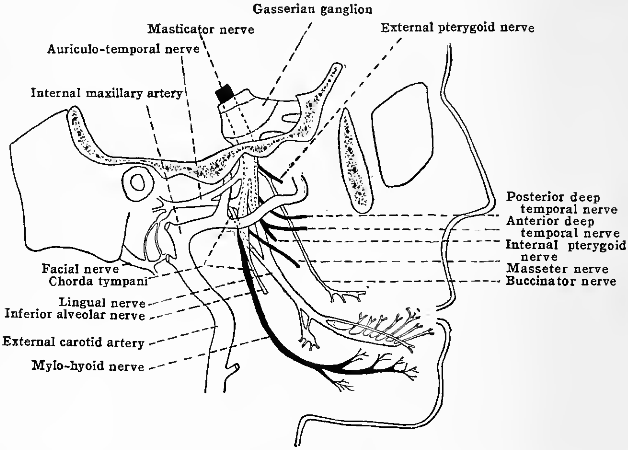
(*d*) The **anterior auricular branches**, usually two in number, are distributed to the skin of the tragus and the upper and outer part of the pinna.

(e) The **superficial temporal branches** supply the integument of the greater part of the temporal region, and anastomose with the temporal branch of the facial nerve.

THE MASTICATOR NERVE (Fig. 737)

The masticator nerve (*motor root or portio minor of trigeminus*). The fibres of the masticator nerve spring from two nuclei, a slender upper or mesencephalic nucleus and a clustered lower or chief nucleus. The fibres arising in the mesencephalic nucleus descend along the lateral aspect of the nucleus to the pons as the *descending* or *mesencephalic root;** here they join the fibres from the chief motor nucleus and issue with them from the side of the pons in from six to ten root filaments. These blend to form the nerve, which is from one and a half to two millimetres broad. At the point where it emerges from the pons the nerve is in front of and ventral to the root of the trigeminus and it is separated from the latter by a few of the transverse fibres of the pons which constitute the *lingula of Wrisberg*. From its superficial exit from the pons, the masticator nerve passes upward, lateralward, and forward in the posterior fossa of the cranum, and along the medial and anterior aspect of the trigeminus, to the mouth of Meckel's cave. In this cavity it runs lateralward below the semilunar (Gasserian) ganglion to the foramen ovale, through which it passes to join the mandibular division of the

FIG. 737.—SCHEMATIC REPRESENTATION OF THE MASTICATOR NERVE AND ITS BRANCHES (IN BLACK). Lateral view. Modified from Spalteholz.



trigeminus immediately outside and below the base of the skull. The nerve is purely motor and its fibres are devoted almost wholly to the muscles having to do with mastication.

Central connections.—The nuclei of origin of the masticator nerve are connected with the lower part of the somæsthetic area of the cerebral cortex of the opposite side by the pyramidal fibres descending in the genu of the internal capsule, and they are associated with the sensory nuclei of other cranial nerves through the reticular formation and by the medial longitudinal fasciculus.

Branches.—Almost immediately after joining the trunk of the mandibular nerve, most of the fibres of the masticator leave it to form the greater part of the so-called anterior portion of the mandibular. However, one branch of masticator fibres, the nerve to the internal pterygoid muscle, is given off from the mandibular just before its division into anterior and posterior portions. The masticator

* Recent investigations indicate that the mesenephalic root is not wholly motor but at least in part sensory in character, and thus belongs partly to the trigeminal nerve. (See page 829.)

branches derived from the anterior portion are the *deep temporal* nerves, the *masseteric* nerve, and the nerve to the *external pterygoid*. One branch, the *mylo-hyoid* nerve, is carried in the posterior portion of the mandibular and is given off from its inferior alveolar branch.

The **nerve to the internal pterygoid** passes under cover of a dense layer of fascia derived from an expansion of the ligamentum pterygo-spinosum, and enters the deep surface of the muscle. Near its commencement this nerve furnishes a visceral motor root to the otic ganglion, and small twigs to the tensor tympani and tensor palati.

The **deep temporal nerves,** usually two in number, posterior and anterior, pass between the bone and the upper border of the external pterygoid muscle, and turn upward around the infra-temporal crest of the sphenoid bone to end in the deep surface of the temporalis (fig. 736). The posterior of the two often arises in common with the masseteric nerve. The anterior is frequently associated with the buccinator (long buccal) nerve till the latter has passed between the two heads of the pterygoideus externus. There is frequently a third branch, the **medius,** which passes lateralward above the pterygoideus externus, and turns upward close to the bone to enter the deep surface of that muscle. A small strand of masticator fibres accompanies the buccinator nerve to enter and end in the anterior part of the temporal muscle.

The **masseteric nerve,** which frequently arises in common with the posterior deep temporal nerve, passes between the bone and the pterygoideus externus, and accompanies the masseteric artery through the notch of the mandible to be distributed to the masseter (fig. 736). It is easily traced through the deeper fibres nearly to the anterior border of the masseter. As it emerges above the pterygoideus externus it gives off a twig to the temporo-mandibular articulation.

The **nerve to the external pterygoid,** after a course of about 3 mm. (an eighth of an inch), divides into twigs which enter the deep surface of the two heads of the muscle. It is usually adherent at its origin to the buccinator nerve.

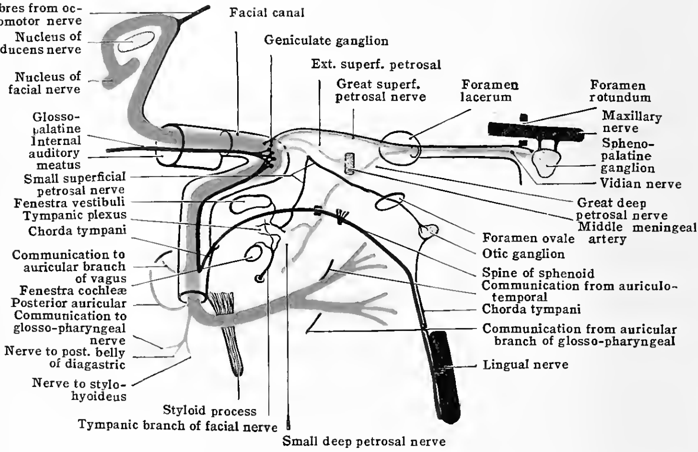
The **mylo-hyoid branch,** carried in the posterior portion of the mandibular nerve, is given off immediately before the inferior alveolar (dental) nerve enters the mandibular (inferior dental) canal. It pierces the lower and back part of the spheno-mandibular ligament and runs downward and forward in the mylo-hyoid groove between the mandible on the lateral side, and the internal pterygoid muscle and the lateral surface of the submaxillary gland on the medial side. In the anterior part of the digastric triangle it is continued forward between the anterior part of the submaxillary gland and the mylo-hyoideus, and it breaks up into branches which supply the mylo-hyoideus and the anterior belly of the digastric (fig. 736).

THE FACIAL NERVE

The facial or seventh nerve is purely motor. It is accompanied a short distance by a bundle usually called its *sensory root* or the *intermediate nerve*. This latter, however, on the basis of its origin, distribution, and mixed instead of sensory character, is described separately below as the *glosso-palatine nerve*. It is smaller than the facial, is fused to the trunk of the facial and the ganglion giving rise to its sensory fibres is situated upon the external genu of the facial (figs. 738 and 741).

The fibres of the facial nerve (fig. 738) spring from a nucleus of cells situated laterally in the reticular formation at the level of the lower pons, dorsal to the superior olive, and between the root fibres of the abducens nerve and the laterally placed spinal tract of the trigeminus. From this nucleus the fibres of the nerve pass medially and dorsalward to the floor of the fourth ventricle and, just under the floor, they turn anteriorly, passing dorsal to the nucleus of the abducens (fig. 653, p. 827). At the anterior end of this nucleus they turn sharply ventralward and lateralward, and at this point it is claimed that fibres descending in the near-by medial longitudinal fasciculus from the nucleus of the oculo-motor nerve of the same side become intermingled with the fibres of the facial nerve and pass outward with them. This, however, is uncertain. Continuing ventralward through the reticular formation the fibres of the facial emerge from the brain-stem at the inferior border of the pons, lateral to the superficial attachment of the abducens. At the point of its emergence, the facial nerve pierces the pia mater, from which it receives a sheath, and then proceeds forward and lateralward in the posterior fossa of the cranium to the internal auditory meatus, which it enters in company with the glosso-palatine nerve and with the cochlear and vestibular nerves. As it lies in the meatus it is situated above and in front of the latter nerves, from which it is separated by the glosso-palatine, and it is surrounded, together with these three nerves, by sheaths of both the arachnoid and the dura mater and by prolongations of the subarachnoid and sub-dural spaces. While it is still in the meatus it blends with the glosso-palatine and thus the combined trunk is formed. At the outer end of the meatus the trunk pierces the arachnoid and the dura mater and enters the facial canal (aqueduct of Fallopius), in which it runs forward and slightly lateralward to the hiatus Fallopii, where it makes an angular bend, the external genu [geniculum], around the anterior boundary of the vestibule of the inner ear; this bend is enlarged by the adhesion of the geniculate ganglion (of the glosso-palatine) upon its anterior border. From the geniculum the facial nerve runs backward in the facial canal along the lateral wall of the vestibule and the medial wall of the tympanum, above the fenestra vestibuli (ovalis), to the junction of the medial and posterior walls of the tympanic cavity; then, bending downward, it descends in the posterior wall to the stylo-mastoid foramen. As soon as it emerges from the stylo-mastoid foramen it turns forward around the lateral side of the base of the styloid process,

Fig. 738.—Diagram of the Facial (Yellow) and Glosso-palatine Nerve (Blue).



and plunges into the substance of the parotid gland, where it divides into its cervico-facial and temporo-facial terminal divisions. Before its terminal divisions, the nerve gives off three, and sometimes four, small branches: one, the nerve to the stapedius muscle, before it leaves the skull, the others after it leaves the skull.

The **nerve to the stapedius** is given off from the facial nerve as it descends in the posterior wall of the tympanum behind the pyramidal eminence. It is stated that filaments are also given off from the facial to the auditory artery (probably visceral motor from the glosso-palatine) while the nerve is passing through the internal auditory meatus.

After it leaves the skull the facial nerve gives off two or three coll teral branches and its two terminal divisions, the temporo-facial and cervico-facial. The collateral branches are the posterior auricular nerve, a branch to the posterior belly of the digastric, and sometimes a lingual branch.

(1) The **posterior auricular nerve** is the first branch of the extracranial portion of the facial nerve. It passes between the parotid gland and the anterior border of the sterno-mastoid muscle and runs upward in the deep interval between the external auditory meatus and the mastoid process. In this situation it communicates with the auricular branch of the vagus. It supplies the auricularis posterior, sends a slender twig upward to the auricularis superior, and ends in a long slender branch, **the occipital branch**, which passes backward to supply the occipitalis muscle. It also receives filaments from the small occipital and great auricular nerves, and supplies the intrinsic muscles of the auricle (pinna).

(2) The **nerve to the posterior belly of the digastric** arises from the facial nerve close to the stylo-mastoid foramen and enters the muscle near its centre, or sometimes near its origin. It usually gives off two branches: the **nerve to the stylo-hyoid**, which sometimes arises directly from the facial nerve and passes to the upper part of the muscle that it supplies, and the **anastomotic branch**, which joins the glosso-pharyngeal nerve below its petrous ganglion.

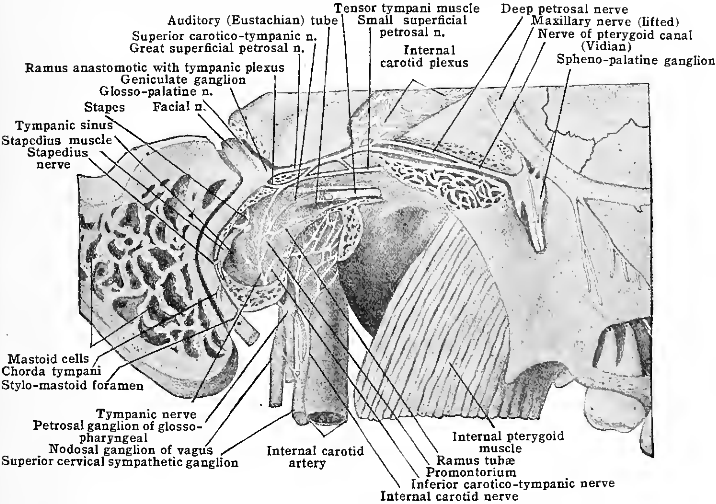
(3) The **lingual branch**, first described by Cruveilhier, is not commonly present. It arises a little below the nerve to the stylo-hyoideus and runs downward and medialward to the base of the tongue. In its course it passes to the medial sides of the stylo-glossus and stylo-pharyn-

geus, and runs downward along the anterior border of the latter muscle to the wall of the pharynx. It pierces the superior constrictor, insinuates itself between the tonsil and the anterior pillar of the fauces, and it is stated that it gives filaments to the base of the tongue and to the stylo-glossus and glosso-palatinus (palato-glossus) muscles.

The terminal divisions.—In the substance of the parotid gland the two terminal divisions of the facial nerve lie superficial to the external carotid artery and to the posterior facial (temporo-maxillary) vein. The way in which these terminal divisions give off their branches varies much in different subjects and often on the opposite sides of the same subject. One of the more common forms is here described.

The **temporo-facial** or upper division runs upward and forward, and, after receiving communicating twigs from the auriculo-temporal nerve, gives off temporal and zygomatic (malar) branches. The **cervico-facial** or lower division runs downward and forward, receives branches from the great auricular nerve, and

Fig. 739.—The Right Facial Nerve, within the Skull, and the Relations of the Glosso-palatine and Glosso-pharyngeal Nerves with the Tympanic and Internal Carotid Plexuses. (From Sobotta's Atlas, modified.)



gives off—(1) *buccal branches*, comprising what have been called infraorbital and buccal branches; (2) the *marginal mandibular* (supra-mandibular) branch; and (3) the *ramus colli* (infra-mandibular branch). These branches from the two terminal divisions anastomose freely to form the **parotid plexus** (pes anserinus).

The **temporal branches** passing upward communicate freely with each other and with the zygomatic branches. They also communicate with the zygomatico-temporal branch of the zygomatic nerve (the orbital branch of the maxillary nerve) and with the supra-orbital nerve. They supply the frontalis, orbicularis oculi, corrugator supercilii, and auricularis anterior and superior (fig. 740).

The **zygomatic** (malar) **branches** passing upward and forward, communicate with the buccal branches of the facial nerve; with the zygomatico-facial branch of the zygomatic nerve (the orbital branch of the maxillary nerve); with the supraorbital and lacrimal branches of the ophthalmic nerve, and with the palpebral twigs of the maxillary. They supply both eyelids, the orbicularis oculi, and the zygomaticus (fig. 740).

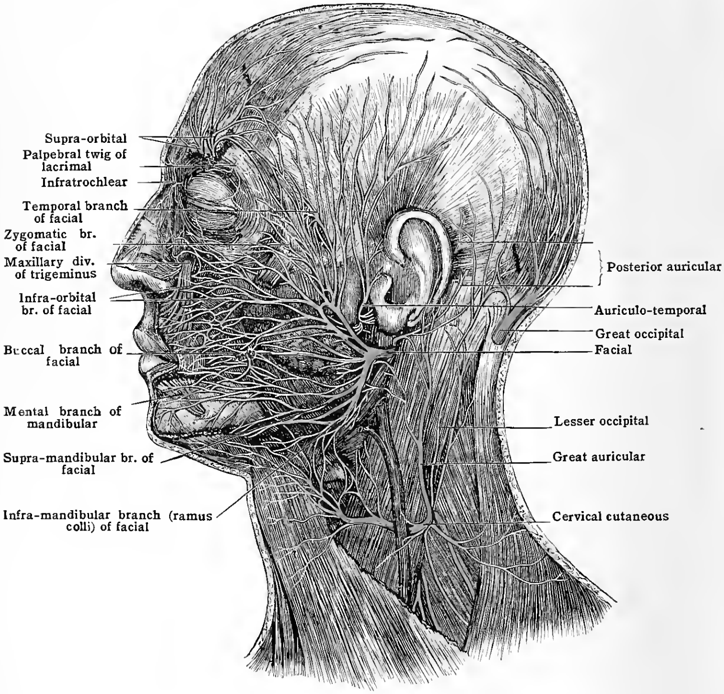
The **buccal (infra-orbital and buccal) branches** arise sometimes from the lower terminal division and sometimes from both the upper and the lower terminal divisions. The buccal branches, passing forward upon the masseter and underneath the zygomaticus and quadratus labii superioris, interlace with the zygomatic and marginal mandibular (supra-mandibular) branches of the facial nerve, with the buccinator (long buccal) branch of the trigeminus, and with the terminal branches of the maxillary nerve, forming with the last-named nerve the **infra-orbital plexus.** They supply the zygomaticus, risorius, quadratus labii superioris, caninus, buccinator, incisivi, orbicularis oris, triangularis, quadratus labii inferioris, and the muscles of the nose (fig. 740).

The **marginal mandibular (supra-mandibular) branch,** passing downward and forward under cover of the risorius and the depressors of the lower lip, communicates with the buccal branches and with the ramus colli of the facial nerve, and with the mental branch of the mandibular nerve. It supplies the quadratus labii inferioris and mentalis.

The ramus colli (infra-mandibular branch) runs downward and forward under cover of the platysma, which muscle it innervates (fig. 740). Beneath the platysma it forms one or more communicating loops, near its commencement, with the great auricular nerve, and longer loops, lower down, with the superficial cervical nerve.

Central connections.—The nucleus of origin of the facial in the rhombencephalon includes an anterior and a posterior group of cells which give rise respectively to its upper and lower terminal divisions. They are associated with the somæsthetic area (lower third of the anterior central gyrus) by way of the pyramidal fasciculi of the opposite and same sides, and with the nuclei of the other cranial nerves, including the nucleus of termination of the glosso-palatine, by way of the reticular formation and the medial longitudinal fasciculus.

Fig. 740.—Superficial Distribution of the Facial and other Nerves of the Head. (After Hirschfield and Leveillé.)



GLOSSO-PALATINE NERVE

The **glosso-palatine nerve** (*sensory root or pars intermedia of facial, nerve of Wrisberg*) contains both sensory and motor fibres. While it has a separate attachment to the medulla, it courses in close company with the facial and, in the internal auditory meatus, it is involved in the same sheath with the facial, which relation is maintained by its larger part thence through the facial canal till a short distance above the stylo-mastoid foramen. Here this larger part leaves the trunk of the facial as the *chorda tympani* nerve. The origin, central connections and peripheral distribution of the glosso-palatine are similar to those of the glosso-pharyngeal nerve and suggest that it may be considered an aberrant portion of that nerve.

The **sensory portion** is much greater than the motor. Its fibres arise from cells situated in the geniculate ganglion which thus corresponds to a spinal ganglion. The *central processes* from these cells pass medialward in the facial canal (aqueduct of Fallopius) enclosed in the sheath of the facial nerve, which they leave in passing through the internal auditory meatus, to turn slightly downward in the posterior fossa of the cranium and enter the medulla at the inferior border of the pons, between the attachments of the facial and vestibular nerves. They course through the reticular formation of the medulla, medianward and dorsalward to terminate about cells which comprise a superior extension of the nucleus of termination of the glosso-pharyngeal nerve (nucleus of ala cinerea). The *peripheral processes* from the geniculate ganglion are distributed chiefly to the epithelium covering the soft palate, portions of the glosso-palatine arches, and the anterior two thirds of the tongue.

The **geniculate ganglion** is so named from the fact that it is embedded upon the anterior border of the external genu (*geniculum*, great bend) of the facial nerve, behind the hiatus Fallopii. It is somewhat triangular in form. From its superomedial angle leave the central processes of its cells, the root of the nerve; from its infero-lateral angle leave the fibres which later leave the sheath of the facial as the chorda tympani, and its anterior angle is connected with the great superficial petrosal nerve (figs. 738 and 741). The geniculate ganglion contains a relatively large number of cell-bodies of sympathetic neurones many of whose processes run in this latter nerve, a relation mentioned below with the gangliated cephalic plexus.

The **motor portion** of the glosso-palatine consists for the most part of visceral efferent fibres, chiefly secretory. These arise in the medulla oblongata from a small group of cells scattered in the reticular formation dorso-medial to the nucleus of the facial and in line with the dorsal efferent nucleus of the vagus below. It is called the *salivatory nucleus*. The fibres course ventralward and lateralward to their exit, mingle with the entering sensory fibres of the glosso-palatine in the sheath of the facial and, through the branches of the glosso-palatine, pass to terminate in sympathetic ganglia of the head, large and small. These ganglia send axones which terminate in the smooth muscle of vessels and about the cells of the glands of the lingual and palatine mucous membrane and of the salivary glands proper. Some of the motor fibres of the nerve terminate in contact with the sympathetic cells remaining in the geniculate ganglion and which give rise to sympathetic fibres issuing from it. Most of the motor fibres pass into the great superficial petrosal nerve and the chorda tympani to terminate in (chiefly) or pass through the spheno-palatine and submaxillary ganglia respectively. Some may pass by the geniculo-tympanic branch and tympanic plexus to end in the otic ganglion. Many no doubt end in the smaller ganglia involved in the various sympathetic plexuses. It is suggested that the motor part carries secretory impulses destined chiefly for the sub-maxillary and sublingual glands. A small gangliated plexus on the capsule of the medial side of the parotid gland has been frequently dissected and found to communicate freely with twigs from the facial nerve and twigs concerned with the trigeminus. It is possible that some glosso-palatine visceral motor fibres terminate in these ganglia for secretory impulses to the parotid gland as well.

Central connections.—The nucleus of termination of the glosso-palatine nerve (superior extension of the nucleus of termination of the sensory portion of the glosso-pharyngeal) is associated with the somæsthetic area of the cerebral cortex of the opposite and same sides by way of the medial lemniscus, and with the salivatory nucleus and motor nuclei of other cranial nerves by way of the reticular formation and medial longitudinal fasciculus. The nucleus of origin of the motor portion (salivatory nucleus) may be associated not only with the nucleus of termination of the sensory part, but with the nuclei of termination of other cranial nerves, and perhaps with the motor area of the cortex of the opposite side by way of the pyramidal fasciculi.

Branches and communications.—Aside from its two or three small collateral twigs of communication, the fibres of the glosso-palatine course in two main branches or nerves: (1) the great superficial petrosal nerve, continued through the Vidian nerve, and extended through and beyond the spheno-palatine ganglion as the palatine portion of the glosso-palatine (palatine nerve); (2) the chorda tympani, the larger branch, which extends to join and contribute its quota of fibres to the lingual nerve, a branch of the trigeminus.

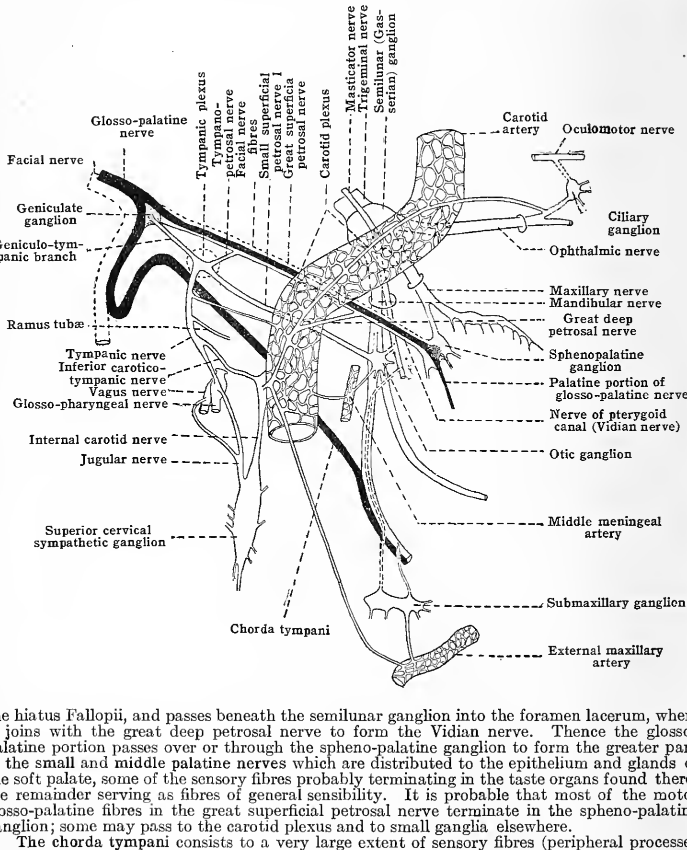
In the internal auditory meatus, the glosso-palatine gives two delicate collaterals to the vestibular nerve, and some filaments (visceral motor probably) are described as given to the auditory artery and to the temporal bone.

A small **geniculo-tympanic branch** is given, in the facial canal, from the geniculate ganglion to the small superficial petrosal nerve. This is probably all visceral motor and sympathetic fibres (fig. 741).

There may occur a twig arising from or near the beginning of the chorda tympani and forming a *communication with the auricular branch of the vagus.*

A large part of the **great superficial petrosal nerve** is formed of glosso-palatine fibres. This nerve is further described below in its relation to the spheno-palatine ganglion. It arises from the anterior angle of the geniculate ganglion, enters the middle fossa of the cranium through

FIG. 741.—DIAGRAM OF THE GLOSSO-PALATINE NERVE (BLACK) AND THE RELATIONS OF THE GANGLIATED CEPHALIC PLEXUS TO OTHER CRANIAL NERVES. (After Bean.) Broken lines, motor; continuous lines, sympathetic; glosso-palatine in solid black. Medial view. Left side.



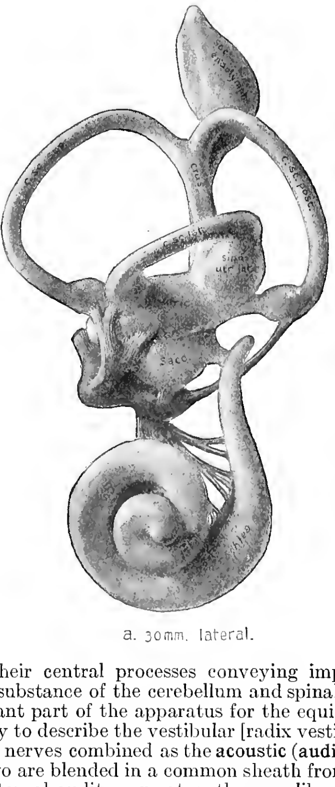
the hiatus Fallopii, and passes beneath the semilunar ganglion into the foramen lacerum, where it joins with the great deep petrosal nerve to form the Vidian nerve. Thence the glosso-palatine portion passes over or through the spheno-palatine ganglion to form the greater part of the small and middle palatine nerves which are distributed to the epithelium and glands of the soft palate, some of the sensory fibres probably terminating in the taste organs found there; the remainder serving as fibres of general sensibility. It is probable that most of the motor glosso-palatine fibres in the great superficial petrosal nerve terminate in the spheno-palatine ganglion; some may pass to the carotid plexus and to small ganglia elsewhere.

The chorda tympani consists to a very large extent of sensory fibres (peripheral processes of the cells of the geniculate ganglion), but it also contains motor fibres and is thus also a mixed nerve. It leaves the trunk of the facial nerve a short distance above the stylo-mastoid foramen, and pursues a slightly recurrent course upward and forward in the canaliculus chordæ tympani (iter chordæ posterius), a minute canal in the posterior wall of the tympanic cavity, and it enters that cavity close to the posterior border of the membrana tympani. It crosses the cavity, running on the medial surface of the tympanic membrane at the junction of its upper and middle thirds, covered by the mucous membrane lining the tympanic cavity, and passes to the medial side of the manubrium of the malleus above the tendon of the tensor tympani. It leaves the tympanic cavity and passes to the base of the skull through a small foramen (the iter chordæ anterius) at the medial end of the petro-tympanic (Glaserian) fissure. At the base of the skull it inclines downward and forward on the medial side of the spine of the sphenoid, which it frequently grooves, and, on the medial side of the pterygoideus externus, it joins the posterior border of the lingual nerve at an acute angle. Some of its fibres (motor chiefly) leave the lingual nerve and pass to the sub-maxillary ganglion, and others (sensory) continue forward to the tongue, where, in company with fibres of the lingual nerve, they terminate in the epithelium covering the anterior two-thirds of the tongue. Some probably serve to convey sensations of taste, most of them are fibres of general sensibility. Before it joins the lingual nerve the chorda tympani receives a communicating twig from the otic ganglion (figs. 738, 741).

THE VESTIBULAR NERVE

The vestibular nerve is purely sensory. With the peripheral processes of its cells of origin terminating in the neuro-epithelium of the semicircular canals and

Fig. 742.—The Left Membranous Labyrinth of a Human Fœtus of 10 Weeks (30 mm.), Lateral Aspect. Vestibular ganglion and nerve, red; cochlear nerve, yellow. (Streeter, American Journal of Anatomy.)



a. 30mm. lateral.

the vestibule, and their central processes conveying impulses which are distributed to the gray substance of the cerebellum and spinal cord, the nerve comprises a most important part of the apparatus for the equilibration of the body. It has been customary to describe the vestibular [radix vestibularis] and the cochlear [radix cochlearis] nerves combined as the **acoustic (auditory) or eighth cranial nerve.** While the two are blended in a common sheath from near the medulla to the bottom of the internal auditory meatus, they are likewise partly enclosed in the same sheath with the facial and glosso-palatine nerves and the internal auditory artery which accompany them in this meatus. At the bottom of the meatus the vestibular and the cochlear are separate; they are separate at their entrance into the lateral aspect of the medulla oblongata; and their central connections, peripheral distributions and functions are different.

The vestibular nerve arises as processes of the cells of the **vestibular ganglion** (ganglion of Scarpa), situated upon and blended within the nerve at the bottom of the internal auditory meatus. Unlike the ordinary spinal ganglion, to which it corresponds, the cells of the vestibular ganglion retain an embryonal, "bipolar," form. The *central processes* course with the cochlear nerve in the internal auditory meatus medialward, caudad and slightly downward, inferior to the accompanying facial and glosso-palatine nerves, and, arching ventrally around the restiform body, they enter the medulla at the inferior border of the pons, lateral to the glosso-palatine and facial and medial to the entrance of the cochlear nerve. They find their nucleus of termination spread in the floor of the fourth ventricle and grouped as the median, the lateral (Deiters'), the superior, and the nucleus of the spinal root of the vestibular nerve. In the internal auditory meatus, the vestibular nerve is connected by two small filaments of fibres with the glosso-palatine nerve. These are either visceral motor fibres for the vessels of the domain of the vestibular or are aberrant fibres which course only temporarily with the vestibular and return to the glosso-palatine.

The *peripheral processes* of the cells of the vestibular ganglion terminate in the specialised or neuro-epithelium comprising the *maculæ* in the sacculus and the utriculus and the *cristæ* in the ampullæ of the three semicircular canals. Thus there are five **terminal branches** of the nerve. None of its fibres terminates in the cochlea. The vestibular ganglion has a lobar form, one lobe giving rise to a superior **utriculo-ampullar** division which divides into three terminal branches; the other giving a **sacculo-ampullar** division which gives two terminals.

The superior or **utriculo-ampullar branch** divides into the following terminal branches:—

(1) The **utricular branch** passes through the superior macula cribrosa of the vestibule and terminates in the macula acustica of the utriculus.

(2) Accompanying the utricular branch through the superior macula cribrosa is a branch, the **superior ampullar,** to the crista acustica of the ampulla of the superior semicircular canal, and—

(3) A similar branch, the **lateral ampullar,** to the ampulla of the lateral semicircular canal.

The inferior or **sacculo-ampullar branch** accompanies the cochlear nerve a short distance further than the superior, and divides into—

(4) A branch, the **posterior ampullar,** which passes through the foramen singulare and the inferior macula cribrosa and terminates in the ampulla of the posterior semicircular canal, and—

(5) A branch, the **saccular,** which passes through the middle macula cribrosa and terminates in the macula acustica of the sacculus.

The **central connections** of the vestibular nerve are described in detail on pages 823, 824. Its large nucleus of termination, spread through the area acustica in the floor of the fourth ventricle, and divided into four sub-nuclei, is associated with the nuclei fastigii, globosus, and emboliformis of the cerebellum, with the nuclei of the eye-moving nerves, with the spinal cord, and probably with the cerebral cortex.

THE COCHLEAR OR AUDITORY NERVE

The fibres of the cochlear nerve are distributed to the organ of Corti in the cochlea, and so are considered as comprising the auditory nerve proper. They arise from the long, coiled **spiral ganglion** of the cochlea, the cells of which, like those of the vestibular ganglion, are bipolar. The *peripheral processes* of these cells are shorter than those of the vestibular ganglion. They terminate about the auditory or hair-cells of the organ of Corti and thus collect impulses aroused by stimuli affecting these cells. The *central processes* of the ganglion cells continue through the modiolar canal and the tractus spiralis foraminosus of the cochlea, and thence, joining the vestibular nerve through the internal auditory meatus, accompanying the facial nerve and internal auditory artery, they course medialward and downward, approach and enclasp the restiform body (fig. 665) and enter the lateral aspect of brain-stem to terminate in their dorsal and ventral nuclei. A description of these nuclei and the further central connections of the cochlea with the superior olive, the nuclei of the eye-moving nerves, the inferior quadrigeminate bodies, the medial geniculate bodies, and with the cerebellum and temporal lobes of the cerebral hemispheres is given on pages 824, 839.

The cochlear nerve is separate from the vestibular at the bottom of the internal auditory meatus and at its entrance into the medulla.

THE GLOSSO-PHARYNGEAL NERVE

The glosso-pharyngeal or *ninth* cranial nerves are mixed nerves and each is attached to the medulla by several roots which enter the postero-lateral sulcus, dorsal to the anterior end of the olivary body and in direct line with the facial nerve.

The filaments, when traced lateralward, are seen to blend, in front of the flocculus, into a trunk which lies in front of the vagus nerve, but which passes through a separate opening through the arachnoid and the dura mater and through the jugular foramen. In the foramen this trunk lies in front, and lateral to the vagus nerve in a groove on the petrous portion of the temporal bone; and in this situation two ganglia are interposed in it, a superior or jugular, and an inferior or petrosal. After it emerges from the jugular foramen the glosso-pharyngeal nerve descends at first between the internal carotid artery and the internal jugular vein and to the lateral side of the vagus; then, bending forward and medialward, it descends medial to the styloid process and the muscles arising from it, and turning around the lower border of the stylo-pharyngeus it passes between the internal and the external carotid arteries, crosses the superficial surface of the stylo-pharyngeus, and runs forward and upward medial to the hyoglossus muscle and across the middle constrictor and the stylo-hyoid ligament, to the base of the tongue (fig. 743).

Ganglia.—The **superior** or **jugular ganglion** (ganglion of Ehrenritter), is a small, ovoid, reddish-grey body which lies on the back part of the nerve-trunk in the upper part of the jugular foramen. No branches arise from it. It is sometimes continuous with the petrosal ganglion or it may be absent.

The **inferior or petrosal ganglion,** (ganglion of Andersch), is an ovoid grey body which lies in the lower part of the jugular foramen, and appears to include all the fibres of the nerve.

Branches and communications.—(1) The petrosal ganglion is connected with the superior cervical ganglion of the sympathetic by a fine filament.

(2) It also has a filament of communication with the auricular branch of the vagus which varies inversely in size with the latter branch and sometimes entirely replaces it. This filament may be absent.

(3) An inconstant communication with the ganglion of the root of the vagus.

(4) A short distance below the petrous ganglion the trunk of the nerve is connected by a twig with that branch of the facial nerve which supplies the posterior belly of the digastric muscle. There is also a small twig (probably sensory) to the stylo-hyoid.

(5) **From the petrosal ganglion: The tympanic branch** (nerve of Jacobson) arises from the petrosal ganglion and passes through a foramen, which lies in the ridge of bone between the carotid canal and the jugular fossa, into the tympanic canaliculus (Jacobson's canal), where it is surrounded by a small, fusiform mass of vascular tissue, the *intumescentia tympanica.* After traversing the tympanic canaliculus it enters the tympanum at the junction of its lower and medial walls, and, ascending on the medial wall, breaks up into a number of branches which take part in the formation of the **tympanic plexus** on the surface of the promontory (fig. 739). The continuation of the nerve emerges from this plexus as the *small superficial petrosal nerve,* which runs through a small canal in the petrous portion of the temporal bone, beneath the canal for the tensor tympani, and appears in the middle fossa of the cranium through a foramen which lies in front of the hiatus Fallopii. From this foramen it runs forward and passes through the foramen ovale, the canaliculus innominatus, or the spheno-petrosal suture, and enters the zygomatic fossa, where it joins the otic ganglion. While it is in the canal in the temporal bone the small superficial petrosal nerve is joined by a **geniculo-tympanic branch** from the geniculate ganglion of the glosso-palatine nerve.

(6) **Branches from the tympanic plexus:**—(*a*) The **tubal branch** (ramus tubæ), a delicate branch, which runs forward to the mucous membrane of the tuba auditiva (Eustachian tube) and sends filaments backward to the region of the fenestra vestibuli (ovalis) and the fenestra cochleæ (rotunda).

(*b*) The **superior and inferior carotico-tympanic (carotid) branches** pass medianward to the internal carotid plexus (fig. 741).

The above communications carry fibres almost entirely concerned with the sympathetic plexuses of the head and they will be again mentioned below with the gangliated cephalic plexus.

Branches from the trunk of the nerve:—(1) **Pharyngeal branches,** which may be two or three in number, arise from the nerve a short distance below the petrosal ganglion. The principal and most constant of these passes on the lateral side of the internal carotid artery, and after a very short independent course joins with the pharyngeal branch of the vagus and with branches of the superior cervical ganglion to form the pharyngeal plexus (fig. 743).

(2) A **muscular branch** is distributed to the stylo-pharyngeus muscle. This branch receives a communication from the facial nerve (fig. 743).

(3) The **tonsillar branches** are a number of small twigs which arise under cover of the hyoglossus muscle; they proceed to the tonsil, around which they form a plexus, the **circulus tonsillaris.** From this plexus fine twigs proceed to the glosso-palatine arches (pillars of the fauces) and to the soft palate.

(4) The **lingual branches** are the terminal branches of the nerve and supply the mucous membrane of the posterior half of the dorsum of the tongue, where, chiefly as taste-fibres, they are distributed to the vallate papillæ. Some small twigs pass backward to the follicular glands of the tongue, and to the anterior surface of the epiglottis. Other twigs are distributed around the foramen cæcum, where they communicate with the corresponding twigs of the opposite side.

The sensory fibres.—The sensory fibres of the glosso-pharyngeal nerve spring from the superior and petrosal ganglia and pass peripherally and centrally. The **peripheral** processes of the ganglion cells are those which are distributed to the mucous membrane (taste-buds) of the tongue and pharynx, and the **central** processes pass medialward to the medulla. In the medulla they pass dorsalward and medianward through the reticular formation and, bifurcating into ascending and descending branches, they end in the nucleus of termination of the glosso-pharyngeal nerve, that is, in the superior part of the nucleus alæ cinereæ and in the nucleus of the tractus solitarius.

The **motor fibres** arise from the nucleus ambiguus in the lateral funiculus of the medulla, in line with the nucleus of origin of the facial nerve. From this nucleus they pass at first dorsalward and then, turning lateralward, they emerge and join the sensory fibres and run with them in the trunk of the nerve (fig. 646).

Van Gehuchten's observations point to the conclusion that one motor nucleus of the glosso-pharyngeal nerve is separate from and lies above and to the medial side of the nucleus ambiguus, and that a portion of the nucleus of the ala cinerea is also a motor nucleus common to the glosso-pharyngeal and vagus nerves. It is quite probable that the former motor nucleus is that now considered as the dorsal motor nucleus of the vagus. An unknown proportion of the motor fibres are visceral motor and course in the various communications of the glosso-pharyngeal nerve with cephalic plexus.

Central connections.—The nuclei of termination of the glosso-pharyngeal nerve are associated with the motor nuclei of other cranial nerves by the medial longitudinal fasciculus, and with the somæsthetic area of the cortex cerebri of the opposite side by the medial lemniscus (fillet). The motor nucleus of the nerve is associated with the somæsthetic area by the pyramidal fibres.

THE HYPOGLOSSAL NERVE

The **hypoglossal nerves** are exclusively motor; they supply the genio-hyoidei and the extrinsic and intrinsic muscles of the tongue except the glosso-palatini. They are usually designated as the twelfth pair of cranial nerves. The fibres of each nerve issue from the cells of an elongated nucleus which lies in the floor of the central canal in the lower half of the medulla and in the floor of the fourth ventricle in the upper half beneath the trigonum hypoglossi. This nucleus is the upward continuation of the ventro-medial group of cells of the ventral horn of the spinal cord. From their origin the fibres run ventralward and somewhat lateralward, probably joined in the medulla by a few fibres from the nucleus ambiguus which is a segment of the upward prolongation of the lateral group of cells of the ventral horn. The conjoined fibres issue from the medulla in the sulcus between the pyramid and the olivary body, in a series of from ten to sixteen root filaments, which pierce the pia mater and unite with each other to form two bundles (fig. 731). These bundles pass forward and lateralward to the hypoglossal (anterior condyloid) foramen, where they pierce the arachnoid and dura mater. In the outer part of the foramen the two bundles unite to form the trunk of the nerve. At its commencement, at the base of the skull, the trunk of the hypoglossus lies on the medial side of the vagus, but as it descends in the neck it turns gradually around the dorsal and the lateral side of the latter nerve, lying between it and the internal jugular vein, and a little above the level of the hyoid bone it bends forward, and crosses lateral to the internal carotid artery, the root of origin of the occipital artery, the external carotid, and the loop formed by the first part of the lingual artery (fig. 743). After crossing the lingual artery it proceeds forward on the lateral surface of the hyo-glossus, crossing to the medial side of the posterior belly of the digastric, and the stylo-hyoid muscles. It disappears in the anterior part of the submaxillary region between the mylo-hyoid and the hyo-glossus, and divides into its terminal branches between the latter muscle and the genio-glossus.

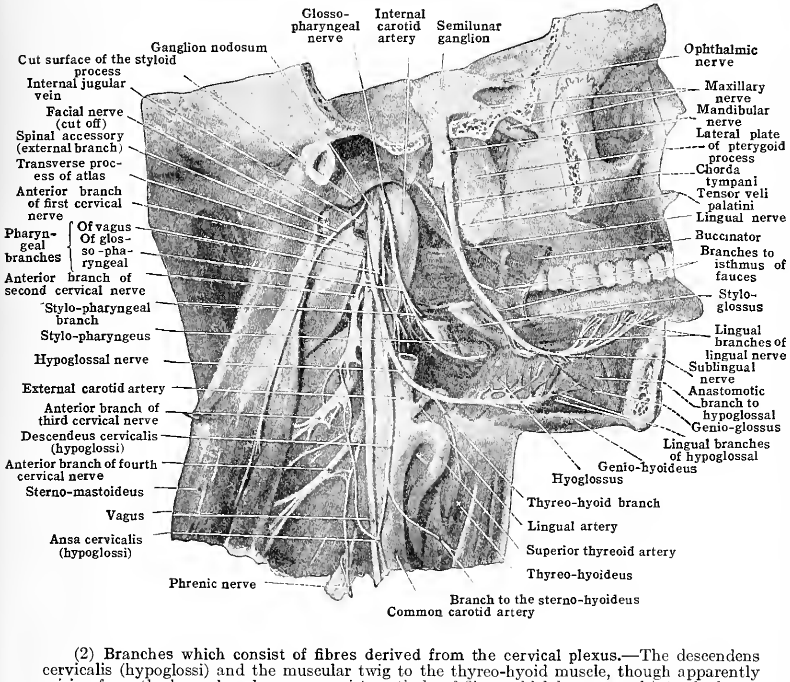
As it descends in the neck the trunk lies deeply between the internal jugular vein and the internal carotid artery under cover of the parotid gland, the styloid muscles, and the posterior belly of the digastric, and it is crossed superficially by the posterior auricular and the occipital arteries. As it turns forward around the root of the occipital artery the sterno-mastoid branch of that vessel hooks downward across the nerve, and as it turns forward on the hyo-glossus muscle it lies immediately above the ranine vein. It is crossed by the posterior belly of the digastric and the stylo-hyoid muscle, and it is covered superficially, behind the mylohyoid, by the lower part of the submaxillary gland.

Communications.—The hypoglossus is connected with the first cervical ganglion of the sympathetic, with the ganglion nodosum of the vagus, with the loop between the first and second cervical nerves, and with the lingual nerve; the latter communication is established along the anterior border of the hyo-glossus muscle (figs. 743 and 744).

Terminal branches.—These include (1) a meningeal branch; (2) branches from the cervical plexus; and (3) branches from the hypoglossus proper.

(1) A meningeal branch, frequently represented by two filaments, is given off in the hypoglossal (anterior condyloid) canal. It passes backward into the posterior fossa of the cranium and is distributed to the dura mater. It was believed at one time that the fibres of the meningeal branch were derived from the lingual nerve, but it is now deemed more probable that they are either sensory or visceral motor fibres from the cervical nerves, or from the vagus.

FIG. 743.—THE HYPOGLOSSAL, GLOSSO-PHARYNGEAL, AND LINGUAL NERVES. (Spalteholz.)



(2) **Branches which consist of fibres derived from the cervical plexus.**—The descendens cervicalis (hypoglossi) and the muscular twig to the thyreo-hyoid muscle, though apparently arising from the hypoglossal nerve, consists entirely of fibres which have passed into the hypoglossal nerve from the loop between the first two cervical nerves. Therefore, neither of them are branches of the hypoglossus proper. (See fig. 752.)

(a) The **descendens cervicalis (hypoglossi)** parts company with the hypoglossus at the point where the latter hooks around the occipital artery (fig. 743). It runs downward and slightly medialward on the sheath of the great vessels (occasionally within the sheath), and is joined at a variable level by branches from the second and third cervical nerves, forming with them a loop, the cervical loop [ansa hypoglossi] (fig. 743). The **cervical loop** may be placed at any level from a point immediately below the occipital artery to about four centimetres above the sternum. From this loop all the muscles attached to the hyoid bone are supplied. A twig to the **anterior belly of the omo-hyoid** arises from the descendens cervicalis in the upper part of its course. The nerves which supply the **sterno-hyoid, sterno-thyreoid,** and **posterior belly of the omo-hyoid** are given off by the cervical loop. Twigs from the first two nerves pass downward in the muscles behind the manubrium sterni and in rare cases communicate with the phrenic nerve within the thorax. The nerve to the posterior belly of the omo-hyoid runs in a loop of the cervical fascia below the central tendon of the muscle.

(b) The **nerve to the thyreo-hyoid** leaves the hypoglossus near the tip of the great cornu of the hyoid bone, and runs obliquely downward and medialward to reach the muscle. All the fibres in (a) and (b) are derived from the first, second and third cervical nerves.

(c) The **nerve to the genio-hyoid** arises under cover of the mylo-hyoid, where loops are formed with the lingual nerve from which loops branches pass into the muscle. It probably contains some true hypoglossal fibres.

(3) The **branches of the hypoglossus proper,** the **rami linguales,** supply the stylo-glossus, hyo-glossus, genio-glossus, and the intrinsic muscular fibres of the tongue.

The **nerve to the stylo-glossus** is given off near the posterior border of the hyo-glossus. It pierces the stylo-glossus, and its fibres pursue a more or less recurrent course within the muscle.

The **nerves to the hyo-glossus** are several twigs which are supplied to the muscle as the hypoglossal nerve crosses it.

The **nerve to the genio-glossus** arises under cover of the mylo-hyoid in common with the terminal branches to the intrinsic muscles of the tongue. It communicates freely with branches of the lingual, forming long loops which lie on the genio-glossus. From these loops twigs pass into the genio-glossus and into the muscular substance of the tongue.

Central connections.—The nucleus of origin of the hypoglossus is associated with the somæsthetic area (operculum) of the cortex cerebri of the opposite side by the pyramidal fibres, and it is connected with the sensory nuclei (nuclei of termination) of other cranial nerves by way of the reticular formation and the medial longitudinal fasciculus.

THE VAGUS OR PNEUMOGASTRIC NERVE

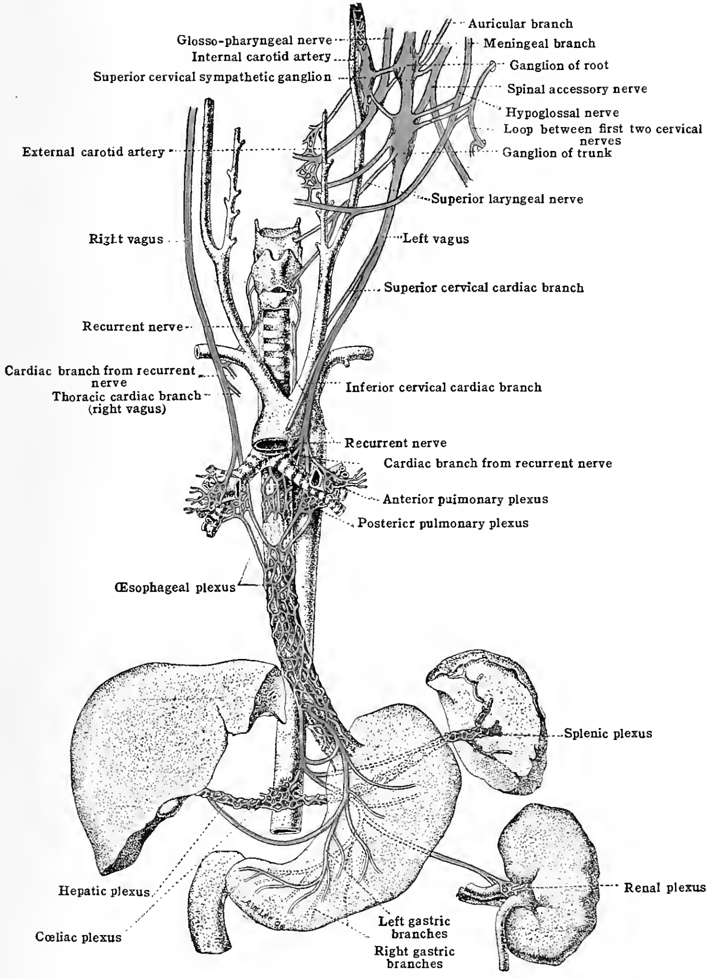
The vagus or pneumogastric nerves are the longest of the cranial nerves, and they are remarkable for their almost vertical course, their asymmetry, and their extensive distribution, for, in addition to supplying the lung and stomach, as the name 'pneumo-gastric' indicates, each nerve gives branches to the external ear, the pharynx, the larynx, the trachea, the œsophagus, the heart, and the abdominal viscera. They are commonly referred to as the tenth pair of cranial nerves.

Each nerve is attached to the side of the medulla, in the postero-lateral sulcus, dorsal to the olivary body, by from twelve to fifteen root filaments which are in linear series with the filaments of the glosso-pharyngeal nerve. The filaments contain both sensory and motor fibres. They pierce the pia mater, from which they receive sheaths, and, traced outward, they pass into the posterior fossa of the cranium toward the jugular foramen and unite to form the trunk of the nerve, which passes through openings in the arachnoid and the dura mater which are common to it and to the spinal accessory nerve. In the jugular foramen a small spherical ganglion, the *jugular ganglion* (ganglion of the root), is interposed in the trunk which here turns at right angles to its former course and descends through the neck. As it leaves the jugular foramen it is joined by the internal or accessory portion of the spinal accessory nerve, and immediately below this junction it enters a large ovoid ganglion, the *ganglion nodosum* or ganglion of the trunk (fig. 743). As it descends through the neck the nerve passes ventral and somewhat lateral to the superior cervical sympathetic ganglion, and in front of the longus capitis and longus colli, from which it is separated by the prevertebral fascia. In the upper part of the neck it is placed between the internal carotid artery and the internal jugular vein, and on a plane dorsal to them, the artery being ventral and mesial, and the vein ventral and lateral. In the lower part of the neck it occupies a similar position in regard to the common carotid artery and the internal jugular vein, and the three structures are enclosed in a common sheath derived from the deep cervical fascia, but within the sheath each structure occupies a separate compartment (fig. 743). In the root of the neck and in the thorax the relations of the nerves of the two sides of the body differ somewhat, and they must, therefore, be considered separately.

The right vagus passes in front of the first part of the right subclavian artery in the root of the neck and then descends in the thorax, passing obliquely downward and backward on the right of the trachea, and behind the right innominate vein and the superior vena cava, to the back of the root of the right lung. Just before it reaches the right bronchus it lies close to the medial side of the vena azygos as the latter hooks forward over the root of the lung. At the back of the right bronchus the right vagus breaks up into a number of branches which join with the branches of the sympathetic to form the **right posterior pulmonary plexus,** and from this plexus it issues in the form of one or more cords, combined sensory, visceral motor and sympathetic, which descend on the œsophagus and break up into branches which join with branches of the left vagus, forming the **posterior œsophageal plexus.** At the lower part of the thorax fibres of this plexus become again associated in one trunk which passes through the diaphragm on the *posterior* surface of the œsophagus, and is distributed to the *posterior* surface of the stomach and to the cœliac (solar) plexus and its offsets.

The **left vagus** descends through the root of the neck between the carotid and subclavian arteries and in front of the thoracic duct. In the upper part of the superior mediastinum it is crossed in front by the left phrenic nerve, and in the lower part of the same region it crosses in

Fig. 744.—Diagram of the Branches of the Vagus Nerves.



front of the root of the subclavian artery and the arch of the aorta and behind the left superior intercostal vein. Below the aortic arch it passes behind the left bronchus and divides into branches which unite with twigs of the sympathetic to form the **left posterior pulmonary plexus.** From this plexus the fibres of the left vagus issue as one or more cords that break up into anastomosing branches to form the anterior œsophageal **plexus.** At the lower part of the thorax this plexus becomes a single trunk, which passes through the diaphragm on the *anterior* surface of the œsophagus, and it is distributed to the *anterior* surface of the stomach and to the liver.

The **jugular ganglion** (ganglion of the root) is a spherical grey mass about five millimetres in diameter which lies in the jugular foramen (fig. 744). It is connected with the spinal accessory nerve and with the superior cervical sympathetic ganglion, and it gives off an auricular branch, by means of which it becomes associated with the facial and glosso-pharyngeal nerves, and a recurrent meningeal branch.

The **ganglion nodosum** (ganglion of the trunk) lies below the base of the skull and in front of the upper part of the internal jugular vein. It is of flattened ovoid form and about seventeen millimetres long and four millimetres broad (figs. 744 and 743). It is joined by the accessory part of the spinal accessory nerve, and is associated with the hypoglossal nerve, with the superior cervical ganglion of the sympathetic, and with the loop between the first two cervical nerves, and it gives off a pharyngeal, a superior laryngeal, and a superior cardiac branch. Both ganglia and especially the nodosal retain numerous cell-bodies of sympathetic neurones and the twigs issuing from the ganglia thus contain sympathetic fibres. The greater part of the cell-bodies are of sensory neurones.

Communications.—The vagus nerve is connected with the glosso-pharyngeal, spinal accessory and hypoglossal nerves, with the sympathetic, and with the loop between the first and second cervical nerves.

(1) Two communications exist between the vagus and glosso-pharyngeal nerves: one between their trunks, just below the base of the skull, and one, in the region of their ganglia, consisting of one or two filaments. When two filaments are present one passes from the jugular ganglion and the other from the auricular nerve to the petrosal ganglion of the glosso-pharyngeal nerve. Either or both of these filaments may be absent.

(2) Two twigs pass from the spinal accessory nerve to the ganglion nodosum, and at a lower level the accessory part of the spinal accessory nerve also joins the same ganglion (fig. 744). The majority of the fibres of the accessory part of the spinal accessory nerve merely pass across the surface of the ganglion and are continued into the pharyngeal and superior laryngeal branches of the vagus, but a certain number blend with the trunk of the vagus and are continued into its recurrent laryngeal and cardiac branches.

(3) Two or three fine filaments connect the ganglion nodosum with the hypoglossal nerve as the latter turns around the lower part of the ganglion (fig. 744).

(4) Fibres pass from the superior cervical ganglion of the sympathetic to both ganglia of the vagus (fig. 744).

(5) A twig sometimes passes from the loop between the first two cervical nerves to the ganglion nodosum (fig. 744).

Terminal branches.—These are the meningeal, auricular, pharyngeal, superior laryngeal, recurrent (inferior laryngeal), cardiac, bronchial, pericardial, œsophageal, and the abdominal branches.

(1) The **meningeal or recurrent branch** is a slender filament which is given off from the jugular ganglion. It takes a recurrent course through the jugular foramen, and is distributed to the dura mater around the transverse (lateral) sinus.

(2) The **auricular branch, or nerve of Arnold,** arises from the jugular ganglion in the jugular foramen. It receives a branch from the petrosal ganglion of the glosso-pharyngeal, enters the petrous part of the temporal bone through a foramen in the lateral wall of the jugular fossa, and communicates with the facial nerve or merely lies in contact with it as far as the stylo-mastoid foramen. It usually leaves the temporal bone by the stylo-mastoid foramen, but it may pass through the tympano-mastoid fissure, and it divides, behind the pinna, into two branches, one of which joins the posterior auricular branch of the facial while the other supplies sensory fibres to the posterior and inferior part of the external auditory meatus and the back of the pinna. It also supplies twigs to the osseous part of the external auditory meatus and to the lower part of the outer surface of the tympanic membrane.

(3) The **pharyngeal branches** may be two or three in number. The principal of these joins the pharyngeal branch of the glosso-pharyngeal on the lateral surface of the internal carotid artery, and after passing with the latter medial to the external carotid artery it turns downward and medialward to reach the posterior aspect of the pharynx. Here the two nerves are joined by branches from the superior cervical ganglion of the sympathetic, with which they form the **pharyngeal plexus** (figs. 743, 744). Branches from this plexus supply sensory fibres to the mucous membrane of the pharynx and motor fibres to the constrictores pharyngis, levator palatini, uvulæ, glosso-palatinus, and pharyngo-palatinus.

(4) The **superior laryngeal nerve** arises from the lower part of the ganglion nodosum, and passes obliquely downward and medialward behind and medial to both internal and external carotid arteries toward the larynx. In this course it describes a curve with the convexity downward and lateralward and divides into (i) a larger internal and (ii) a smaller external branch (fig. 744). Before its division it is joined by twigs with the sympathetic and with the pharyngeal plexus, and it gives a small branch to the internal carotid artery.

(a) The **internal branch** accompanies the superior laryngeal artery to the interval between the upper border of the thyreoid cartilage and the great cornu of the hyoid bone. It passes under cover of the thyreo-hyoid muscle and pierces the hyo-thyreoid membrane to gain the interior of the pharynx, where it lies in the lateral wall of the sinus piriformis and divides into a number of diverging branches. The ascending branches supply the mucous membrane on both surfaces of the epiglottis, and probably that of a small part of the root of the tongue. The descending branches ramify in the mucous membrane lining the larynx, and supply the mucous membrane which covers the back of the cricoid cartilage. One of the descending branches passes downward on the internal muscles of the larynx to anastomose with the terminal part of the inferior (recurrent) laryngeal nerve.

(b) The **external branch** runs downward on the inferior constrictor to the lower border of the thyreoid cartilage, where it ends, for the most part, in the crico-thyreoid muscle. A few filaments pierce the crico-thyreoid membrane and are distributed to the membrane lining the larynx. It occasionally gives off a cardiac branch which joins one of the cardiac branches of the sympathetic; it also furnishes twigs to the inferior constrictor, and communicating twigs to the pharyngeal plexus, and it receives a communication from the superior cervical ganglion of the sympathetic.

(5) The **recurrent (inferior or recurrent laryngeal) nerve** of the **right side** arises from the vagus at the root of the neck in front of the right subclavian artery. It hooks around the artery, passing below and then behind that vessel, and runs upward and slightly medialward, crossing obliquely behind the common carotid artery (fig. 744). Having gained the side of the trachea, it runs upward in the groove between the trachea and the œsophagus, accompanying branches of the inferior thyreoid artery, and, near the level of the lower border of the cricoid cartilage, becomes the inferior laryngeal nerve.

In its course the right recurrent nerve gives off branches to the trachea, œsophageal branches to the œsophagus and pharynx, and, near its commencement, one or more **inferior cardiac** branches. It communicates with the inferior cervical sympathetic ganglion and with the superior laryngeal nerve.

The **inferior laryngeal nerve,** the continuation of the recurrent, ascends between the trachea and œsophagus, enters the larynx under cover of the inferior constrictor of the pharynx, and divides into two branches, anterior and posterior. The *anterior branch* passes upward and forward on the crico-arytænoideus lateralis and thyreo-arytænoideus, and supplies these muscles and also the vocalis, arytænoideus obliquus, ary-epiglotticus, and thyreo-epiglotticus. The *posterior branch,* passing upward, supplies the crico-arytænoideus posterior and arytænoideus obliquus, and anastomoses with the medial branch of the superior laryngeal nerve.

On the **left side** the recurrent nerve arises in front of the aortic arch and winds around the concavity of the arch lateral to the ligamentum arteriosum. It crosses obliquely behind the root of the left common carotid artery, gains the angular interval between the œsophagus and trachea, and corresponds with the nerve of the right side in the remainder of its course and distribution (fig. 744).

(6) **Cardiac branches.**—Of these branches of the vagus, there are two sets, the superior and inferior. All the branches of both sets pass to the deep part of the cardiac plexus except a superior branch on the left side that passes to the superficial part of the cardiac plexus. All contain visceral motor, sympathetic and sensory fibres.

(a) The **superior (superior and inferior cervical) cardiac nerves** arise from the vagus and its branches in the neck (figs. 744, 786). Some of these branches on both sides join with the cardiac branches of the sympathetic in the neck and pass with them to the cardiac plexus. Some on the right side pass independently through the thorax to the deep part of the cardiac plexus, and a branch on the left side passes through the thorax to the superficial part of the cardiac plexus.

(b) The **inferior (thoracic) cardiac branches.**—These branches on the right side arise in part from the recurrent nerve and in part from the main trunk of the vagus, while on the left side they usually arise entirely from the recurrent. All these branches pass to the deep part of the cardiac plexus (figs. 744, 786).

(7) The **bronchial (pulmonary) branches** are anterior and posterior (fig. 744).

(a) The **anterior bronchial (pulmonary) branches** consist of a few small branches which arise at the upper border of the root of the lung. They pass forward to gain the anterior aspect of the bronchus, where they communicate with the sympathetic and form the **anterior pulmonary plexus,** from which fine twigs pass along the bronchus.

(b) The **posterior bronchial (pulmonary) branches.**—Almost the entire remaining trunk of the vagus usually divides into these branches, which join with branches from the second, third, and fourth thoracic ganglia of the sympathetic to form the **posterior pulmonary plexus** (fig. 744). The plexuses of the two sides join freely behind the bifurcation of the trachea, and branches from the plexus pass along each bronchus into the lung.

(8) The **pericardial branches** pass from the trunk of the vagus or from the bronchial or œsophageal plexuses to the anterior and posterior surfaces of the pericardium. They are chiefly sensory.

(9) **Œsophageal branches,** given off by the trunk of the nerve above the bronchial plexuses and from the œsophageal plexuses lower down, pass to the wall of the œsophagus.

(10) **Abdominal branches.**—The terminal part of the left vagus divides into many branches, some of which communicate freely along the lesser curvature of the stomach with filaments from the gastric plexus of the sympathetic, and to some extent with branches of the right vagus, to form the elongated **anterior gastric plexus** (fig. 744). From this plexus as well as from the nerve-trunk, **gastric branches** are given to the anterior surface of the stomach. **Hepatic branches** from the trunk or from this plexus pass in the lesser omentum to the hepatic plexus (fig. 744). The terminal part of the right vagus divides into many branches, and forms along the lesser curvature of the stomach an elongated **posterior gastric plexus** by communications with branches from the gastric plexus of the sympathetic and with branches from the right vagus. **Gastric branches** are given off by the trunk of the nerve and from this plexus. **Cœliac branches** are given by the trunk to the cœliac (solar) plexus, and **splenic** and **renal branches,** either directly or through the cœliac (solar) plexus, are given to the splenic and renal plexuses (fig. 744).

Central connections.—The **sensory fibres** of the vagus are processes of the cells of the jugular ganglion and the ganglion nodosum. The peripheral fibres from these cells bring in sensory impulses from the periphery, and their central fibres convey the impulses to the brain. The latter fibres enter the medulla in the filaments of attachment in the postero-lateral sulcus, and, in the reticular formation, they bifurcate into ascending and descending branches which end in the nuclei of termination of the vagus, namely, in the nucleus alæ cinereæ in the floor of the fourth ventricle and in the nucleus tractus solitarii. The tractus solitarius consists largely of the descending branches. These and the axones arising from the nuclei of termination of the vagus descend the spinal cord to terminate about ventral horn cells which give origin to the phrenic nerve and to motor fibres supplying other muscles of respiration, and they also convey impulses which are distributed to visceral motor neurones along the spinal cord.

The **motor fibres** spring from the nucleus ambiguus and from the dorsal efferent (motor) nucleus of the vagus, described on page 820. They join the sensory fibres in the reticular formation. Some of the motor fibres, especially those from the dorsal efferent nucleus, are visceral motor fibres.

The central connections of the vagus are similar to those of the glosso-pharyngeal nerve (fig. 647). Van Gehuchten's observations point to the conclusion that the chief nucleus of termination of the vagus nerve is that of the tractus solitarius.

THE SPINAL ACCESSORY NERVE

The spinal accessory nerve [n. accessorius] is exclusively motor. It consists of two parts, the accessory or superior, and the spinal or inferior part.

The fibres of the **accessory or superior portion** [ramus internus] ("accessory vagus") spring chiefly from the inferior continuation of the nucleus ambiguus, in common with the motor fibres of the vagus above, and they pass through the reticular formation to the postero-lateral sulcus of the medulla, where they emerge as a series of filaments, below those of the vagus. The filaments pierce the pia mater and unite, as they pass outward in the posterior fossa of the cranium, to form a part of the nerve which enters the aperture in the dura mater common to the vagus and spinal accessory nerves. In the aperture this trunk is joined by the spinal portion of the nerve.

The **spinal** or **inferior portion** [ramus externus] arises from the ventro-lateral cells of the ventral horn of the cord as low as the fifth, and rarely the seventh, cervical nerve. The fibres pass dorsalward and lateralward from their origins through the lateral part of the ventral horn and through the lateral funiculus of white substance, and they emerge from the lateral aspect of the cord behind the ligamentum denticulatum, along an oblique line, the lower fibres passing out immediately dorsal to the ligament, and the upper close to and sometimes in association with the dorsal roots of the upper two spinal nerves. As the spinal fibres pass out of the surface of the cord they unite to form an ascending strand which enters the posterior fossa of the cranium, through the foramen magnum, and, turning lateralward, blends more or less intimately with the accessory portion. Thus combined, the nerve enters the jugular foramen in company with the vagus, but here it is again separated into its two branches, which contain chiefly the same fibres as the original superior and inferior parts.

The **superior branch,** or accessory portion of the nerve, gives one or more filaments to the jugular ganglion (ganglion of the root of the vagus), and then joins either the trunk of the vagus directly or its ganglion nodosum, the fibres of the branch being contributed to the pharyngeal, laryngeal, and cardiac branches of the vagus. Fibres corresponding to the white rami communicantes, absent in the cervical nerves, probably enter the cervical sympathetic ganglion through this ramus of the spinal accessory nerve. The fibres from the accessory to the vagus therefore probably include visceral motor and cardio-inhibitory fibres.

The **inferior branch** or the spinal portion runs backward and downward under cover of the posterior belly of the digastric and the sterno-mastoid. It usually crosses in front of and to the lateral side of the internal jugular vein and between it and the occipital artery; then it pierces the *sterno-mastoid*, supplies filaments to it, and interlaces in its substance with branches of the second cervical nerve. It emerges from the posterior border of the sterno-mastoid slightly above the level of the upper border of the thyreoid cartilage, passes obliquely downward and backward across the occipital portion of the posterior triangle, and disappears beneath the trapezius about the junction of the middle and lower thirds of the anterior border of that muscle (fig. 743). In the posterior triangle it receives communications from the third and fourth cervical nerves, and beneath the trapezius its fibres form a plexus with other branches of the same nerves. Its terminal filaments are distributed to the *trapezius* and they can be traced almost to the lower extremity of that muscle.

Central connections.—The nuclei of origin, like other motor nuclei, are connected with the somæsthetic area of the cerebral cortex of the opposite side by the pyramidal fibres, and they are associated with the sensory nuclei of other cranial nerves by the medial longitudinal fasciculus, and with sensations brought in by the spinal nerves by the fibres of the fasciculi proprii.

THE GANGLIATED CEPHALIC PLEXUS

The Sympathetic Ganglia of the Head and Their Associations with the Cranial Nerves

The sympathetic system of the head, like that of the remainder of the body described below, is arranged in the form of a continuous gangliated plexus subdivided into sub-plexuses. Unlike the great unpaired prevertebral plexuses in the thoracic and abdominal cavities, all the larger sympathetic ganglia of the head are paired, ganglia corresponding to each other being found on either side. Thus they may be considered as an upward extension of the series of paired lumbar, thoracic and cervical ganglia belonging to the sympathetic trunks lying along either side of the vertebral column. Numerous small ganglia, many of them microscopic, occur in the sub-plexuses throughout the head. These are irregular in size and position and those in the region of the median line are no doubt unpaired.

In **origin**, the ganglia of the cephalic plexus consist of cell-bodies which, in the early stages of development, migrated from the fundaments of the ganglia of the vagus, glosso-pharyngeal and glosso-palatine nerves, and most especially from that of the semilunar (Gasserian) ganglion of the trigeminus—a developmental relation identical with that of the remainder of the sympathetic system to the ganglia of the spinal nerves. Just as is known for the spinal ganglia, some cell-bodies destined to develop into sympathetic neurones, instead of migrating, remained within the confines of the ganglia of the above nerves, in company with the cell-bodies of their sensory neurones. This is thought to be especially true for the geniculate, the petrosal and the jugular ganglion. Therefore these ganglia must be considered as in small part sympathetic ganglia.

The gangliated cephalic plexus could properly be included as a division of the general sympathetic system described later. However, because its larger ganglia are so intimately associated with branches of the oculomotor, trigeminal, masticator, glosso-palatine, glosso-pharyngeal and vagus nerves, it is customary to describe it in connexion with the cranial nerves.

The larger **ganglia,** one on either side of the head, comprise the ciliary ganglion, the spheno-palatine (Meckel's) ganglion, the otic and the submaxillary ganglion. To these must be added portions of the geniculate, petrosal, jugular and the ganglion nodosum, and a part of the superior cervical sympathetic ganglion. The chief relations of the gangliated cephalic plexus to the cranial nerves are shown in fig. 741.

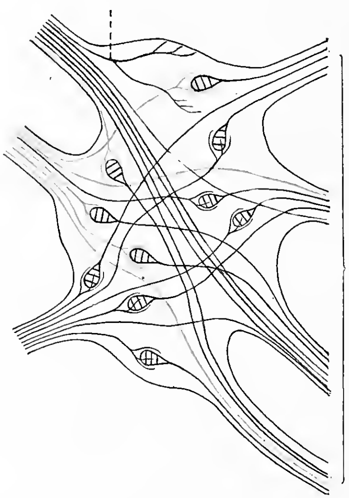
The so-called **roots and branches of the ganglia** carry three varieties of fibres: (1) Sensory, (2) Motor (visceral motor or preganglionic), and (3) Sympathetic. Most roots and branches are mixed, the name of a root being determined only by the variety of fibres predominating in it.

A bundle of sensory fibres going to a ganglion is called its **sensory root.** Such, however, cannot comprise a true root since none of its fibres arises in the ganglion and very few or none may terminate in it. The only sensory fibres terminating in a ganglion are the few which may approach it in any of the roots to terminate in its capsule or the capsules of its cells and convey impulses of general sensibility from the ganglion to the central nervous system. Almost all of the fibres of a "sensory root" merely pass around or through a ganglion and into its branches beyond, which they borrow as paths for reaching their allotted fields of distribution. In this relation it should be realized that while the ciliary, spheno-palatine, otic and submaxillary ganglia are customarily described under the discussion of the trigeminus, this nerve has functionally less to do with them than any of the other cranial nerves with which they are associated. Bundles of trigeminal (sensory) fibres, traceable in gross anatomy because medullated and of appreciable size, pass to the ganglia, but only to pass through them as continuations of the terminal branches of the trigeminus.

The so-called **motor root** of a ganglion may carry two kinds of fibres: (a) visceral motor (preganglionic) fibres, arising in the nuclei of origin in the central system and passing in the trunk and branches of a cranial nerve (oculomotor, masticator, etc.) to enter and terminate in contact with the cell-bodies of the ganglion, which, in their turn, give fibres to the branches of the ganglion; (b) fibres of the same origin, name and course but which may pass through the ganglion to terminate in contact with the cells of a more distant ganglion. Any root, the motor especially, may contain somatic motor fibres, that is, fibres of central origin which pass through the ganglion uninterrupted and into its branches to terminate upon the fibres of skeletal (voluntary) muscle.

A **sympathetic root** likewise may carry two and perhaps three varieties of fibres conforming to the name: (a) fibres arising from the cells of other sympathetic ganglia and terminating in the ganglion in question; (b) fibres arising in other ganglia which pass through the ganglion in question to enter its branches and terminate either in other ganglia or upon their allotted muscular or glandular elements. A third is the fibre of the sensory sympathetic neurone, probably quite rare, which may arise from a cell-body in the ganglion and pass centralward in its root and in the appropriate cranial nerve to terminate about a cell-body of the dorsal-root or spinal ganglion type, the central process of which latter conveys this sensory impulse of sympathetic origin into the central system just as sensory cranio-spinal impulses are conveyed.

Fig. 745.—Diagram to Illustrate the Structural Relations of the Roots and Branches of a Cephalic Sympathetic Ganglion. Sensory fibres, blue; motor, red; sympathetic, black.



The **branches of distribution** of the ganglia, the larger of them often called nerves, are those bundles in which the fibres, both arising in or passing through the ganglia, course toward their terminations upon their allotted tissue elements of the head. The larger ganglia of the head are described as each possessing the three roots above mentioned. In the branches pass fibres motor to the vessels of the head, to the intrinsic muscles of the eye bulb, to the lacrimal glands, the mucous membranes (gland cells) of the nasal and oral cavities and the salivary glands, and sensory fibres conveying impulses from these structures.

The **plexuses** into which the gangliated cephalic plexus is divided and which connect the ganglia to form it, are numerous and vary greatly in size. They underlie the mucous membranes and they surround all the vessels and glands. They are named according to their locality. The largest of them are the tympanic plexus and the carotid and cavernous plexuses. They have been repeatedly referred to in their relations to the branches of the cranial nerves.

Of the numerous branches described from the **superior cervical sympathetic ganglion**, the two large ones which pass upward associate it especially with the gangliated cephalic plexus. That branch known as the *internal carotid nerve* may be considered as the direct continuation upward of the gangliated sympathetic trunk of the body. Through the branches of this, the carotico-tympanic and the deep petrosal nerves, and through the plexuses derived from it, the superior cervical ganglion may be associated with practically all the other sympathetic ganglia of the head (figs. 739 and 741). The other branch from the superior cervical ganglion, the *jugular nerve*, associates it with the ganglia of the glosso-pharyngeal and vagus nerves, with the petrosa ganglion by a direct branch and with the ganglia of the vagus through the nodosal plexus. These latter ganglia (and the nerves to which they belong) are connected, chiefly by way of the tympanic nerve, which is from the petrosal ganglion, with the tympanic plexus (fig. 741).

The **tympanic plexus** serves as a common point of distribution of fibres from the superior cervical sympathetic ganglion, the ganglia of the vagus, the petrosal ganglion, and the geniculate ganglion, to the cavernous and carotid plexuses and to the spheno-palatine and otic ganglia. The superior cervical ganglion is associated with the cavernous and carotid plexuses direct by the internal carotid nerve and with the tympanic plexus by the inferior and superior carotico-tympanic nerves. The tympanic plexus receives fibres from the geniculate ganglion by a small *geniculo-tympanic branch* and it is connected with the spheno-palatine ganglion by a small anastomotic or *tympano-petrosal branch* to the great superficial petrosal nerve, and with the otic ganglion by the small superficial petrosal nerve. It is not directly connected with either the ciliary or the submaxillary ganglion. However, these ganglia, as well as the sphenopalatine and otic, are connected with the carotid plexus either directly by named branches or indirectly by way of plexuses derived from the carotid. The geniculo-tympanic branch, the tympanic nerve and twigs of the nodosal plexus may be considered as analogous to the rami communicantes of the spinal nerves.

The *parotid branches*, described above as branches of the auriculo-temporal nerve (from the trigeminus) and as containing fibres from the glossopharyngeal, should be mentioned here as belonging to the gangliated cephalic plexus. These branches are sympathetic fibres arising in the otic ganglion and passing as branches of the ganglion to the auriculo-temporal in which they remain till this nerve enters the parotid gland and then they are distributed to the gland. The visceral motor or preganglionic fibres which terminate about their cells of origin in the otic ganglion are derived from the glosso-pharyngeal nerve and pass successively through the tympanic nerve, the tympanic plexus, and the small superficial petrosal nerve to the otic ganglion.

The *tympanic nerve* (tympanic branch of the glosso-pharyngeal, or nerve of Jacobson), the branch to the Eustachian tube (*ramus tubæ*), and the superior and inferior *carotico-tympanic branches* are also described as branches of the glosso-pharyngeal nerve. These must likewise be considered as belonging to the gangliated cephalic plexus.

For purposes of dissection, it may be more expedient to consider separately, with its roots and branches, each of the larger ganglia of the gangliated cephalic plexus. Under this heading belong in part the *geniculate ganglion* of the glosso-palatine nerve, and the *ganglia of the glosso-pharyngeal and vagus*, especially the petrosal ganglion of the former and the jugular ganglion of the latter, from the fact that these ganglia contain numerous cell-bodies of sympathetic neurones as well as those of the sensory neurones of their nerves.

These ganglia, however, have been described with their corresponding cranial nerves. The sensory and motor roots of their sympathetic portions are contained in the roots of their nerves. The geniculate probably has no sympathetic root. The sympathetic roots of the petrosal and jugular ganglia are contained in the branches of the jugular nerve. The chief branches of distribution of the geniculate are the geniculo-tympanic branch, the great superficial petrosal nerve, and the external superficial petrosal nerve. The branches of the petrosal ganglion are the tympanic nerve and its branches of the tympanic plexus. The chief branch of distribution from the jugular ganglion is contained in the auricular branch of the vagus, or nerve of Arnold, supplemented by sympathetic fibres in the trunk of the vagus itself.

The principal cephalic sympathetic ganglia are the ciliary, the spheno-palatine (Meckel's), the otic and the submaxillary.

The Ciliary Ganglion

The ciliary, lenticular, or ophthalmic ganglion lies in the posterior part of the orbital cavity, about 6 mm. in front of the superior orbital (sphenoidal) fissure, to the lateral side of the optic nerve, and between the optic nerve and the external rectus muscle. It is a small, reddish, quadrangular body, compressed laterally, and it measures about two millimetres from before backward (fig. 734).

Roots.—(*a*) Its motor or short root enters its lower and posterior angle and is a visceral motor branch derived from the branch of the inferior division of the oculomotor nerve which supplies the inferior oblique muscle. The fibres of the motor root probably all terminate in the ciliary ganglion in connection with motor sympathetic neurones.

(*b*) The sensory or long root passes through the upper and back part of the ganglion. It is a branch of the naso-ciliary (nasal) nerve and is, therefore, composed of fibres from the trigeminus passing through the ganglion.

(*c*) The sympathetic root consists of fibres derived from the cavernous plexus of the sympathetic; it passes to the ganglion with the long root.

Branches.—From three to six **short ciliary nerves** emerge from the anterior border of the ganglion; they divide as they pass forward and eventually form about twenty nerves which are arranged in an upper and a lower group, and the latter group is joined by the long ciliary branches of the naso-ciliary (nasal) nerve, now sensory and sympathetic (fig. 734). When they reach the eyeball, the ciliary nerves pierce the sclerotic around the optic nerve, and pass forward in grooves on the inner surface of the sclera. The sympathetic fibres contained are distributed as motor fibres to the ciliary muscle, the sphincter of the iris, and to the vessels of these and of the cornea.

The Spheno-palatine or Meckel's Ganglion

This ganglion is associated with the maxillary nerve (fig. 743). It is a small reddish-grey body of triangular form, which is flattened at the sides, and measures about five millimetres from before backward. It lies deeply in the pterygo-palatine (spheno-maxillary) fossa at the lateral side of the spheno-palatine foramen and in front of the anterior end of the pterygoid (Vidian) canal. It is attached to the maxillary nerve, from which it receives its sensory root, and it is connected with the Vidian nerve, which furnishes it with motor and sympathetic filaments (fig. 739).

The exact position of the ganglion depends upon the size and shape of the sphenoidal air cells. When these are small, or high and narrow, the ganglion lies lateral to them; when they are large, or broad and flat, the ganglion lies inferior to them. Sometimes it may lie anterior to them if the cells are short from in front backward. The ganglion may be reached with ease by chipping away the bone around the sphenoidal air cells after the skull is divided sagitally.

Roots.—(*a*) Its **motor root**, consisting of visceral motor fibres of the glosso-palatine nerve, is contained in the great superficial petrosal nerve which is incorporated in the Vidian nerve. It springs from the anterior angle of the geniculate ganglion and passes through the hiatus of the facial canal (hiatus Fallopii) into the middle fossa of the cranium, where it runs forward and medialward, in a groove on the upper surface of the petrous part of the temporal bone, to the foramen lacerum, and in this part of its course it passes beneath the semilunar (Gasserian) ganglion and the masticator nerve. In the foramen lacerum it joins with the great deep petrosal nerve to form the Vidian nerve (nerve of the pterygoid canal), which passes forward through the pterygoid (Vidian) canal and its motor and sympathetic fibres terminate in the spheno-palatine ganglion in the pterygo-palatine (spheno-maxillary) fossa. The great superficial petrosal nerve contains sensory as well as sympathetic and motor fibres. The sensory fibres pass through the ganglion and, in the small palatine nerve, descend to the soft palate, where they terminate in the epithelium covering it and some are probably concerned with peripheral taste organs found there. They arise from the cells of the geniculate ganglion and therefore belong to the glosso-palatine nerve.

(*b*) The **sympathetic root** is the great deep petrosal portion of the Vidian nerve. This root, which is of reddish colour and of soft texture, springs from the carotid plexus which lies on the outer side of the internal carotid artery in the carotid canal. It enters the foramen lacerum through the apex of the petrous portion of the temporal bone, and unites with the great superficial petrosal branch of the facial nerve to form the Vidian nerve. The great superficial petrosal nerve also carries sympathetic fibres to the spheno-palatine ganglion, derived from the geniculate ganglion and from the tympanic plexus.

The **Vidian nerve [n. canalis pterygoidei]** commences by the union of the great superficial and deep petrosal nerves in the foramen lacerum, and runs forward through the pterygoid (Vidian) canal to the pterygo-palatine (spheno-maxillary) fossa to the spheno-palatine ganglion. The Vidian nerve often may be seen in a ridge of bone along the floor of the sphenoidal cells and its direction there depends upon the position of the spheno-palatine ganglion. While it is in the pterygoid canal the Vidian nerve is joined by a sphenoidal filament from the otic ganglion, and it gives branches to the upper and back part of the roof and septum of the nose, and to the lower end of the Eustachian tube.

(*c*) The **sensory roots** consist of the sensory fibres mentioned above in the great superficial petrosal nerve and of usually two spheno-palatine branches from the maxillary nerve. The majority of the fibres of these roots do not join the ganglion, but pass by its medial side and enter the palatine branches.

Branches.—The branches of the ganglion, containing sensory, vaso-motor and secretory fibres, are orbital or ascending, internal or nasal, descending or palatine, and posterior or pharyngeal.

Ascending branches.—The **orbital** or **ascending branches** are two or three small twigs which enter the orbit through the inferior orbital (spheno-maxillary) fissure and proceed, within the periosteum, to the inner wall of the orbit, where they pass through the posterior ethmoidal foramen and through the foramina in the suture behind that foramen to be distributed to the mucous membrane which lines the posterior ethmoidal cells and the sphenoidal sinus.

Internal branches.—The internal or nasal branches are derived in part from the medial side of the ganglion, but are also largely made up of fibres which pass from the spheno-palatine branches of the maxillary nerve without traversing the ganglionic substance. They are disposed in two sets, the lateral and the medial (septal) posterior superior nasal branches.

The **lateral posterior superior nasal branches** are six or seven small twigs which pass through the spheno-palatine foramen, and are distributed to the mucous membrane covering the posterior parts of the superior and middle nasal conchæ (turbinated bones) (fig. 732). They also furnish twigs to the lining membrane of the posterior ethmoidal cells.

The **medial posterior superior nasal (septal) branches**, two or three in number, pass medialward through the spheno-palatine foramen. They cross the roof of the nasal fossa to reach the back part of the nasal septum, where the smaller twigs terminate. The largest nerve of the set, the **naso-palatine nerve**, or **nerve of Cotunnius**, runs downward and forward in a groove in the vomer between the periosteum and the mucous membrane to the incisive (anterior palatine) canal, where it communicates with the nasal branch of the anterior superior alveolar nerve. The two naso-palatine nerves then pass through the foramina of Scarpa in the intermaxillary suture, the left nerve passing through the anterior of the two foramina. In the lower part of the incisive (anterior palatine) canal the two nerves form a plexiform communication (formerly described as Cloquet's ganglion) and they furnish twigs to the anterior or premaxillary part of the hard palate behind the incisor teeth. In this situation they communicate with the anterior palatine nerves.

Descending branches.—The descending branches are the great or anterior, the posterior, and the middle (external) palatine nerves. Like the internal set of branches, they are in part derived from the ganglion and in part are directly continuous with the spheno-palatine nerves (fig. 732).

The **great or anterior palatine nerve**, its sensory fibres derived from the maxillary nerve, arises from the inferior angle of Meckel's ganglion, and passes downward through the pterygo-palatine canal, accompanied by the descending palatine artery. Emerging from the canal at the greater (posterior) palatine foramen it divides into two or three branches, which pass forward in grooves in the hard palate and supply the glands and mucous membrane of the hard palate and the gums on the inner aspect of the alveolar border of the upper jaw. During its course through the pterygo-palatine canal the anterior palatine nerve gives off the **posterior inferior nasal nerves.** These nerves pass through small openings in the perpendicular plate of the palate bone to supply the mucous membrane covering the posterior part of the inferior nasal concha (turbinated bone) and the adjacent portions of the middle and inferior meatuses of the nose.

The **posterior** or **small palatine nerve** passes downward through a lesser palatine foramen (accessory palatine canal), and enters the soft palate, distributing branches to that organ, to the uvula, and to the tonsil. Its sensory fibres are derived from the glosso-palatine nerve, through the great superficial petrosal nerve and through the spheno-palatine ganglion. It was formerly believed to convey motor fibres from the facial nerve to the levator palati and azygos uvulæ, but it is now believed that these muscles are supplied by the spinal accessory nerve through the pharyngeal plexus (fig. 732).

The **middle (external) palatine nerve,** the smallest of the three, in part, likewise from the glosso-palatine nerve, traverses a lesser palatine foramen and supplies twigs to the tonsil and to the adjacent part of the soft palate (fig. 732).

Posterior branch.—The **pharyngeal branch,** which is of small size, passes backward and somewhat medialward through the pharyngeal canal accompanied by a pharyngeal branch of the spheno-palatine artery. It is distributed to the mucous membrane of the uppermost part of the pharynx, to the upper part of the posterior nares, to the opening of the Eustachian tube, and to the lining of the sphenoidal sinus. Its sensory fibres are derived from the maxillary nerve.

The Otic Ganglion

The otic or Arnold's ganglion is a small reddish-grey body which is associated with the mandibular nerve. It lies deeply in the zygomatic fossa, immediately below the foramen ovale, on the inner side of the trunk of the mandibular nerve. It is in relation internally with the tensor palati, which separates it from the Eustachian tube. In front of it is the posterior border of the pterygoideus internus, and behind it lie the middle and small meningeal arteries. It is compressed laterally, and its greatest diameter, which lies antero-posteriorly, is about three millimetres.

Roots.—The ganglion is closely connected with the nerve to the pterygoideus internus, through which it may receive a motor root from the masticator nerve. Through the small superficial petrosal nerve, which joins the upper and back part of the ganglion, it receives a motor root from the glosso-palatine nerve and sensory and motor fibres from the glosso-pharyngeal nerve. It receives also a slender *sphenoidal filament* from the Vidian nerve. The **sympathetic roots** are derived from the small superficial petrosal nerve and from the sympathetic plexus on the middle meningeal artery.

Branches.—The communicating branches which pass from the ganglion are:—(1) The filaments to the chorda tympani; some of whose fibres probably terminate in the submaxillary ganglion; (2) filaments to the auriculo-temporal nerve; (3) filaments to the spinous nerve (the recurrent branch of the mandibular nerve). The branches of distribution are sympathetic to the vessels and somatic motor branches to the tensor tympani, and tensor veli palatini.

The Submaxillary Ganglion

The submaxillary ganglion is suspended from the lingual division of the mandibular nerve by anterior and posterior branches. It is a small reddish body, of triangular or fusiform shape, which lies between the mylo-hyoideus and hyoglossus and above the duct of the submaxillary gland.

Roots.—The **sensory root** is received from the lingual nerve. The **motor root** is from both the masticator nerve by way of the lingual nerve, and from the glosso-palatine nerve by way of the chorda tympani. The motor fibres pass from the chorda tympani after it has joined the lingual, and the sensory fibres come directly from the lingual nerve. The **sympathetic root** is formed by filaments from the sympathetic plexus on the facial artery.

Branches.—(*a*) Five or six glandular branches are given to the submaxillary gland and to Wharton's duct.

(*b*) Branches to the lingual nerve and the sublingual gland.

(*c*) To the mucous membrane of the floor of the mouth.

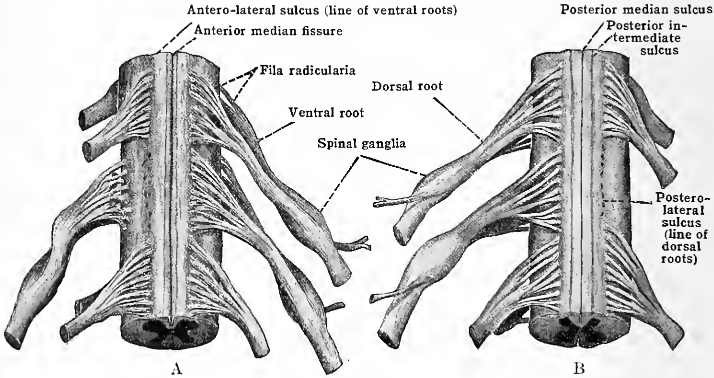
II. THE SPINAL NERVES

The spinal nerves are arranged in pairs, the nerves of each pair being symmetrical in their attachment to either side of their respective segment of the spinal cord, and, in general, symmetrical in their course and distribution. There are usually thirty-one pairs of functional spinal nerves. For purposes of description these are topographically separated into *eight* pairs of *cervical* nerves, *twelve* pairs of *thoracic* nerves, *five* pairs of *lumbar*, *five* pairs of *sacral*, and *one* pair of *coccygeal* nerves. Occasionally the coccygeal or thirty-first pair is practically wanting, while, on the other hand, there may be frequently found small filaments representing one or even two additional pairs of coccygeal nerves below the thirty-first pair. These **rudimentary coccygeal nerves** are probably not functional. They never pass outside the vertebral canal, and often even remain within the tubular portion of the filum terminale. There sometimes occurs an increase in the number of vertebræ in the vertebral column and in such cases there is always a corresponding increase in the number of the spinal nerves.

Origin and attachment.—Each spinal nerve (unlike the cranial nerves) is attached to the spinal cord by two roots:—a sensory or afferent **dorsal root** [radix posterior] and a motor or efferent **ventral root** [radix anterior]. Each dorsal root has interposed in its course an ovoid mass of nerve-cells, the **spinal ganglion,** and the nerve-fibres forming the root arise from the cells of this ganglion and are thus of peripheral origin. The fibres composing the ventral root, on the other hand, are of central origin; they arise from the large motor cells of the ventral horn of the grey column within the spinal cord.

Each dorsal root-fibre upon leaving its cell of origin pursues a short tortuous course within the spinal ganglion and then undergoes a **T**-shaped bifurcation, one product of which passes toward the periphery, where it terminates for the collection of sensations and is known as the *peripheral branch*, or, since it conveys impulses toward the cell-body, the *dendrite* of the spinal

Fig. 746.—Ventral and Dorsal Views of Spinal Cord showing Manner of Attachment of Dorsal and Ventral Roots.



ganglion neurone. It is more correct, however, to consider the **T**-fibre as a bifurcated axone. The other product of the bifurcation, the *central branch,* passes into the spinal cord and in its course toward the cord contributes to form the dorsal root proper.

The central branches, upon emerging from the spinal ganglia, form a single compact bundle at first, which passes through the dura mater of the spinal cord and then breaks up into a series of **root-filaments** [fila radicularia]. These thread-like bundles of fibres spread out vertically in a fan-like manner and enter the cord in a direct linear series along its postero-lateral sulcus. The fibres of the ventral root emerge from the cord in a series of more finely divided root filaments, which, unlike the entering filaments of the dorsal root, are not arranged in direct linear series, but make their exit over a strip of the ventro-lateral aspect of the cord in some places as much as two millimetres wide.

As they enter the spinal cord the fibres of the dorsal roots undergo a **Y**-shaped division, both products of which course in the cord longitudinally, an ascending and a descending branch. The descending or caudal branches are shorter than the ascending, and soon enter and terminate about the cells within the grey column of the cord, forming either associational, commissural, or reflex connections, or about cells whose fibres form cerebellar connections. The ascending or cephalic branches are either short, intermediate, or long. The short and intermediate branches are similar in function to the descending branches, save that they become associated with the grey substance of segments of the cord above rather than below the level of their entrance. The long branches convey impulses destined for the structures of the brain, and pass upward in the fasciculus gracilis or fasciculus cuneatus of the cord, and terminate in the nuclei of these fasciculi in the medulla oblongata (figs. 618 and 620).

Aberrant spinal ganglia.—In serial sections on either side of the spinal ganglion of a nerve there may often be found outlying cells either scattered or in groups of sufficient size to be called small ganglia. Such are more often found in the dorsal roots of the lumbar and sacral nerves. These cells are nothing more than spinal ganglion-cells displaced in the growth processes, and have the same nature and function as those in the ganglion. In some animals occasional cells very rarely have been found in the outer portion of the ventral root. These probably represent afferent fibres which enter the cord by way of the ventral root. Likewise, especially in the birds and amphibia, it has been shown that occasional efferent fibres may pass from the grey substance of the cord to the periphery by way of the dorsal instead of the ventral root.

Relative size of the roots.—The sensory or dorsal root is larger than the ventral root, indicating that the sensory area to be supplied is greater and perhaps more abundantly innervated than the area requiring motor fibres.

It has been shown that in the entire thirty-one spinal nerves of one side of the body of man the dorsal root-fibres number 653,627, while all the corresponding ventral roots contain but 233,700 fibres, a ratio of 3.2 : 1. (Ingbert.) In the increase in the size of the nerves for the supply of the limbs the gain of dorsal root or sensory fibres is far greater than the gain of ventral root-fibres. The first cervical or the sub-occipital nerve is always an exception to the rule; its dorsal root is always smaller than its ventral, and in rare cases may be rudimentary or entirely absent. The spinal ganglion and, therefore, the sensory root of the coccygeal nerve, is also quite frequently absent.

The dorsal and ventral root-fibres of each spinal nerve proceed outward from their segment of attachment to the spinal cord, pierce the pia mater and arachnoid, collect to form their respective roots, and pass into their respective intervertebral foramina. On the immediate peripheral side of the spinal ganglion the two roots blend, giving origin to the thus mixed **nerve-trunk.** As the trunk, the sensory and motor fibres make their exit from the vertebral canal through the intervertebral foramen.

Relation to the meninges.—The root filaments of each nerve receive connective-tissue support from the pia mater and arachnoid in passing through them. In the sub-arachnoid cavity they become assembled into their respective nerve-roots; and the roots, closely approaching each other, pass into the dura mater, from which they receive separate sheaths at first, but at the peripheral side of the ganglion these sheaths blend into one, which, with the subsequent blending of the roots, becomes the sheath or epineurium of the nerve trunk. By means of the sheaths derived from the meninges, especially the dura, the nerve-roots and the trunk are attached to the periosteum of the margins of the intervertebral foramina and thus are enabled to give some lateral support to the spinal cord in the upper portion of the canal.

The majority of the spinal ganglia lie in the intervertebral foramina, closely ensheathed, and thus outside the actual sac or cavity of the dura mater. The ganglia of the last lumbar and first four sacral nerves lie inside the vertebral canal, but since the sheath derived from the dura mater closely adheres to them, they are still outside the sac of the dura mater. The ganglia of the last sacral and of the coccygeal nerves (when present) lie in tubular extensions of the sub-dural cavity, and thus not only within the vertebral canal, but actually within the sac of the dura mater. The trunk of the first cervical nerve is assembled within the sac of the dura mater, and, therefore, the spinal ganglion of this nerve, when present, may lie within the sac.

Course and direction of emergence.—Invested with the connective-tissue sheath derived from the meninges, each thoracic, lumbar and sacral nerve emerges from the vertebral canal through the intervertebral foramen below the corresponding vertebra, and all the nerves are in relation with the spinal rami of the arteries and veins associated with the blood supply of the given localities of the spinal cord.

The first cervical nerve does not pass outward in an intervertebral foramen proper, but between the occipital bone and the posterior arch of the atlas and beneath the vertebral artery. Thus the eighth or last cervical nerve emerges between the seventh cervical and the first thoracic vertebra.

The first and second pairs of cervical nerves pass out of the vertebral canal almost at right angles to the levels of their attachment to the spinal cord. During the early periods of development the level of exit of each pair of spinal nerves is opposite the level of its attachment to the cord, but, owing to the fact that in the later periods the vertebral column grows more rapidly than the cord and increases considerably in length after the cord has practically ceased growing, all the spinal nerves, with the exception of the first two, pass downward as well as outward. The obliquity of their course from the level of attachment to the level of exit increases progressively from above downward, and, as the cord ends at the level of the first or second lumbar vertebra, the roots of the lower lumbar and of the sacral nerves pass at first vertically downward within the dura mater, and form around the filum terminale a tapering sheaf of nerve-roots, the **cauda equina** (horse's tail) (fig. 613, p. 773).

Topography of attachment.—The relations between the levels of attachment of the spinal nerves to the cord and the spinous processes of the vertebræ situated opposite these levels have been investigated by Nuhn and by Reid. The following table compiled by Reid gives the extreme limits of attachment as observed in six subjects.

Table of Topography of Attachment of Spinal Nerves to the Spinal Cord. (Reid.)

(A) signifies the highest level at which the root filaments of a given nerve are attached to the cord, and (B) the lowest level observed. For example, the root filaments of the sixth thoracic nerve *may* be attached as high as the lower border of the spinous process of the second thoracic vertebra, or some may be attached as low as the upper border of the spinous process of the fifth thoracic vertebra, but in a given subject they do not necessarily extend either as high or as low as either of the levels indicated.

Nerves		
Second cervical	(A)	A little above the posterior arch of atlas.
	(B)	Midway between posterior arch of atlas and spine of epistropheus.
Third "	(A)	A little below posterior arch of atlas.
	(B)	Junction of upper two-thirds and lower third of spine of epistropheus.
Fourth "	(A)	Just below upper border of spine of epistropheus.
	(B)	Middle of spine of third cervical vertebra.
Fifth "	(A)	Just below lower border of spine of epistropheus.
	(B)	Just below lower border of spine of fourth cervical vertebra.
Sixth "	(A)	Lower border of spine of third cervical vertebra.
	(B)	Lower border of spine of fifth cervical vertebra.
Seventh "	(A)	Just below upper border of spine of fourth cervical vertebra.
	(B)	Just above lower border of spine of sixth cervical vertebra.
Eighth "	(A)	Upper border of spine of fifth cervical vertebra.

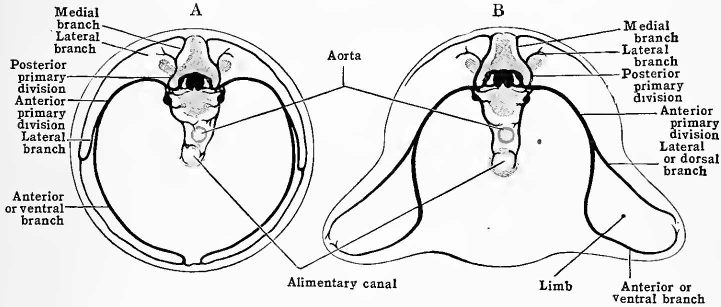
Fifth "	(B)	Lower border of spine of first lumbar vertebra.
Coccygeal	(A)	Lower border of spine of first lumbar vertebra.
	(B)	Just below upper border of spine of second lumbar vertebra.

Relative size of the nerves.—The size of the different spinal nerves varies greatly. Just as the spinal cord shows marked enlargements in the cervical and lumbar regions necessitated by the greater amount of innervation required of these regions for the structures of the upper and lower limbs, so the nerves attached to these regions are considerably larger than elsewhere.

The smaller nerves are found at the two extremities of the cord and in the mid-thoracic region. The smallest nerve is the coccygeal, and the next in order of size are the lower sacral and the first two or three cervical nerves. The largest nerves are those which contribute most to the great nerve trunks for the innervation of the skin and muscles of the limbs:—the lower cervical and first thoracic for the upper limbs and the lower lumbar and first sacral for the lower limbs. The nerves gradually increase in the series in passing from the smaller toward the larger.

Fig. 747.—Diagrams Illustrating the Origin and Distribution of a Typical Spinal Nerve.

A, in thoracic region; B, in region of a limb (highly schematic).



The primary divisions of the nerve-trunk.—A typical spinal nerve (middle thoracic, for example), just as it emerges from the intervertebral foramen, divides into four branches:—the two large primary divisions; viz., the **posterior primary division** [ramus posterior] and the **anterior primary division** [ramus anterior]; third, the small **ramus communicans,** by which it is connected with the sympathetic; and fourth, the smaller, **ramus meningeus** (*recurrent branch*), which immediately turns centralward for the innervation of the membranes and vessels of the spinal cord.

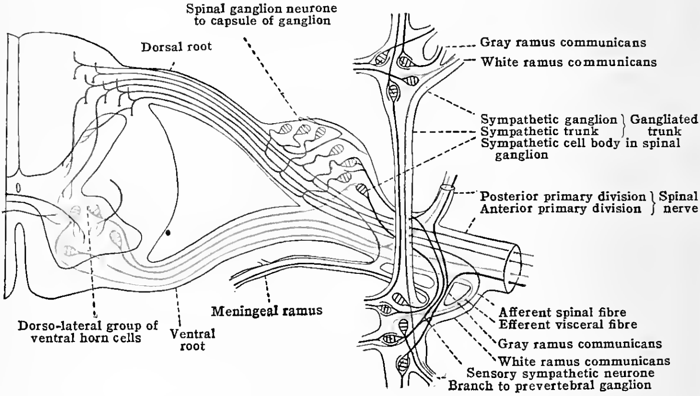
In general, the **posterior primary division** passes dorsalward between the arches or transverse processes of the two adjacent vertebræ in relation with the anterior costo-transverse ligament, and then divides (with the exception of the first cervical, the fourth and fifth thoracic, and the coccygeal nerves) into a **medial (internal) branch** and a **lateral (external) branch.** The medial branch turns toward the spinous processes of the vertebræ, and supplies the bones and joints and the muscles about them, and may or may not supply the skin overlying them. The lateral branch turns dorsalward and also supplies the adjacent muscles and bones, and, if the medial branch has not supplied the overlying skin, it also terminates in cutaneous twigs.

In the upper half of the spinal nerves the medial branches supply the skin; in the lower balf, it is the lateral branches which do so. Both branches of almost all the posterior divisions, especially those of the lower nerves, show a tendency to run caudalward and thus are distributed to muscles and skin below the levels of their respective intervertebral foramina. They never supply the muscles of the limbs, though their cutaneous distribution extends upon the buttock, the shoulder, and the skin of the back of the head as far upward as the vertex. The posterior primary divisions, with the exception of those of the first three cervical nerves, are much smaller than the anterior primary divisions.

As their mixed function suggests, the posterior primary divisions contain both nerve-fibres from the ventral roots and peripheral processes of the spinal ganglion-cells. If the nerve-trunk on the immediate peripheral side of the spinal ganglion be teased, bundles of ventral root-fibres may be seen crossing the trunk obliquely to enter the posterior division, and fibres from the spinal ganglion may be also traced into it. Also a few sympathetic fibres, derived chiefly by way of the ramus communicans, are known to course in it for distribution in the walls of the blood-vessels, etc., of the area it supplies.

The anterior primary divisions run lateralward and ventralward. With the exception of the first two cervical nerves, which contribute the hypoglossal loop, they are larger than the posterior primary divisions, and appear as direct continuations of the nerve-trunks. Only in case of most of the thoracic nerves do they remain independent in their course. In these they run lateralward and ventralward in the body-wall. In general, these divisions supply the lateral and ventral

Fig. 748.—Diagram Illustrating the Origin of the Component Nerve-fibres of the Primary Divisions of a Typical Spinal Nerve.



parts of the body, the limbs, and the perineum. In the cervical, lumbar, and sacral regions they lose their anatomical identity by dividing, subdividing, and anastomosing with each other so as to give rise to the three great spinal plexuses of the body—the **cervical,** the **brachial,** and the **lumbo-sacral plexuses.** The majority of the thoracic nerves retain the typical or primitive character in both their anterior and posterior primary divisions. In them the anterior division (intercostal nerve) divides into a **lateral** or dorsal and an **anterior** or ventral branch, both of which subdivide. The lateral branch is chiefly cutaneous; it pierces the superficial muscles and, in the subcutaneous connective tissue, divides into a smaller posterior and a larger anterior ramus, which respectively supply the skin of the sides and the lateral part of the ventral surface of the body. The anterior branch continues ventralward in the body-wall, giving off twigs along its course to the adjacent muscles and bones, and, as it approaches the ventral mid-line of the body, it turns sharply lateralward and sends rami medialward and lateralward to supply the skin of the ventral aspect of the body. In the region of the limbs the typical arrangement is interfered with in that what corresponds to the lateral and anterior branches of the division are carried out into the limbs for the skin and muscles there, instead of supplying the lateral and ventral parts of the body-wall.

Nerve-fibres arising in the spinal ganglion and fibres from the ventral root pass directly from the nerve-trunk into the anterior primary division of the spinal nerve. This division also receives sympathetic nerve-fibres by way of the ramus communicans. These latter accompany the division and are distributed to their allotted elements in the territory it supplies.

The rami communicantes are small, short, thread-like branches by which the nerve-trunks are connected with the nearest ganglion of the vertically running gangliated cord of the sympathetic (sympathetic trunk). The trunk or anterior primary division of every spinal nerve has at least one of these; most of the nerves have two, and sometimes there are three. The nerves of the cervical region usually have but one, and this is composed largely of sympathetic fibres (grey ramus). Where there are two, one usually contains medullated fibres, chiefly from the ventral root, sufficient to give it a whiter appearance (white ramus).

In the upper cervical and in the sacral regions one sympathetic ganglion may be connected with two or more spinal nerves, and sometimes one nerve is connected with two ganglia. The rami communicantes of the spinal nerves are equivalent to the communicating rami connecting certain of the cranial nerves with the sympathetic system (trigeminus, glosso-pharyngeus, vagus). The medullated fibres of the rami and, therefore, the white rami consist chiefly of fibres from the spinal nerves, viz., fibres from the spinal ganglion-cells which enter and course to their distribution through branches of the sympathetic nerves, **visceral afferent fibres**, and fibres from the ventral roots of the spinal nerves which terminate in the sympathetic ganglia, **visceral efferent**(preganglionic) **fibres.** Thus the white rami have been termed the **visceral divisions** of the spinal nerves. The grey rami consist chiefly of sympathetic fibres, most of which are non-medullated or partially medullated, and which course to their distribution by way of the spinal nerves. Some of the sympathetic fibres terminate in the spinal ganglion, **afferent sympathetic fibres** (fig. 748). The usual absence of white rami communicantes from the cervical nerves is explained on the grounds—(1) that probably relatively few efferent visceral fibres are given to the sympathetic from this region of the cord; (2) that many of the visceral efferent fibres which do arise from this region of the cord probably join the rootlets of the spinal accessory nerve and pass to the sympathetic system through the trunk of this nerve, and through the vagus with which it anastomoses; and (3) that such of these fibres as are given off from the lower segments of the cervical region, descend the cord and pass out by way of the upper thoracic nerves which give very evident white rami to the sympathetic.

The meningeal or recurrent branch (figs. 747, 748, and 762) is very small and variable, and is often difficult to find in ordinary dissections. It is given off from the nerve-trunk just before its anterior and posterior primary divisions are formed. It consists of a few peripheral branches of spinal ganglion-cells (sensory fibres) which leave the nerve-trunk and re-enter the vertebral canal for the sensory innervation of the meninges, and which are joined by a twig from the grey ramus or directly from the nearest sympathetic ganglion (vaso-motor fibres). There is considerable evidence, both physiological and anatomical, obtained chiefly from the animals, which shows that at times certain of the peripheral spinal ganglion or sensory fibres may turn backward in the nerve-trunk and pass to the meninges within the ventral root instead of contributing to a recurrent branch. The occurrence of such fibres in the ventral root explains the physiological phenomenon known as *'recurrent sensibility.'* Likewise, sympathetic fibres entering the trunk through the grey ramus may pass to the meninges by way of the ventral root, and at times the recurrent branch is probably absent altogether, its place being taken entirely by the meningeal fibres passing in the ventral root.

Areas of distribution of the spinal nerves.—Both the posterior and anterior primary divisions divide and subdivide repeatedly, and their component fibres are distributed to areas of the body more or less constant for the nerves of each pair, but the distribution of the different nerves is very variable. Corresponding to their attachment, each to a given segment of the spinal cord, the nerves have primarily a segmental distribution, but, owing to the developmental changes and displacement of parts during the growth of the body, the segmental distribution becomes greatly obscured and in some nerves practically obliterated. Naturally it is more retained by the nerves supplying the trunk than by those contributing to the innervation of the limbs and head, and the areas supplied by the posterior primary divisions are less disturbed than those supplied by the anterior. The segmental areas of cutaneous distribution of the posterior divisions are more evident than the areas of muscle supplied by these divisions, from the fact that the segmental myotomes from which the dorsal muscles arise fuse together and overlap each other considerably during development. No nerve has a definitely prescribed area of distribution, cutaneous or muscular, for its area is always considerably overlapped by the areas of the nerves adjacent to it. The mid-thoracic nerves more nearly supply a definitely prescribed belt of the body.

A. POSTERIOR PRIMARY DIVISIONS

The posterior primary divisions of the spinal nerves spring from the trunks immediately outside the intervertebral foramina, and they pass dorsalward between the adjacent transverse processes. With the exceptions of the first and second cervical nerves they are smaller than the corresponding anterior primary divisions, which in these nerves is smaller from the fact that a large portion of them go over into the hypoglossal or cervical loop. The posterior primary divisions, after passing between the transverse processes into the region of the back, divide into medial and lateral branches. This division, however, does not occur in the cases of the first cervical, the last two sacral, and the coccygeal nerves.

1. Cervical Nerves

The **posterior primary division of the first cervical** or **sub-occipital nerve** springs from the trunk, between the vertebral artery and the posterior arch of the atlas, passes dorsalward into the sub-occipital triangle, and breaks up into branches which supply the superior oblique, the inferior oblique, and the major rectus capitis posterior muscles, which form the lateral boundaries of the triangle. It also gives a branch across the posterior surface of the major rectus capitis posterior to the minor rectus capitis posterior, and a branch to the semispinalis capitis (complexus) in the roof of the triangle.

It communicates with the medial branch of the posterior primary division of the second cervical nerve, either through or over the inferior oblique muscle, and it occasionally gives a cutaneous branch to the skin of the upper part of the back of the neck and the lower part of the scalp.

The **posterior primary division of the second cervical nerve** is the largest posterior division of all the cervical nerves. It divides into a small lateral branch and a very large medial branch. The **lateral branch** gives a twig to the inferior oblique and terminates in branches which supply the splenius and longissimus capitis (trachelo-mastoid) muscles. The **medial branch** is the **greater occipital nerve.** It turns around the lower border of the inferior oblique, crosses the sub-occipital triangle obliquely, pierces the semispinalis capitis (complexus), the tendon of the trapezius, and the deep cervical fascia, passing through the latter immediately below the superior nuchal line of the occipital bone, and it divides into several terminal sensory branches which ramify in the superficial fascia of the scalp.

It gives one or two motor twigs to the semispinalis capitis (complexus), and its terminal branches which are accompanied by branches of the occipital artery supply the skin of the scalp, above the superior nuchal line, as far forward as the vertex. Occasionally one branch reaches the pinna and supplies the skin on the upper part of its medial aspect. As it turns around the inferior oblique it gives branches which join with the medial branches of the posterior primary divisions of the first and third cervical nerves, and in this manner a small looped plexus is formed beneath the semispinalis capitis (complexus) muscle, the *posterior cervical plexus of Cruveilhier.*

The **posterior primary branches of the third, fourth, and fifth cervical nerves** divide at the lateral border of the semispinalis colli into medial and lateral branches. The **medial branches** of the third, fourth, and fifth nerves run backward between the semispinalis colli and capitis (complexus), supplying both muscles. Then, after passing backward between the semispinalis capitis and the ligamentum nuchæ, they pierce the origin of the trapezius and supply the skin of the back of the neck. The greater part of the medial branch of the third nerve, which runs upward in the superficial fascia to the scalp, is called the **third** or **smallest occipital nerve**; it interlaces with the greater occipital nerve, and it supplies the skin of the upper part of the back of the neck, near the middle line, and the skin of the scalp in the region of the external occipital protuberance.

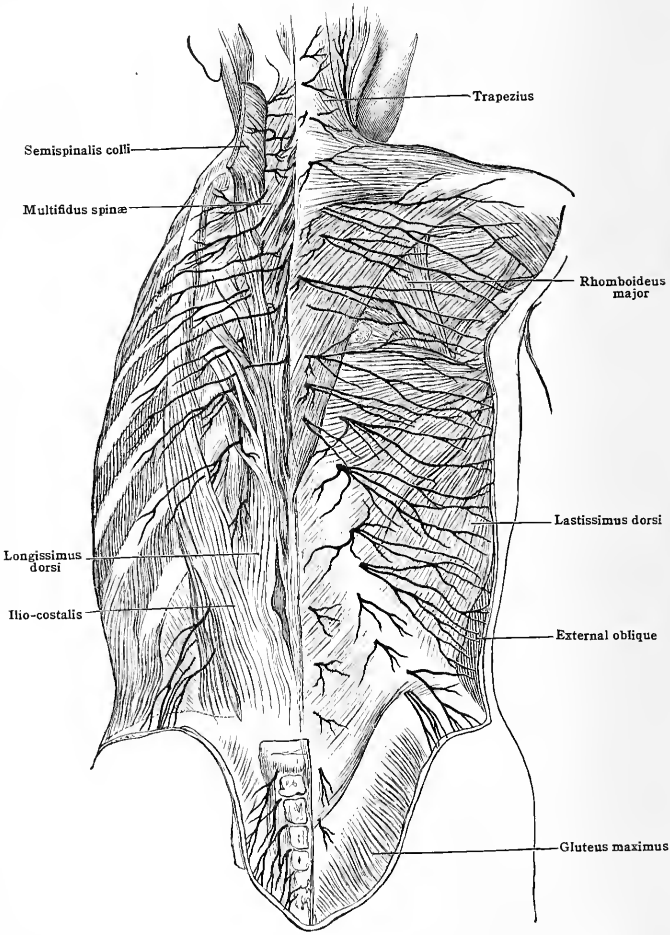
The **medial branches** of the posterior primary divisions of the sixth, seventh, and eighth cervical nerves pass to the median side of the semispinalis colli, between it and the subjacent multifidus spinæ, and they end in the neighbouring muscles. The **lateral branches of the posterior primary divisions of the last five cervical nerves** are small and they are distributed to the longissimus capitis (trachelo-mastoid), the ilio-costalis cervicis (cervicalis ascendens), the longissimus cervicis (transversalis cervicis), the semispinalis capitis (complexus), and the splenius muscles.

2. Thoracic Nerves

The **posterior primary divisions of all the thoracic nerves** divide into medial and lateral branches while in the vertebral groove. The **medial branches of the upper six thoracic nerves** pass dorsalward between the semispinalis dorsi and the multifidus spinæ; they supply the spinalis dorsi, the semispinalis dorsi, the multifidus spinæ, the rotatores spinæ, the intertransversales, and the interspinales muscles; and they end in cutaneous branches which, after piercing the trapezius, turn lateralward in the superficial fascia of the back, and supply the skin as far as the middle of the scapula. The cutaneous branch of the second nerve is the largest; it can be traced lateralward as far as the acromion process. The **medial branches of the lower six thoracic nerves** run dorsalward, between the longissimus dorsi and the multifidus spinæ; they chiefly end in twigs to the adjacent muscles, but not uncommonly they give small cutaneous twigs which pierce the latissimus dorsi and the trapezius and end in the skin near the mid-line of the back.

The **lateral branches of the upper six thoracic nerves** pass between the longis-

Fig. 750.—Distribution of the Posterior Primary Divisions of the Spinal Nerves. (Henle.)



simus dorsi and the ilio-costalis dorsi (accessorius) and end in those muscles, but the **lateral branches of the six lower nerves** are longer; they pass into the interval between the longissimus dorsi and the ilio-costalis dorsi and give branches to them, and then they pierce the latissimus dorsi and are distributed to the skin of the lower and lateral part of the back.

3. Lumbar Nerves

The **medial branches** of the posterior primary divisions of all the lumbar nerves end in the multifidus spinæ and those of the three lower nerves send very small branches to the skin of the sacral region.

The **lateral branches of the upper three nerves** pass obliquely lateralward, supplying twigs to the adjacent muscles, pierce the posterior layer of the lumbar aponeurosis at the lateral border of the sacro-spinalis (erector spinæ) and enter the subcutaneous tissue. They are, for the most part, cutaneous, forming the **superior clunial nerves,** which cross the crest of the ilium and pass downward to occupy different planes in the thick superficial fascia which covers the upper part of the gluteus medius.

The branch from the first lumbar nerve is comparatively small, and occupies the most superficial plane. The second occupies an intermediate position. The lateral branch from the third nerve is the largest of the three, and occupies the lowest position; it distributes branches over the gluteus maximus as far as the great trochanter. The three nerves anastomose with one another and also with the cutaneous branches from the posterior primary divisions of the two upper sacral nerves.

The **lateral branch of the fourth lumbar nerve** is of small size and ends in the lower part of the sacro-spinalis (erector spinæ). That of the **fifth lumbar** is distributed to the sacro-spinalis and communicates with the first sacral nerve.

4. Sacral Nerves

The posterior primary divisions of the upper four sacral nerves escape from the vertebral canal by passing through the posterior sacral foramina; those of the fifth sacral nerve pass out through the hiatus sacralis between the posterior sacro-coccygeal ligaments. Those of the upper three sacral nerves divide in the ordinary manner into medial and lateral branches. Those of the lower two sacral nerves remain undivided.

The **medial branches** of the upper three sacral nerves are of small size, and are distributed to the multifidus spinæ. The **lateral branches** anastomose with one another and with the lateral branch of the last lumbar nerve, forming loops on the posterior surface of the sacrum from which branches proceed to the posterior surface of the sacro-tuberous (great sacro-sciatic) ligament, where they anastomose and form a second series of loops, from which loops two or three branches are given off. These branches pierce the gluteus maximus and come to the surface of that muscle in a line between the posterior superior spine of the ilium and the tip of the coccyx. Then, as the **middle clunial nerves,** they are distributed to the integument over the medial part of the gluteus maximus, and communicate, in their course through the superficial fascia, with the posterior branches of the lumbar nerves.

The posterior divisions of the **lower two sacral nerves** unite with one another, with the posterior branch of the third sacral, and with the coccygeal nerve, forming loops from which twigs pass to the integument over the lower end of the coccyx.

The **posterior primary division of the coccygeal nerve** is also undivided. It separates from the anterior division in the sacral canal and emerges through the hiatus sacralis, pierces the ligaments which close the lower part of that canal, receives a communication from the posterior division of the last sacral nerve, and ends in the skin over the dorsal aspect of the coccyx.

B. ANTERIOR PRIMARY DIVISIONS

The anterior primary divisions of the spinal nerves are larger than the posterior primary divisions, and each is joined near its origin by a grey ramus communicans from the sympathetic gangliated cord (figs. 751, 752, 762). Beginning with the first or second thoracic nerve and ending with the second or third lumber nerve, each anterior division sends to the gangliated cord a white ramus communicans. The same is true of the second and third or of the third and fourth sacral nerves. These white rami are appropriately designated the **visceral branches** of the spinal nerves. The anterior primary divisions of the cervical, lumbar, sacral, and coccygeal nerves unite with one another to form **plexuses,** but the anterior primary divisions of the thoracic nerves, except the first and last, remain separate, pursue independent courses, and each divides, in a typical manner, into a lateral and an anterior or ventral branch. The separation of the anterior primary division into lateral and anterior branches is not confined to the thoracic nerves; it occurs also in the lower cervical, the lumbar, and the sacral nerves, but such a division cannot be clearly distinguished either in the upper cervical nerves, or in the coccygeal nerve.

1. *CERVICAL NERVES*

The anterior primary divisions of the **upper four cervical nerves** unite to form the **cervical plexus,** and each receives a communicating branch from the superior cervical sympathetic ganglion. The anterior divisions of the **lower four cervical nerves** are joined by the greater part of the first thoracic nerve and they unite to form the **brachial plexus** (figs. 751, 754, 755). The fifth and sixth cervical nerves receive communicating branches from the middle cervical sympathetic ganglion, and the seventh and eighth from the inferior cervical ganglion, while the first thoracic nerve is always connected with the first thoracic sympathetic ganglion by a grey ramus (figs. 751, 786) and in most cases also by a white ramus communicans.

THE CERVICAL PLEXUS

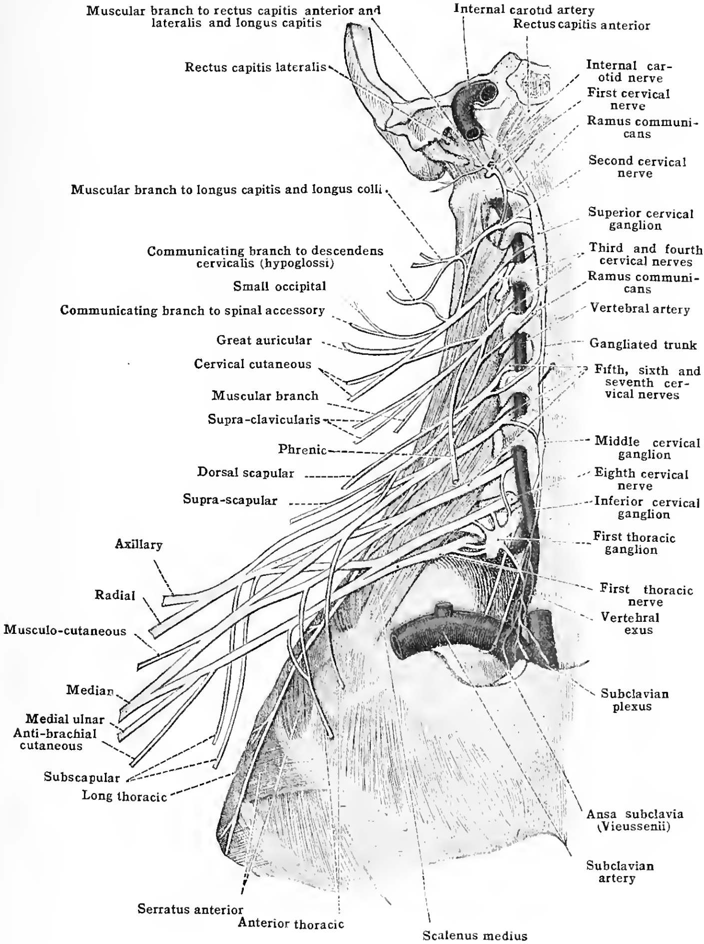
The cervical plexus (figs. 751, 752) is formed by the anterior primary divisions of the upper four cervical nerves which constitute the roots of the plexus. It lies in the upper part of the side of the neck, under cover of the sterno-mastoid, and upon the levator scapulæ and the scalenus medius. It is a looped plexus, consisting of three loops.

A large part of the anterior primary division of the **first cervical nerve** is given to the hypoglossal or cervical loop; the remainder passes to the cervical plexus and in doing so it runs lateralward on the posterior arch of the atlas beneath the vertebral artery, then it turns forward, between the vertebral artery and the outer side of the upper articular process of the atlas, and finally it descends, in front of the transverse process of the atlas, and unites with the upper branch of the second nerve, forming with it the first loop of the plexus. It gives branches to the rectus capitis lateralis, longus capitis (major rectus capitis anterior), and to the rectus capitis anterior (minor). The division communicates with the ganglion of the trunk of the vagus and with the superior cervical ganglion of the sympathetic system (fig. 752). From the first loop of the plexus, two branches of the division pass over into the sheath of the hypoglossal nerve and descend with it to contribute to the **hypoglossal loop** [ansa hypoglossi] or better, the *cervical loop*. The fibres entering the sheath of the hypoglossus, after giving a few twigs to the genio-hyoid and thyreo-hyoid muscles, leave the sheath as the **descendens cervicalis** (*hypoglossi*) and this latter joins the *communicans cervicalis,* (the portion of the loop from the second and third cervical nerves) and thus completes the cervical or hypoglossal loop.

This loop usually may be found between the sheaths of the sterno-mastoid muscle and the carotid artery, superficial to the internal jugular vein; sometimes it may lie in the carotid sheath between the carotid artery and the internal jugular vein; rarely it may lie dorsal to both the artery and vein. Sometimes it is relatively long, descending toward the sternum below the level of the thyreoid cartilage; again it is quite short and occurs near the level of the hyoid bone. The descendens cervicalis (hypoglossi) parts company with the hypoglossal nerve at the level at which the nerve curves around the occipital artery. It runs downward and slightly medialward on the sheaths of the great vessels and occasionally within the sheath of one of them.

The **second cervical nerve** (anterior primary division) passes behind the upper articular process of the axis and the vertebral artery, and between the intertransverse muscles extending from the first to the second cervical vertebræ, to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where it divides into two parts. The upper part ascends and unites with the first nerve to form the first loop of the plexus, and the lower branch passes downward and dorsalward and joins the upper branch of the third nerve in the second loop of the plexus (figs. 751, 752). This branch gives off the small occipital nerve and a filament to the sterno-mastoid, which communicates with the spinal accessory nerve in the substance of the muscle, and it gives branches which assist in forming the hypoglossal or cervical loop (ansa hypoglossi) the cervical cutaneous and the great auricular nerves (fig. 752).

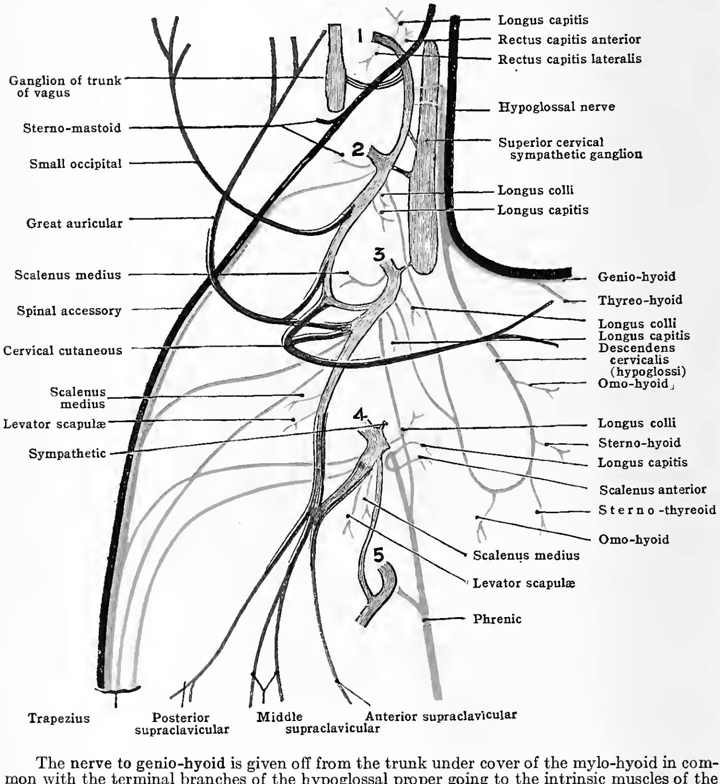
Fig. 751.—Origin of the Cervical and Brachial Plexus. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



The **third and fourth cervical nerves** pass behind the vertebral artery (fig. 751) and between the intertransverse muscles to the interval between the scalenus medius and the longus capitis (rectus capitis anterior major), where the third unites with the second and fourth nerves and completes the lower two loops of the plexus. The anterior primary divisions of these nerves are about double the size of the preceding. The third gives off branches to the hypoglossal loop, to the larger part of the great auricular and cervical cutaneous nerves, a branch to the phrenic, a branch to the supra-clavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus capitis, and trapezius (fig. 752). The trapezius branch joins the spinal accessory nerve beneath the muscle. The fourth nerve gives a branch to the phrenic, a branch to the supra-clavicular nerves, and muscular branches to the scalenus medius, levator scapulæ, longus colli, and trapezius (fig. 752). The branch to the trapezius unites with the one from the third nerve and joins the spinal accessory nerve beneath the muscle.

The fibres forming the cervical (hypoglossal) loop innervate all the muscles of the infra-hyoid group, though twigs to the genio-hyoid and thyreohyoid seemingly enter these muscles from the trunk of the hypoglossus (fig. 752).

Fig. 752.—Diagram of the Cervical Plexus.



The **nerve to genio-hyoid** is given off from the trunk under cover of the mylo-hyoid in common with the terminal branches of the hypoglossal proper going to the intrinsic muscles of the tongue. **The nerve to the thyreo-hyoid** muscles leaves the trunk of the hypoglossal near the tip of the great cornu of the hyoid bone, running obliquely downward and medianward to reach its muscle. A twig to the anterior belly of the **omo-hyoid** is given from the upper part of the descendens cervicalis and the **nerves for the sterno-hyoid,** the **sterno-thyreoid** and the posterior belly of the **omo-hyoid** are supplied from the turn of the loop (fig. 752). The nerves to the sterno-hyoid and sterno-thyreoid send twigs downward in the muscles behind the manubrium sterni and fibres from these in rare cases join the phrenic nerve in the thorax. The nerve to the posterior belly of the **omo-hyoid** courses as a loop in the cervical fascia below the central tendon of its muscle.

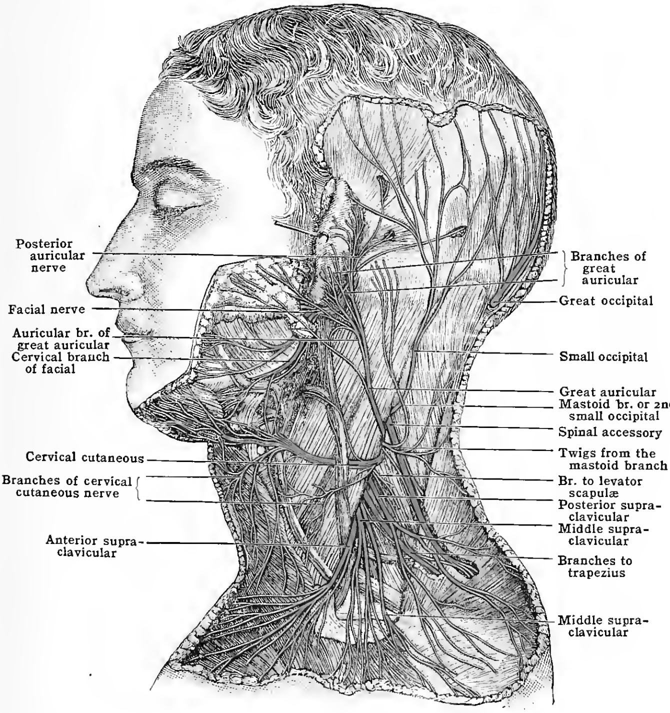
Each root of the cervical plexus receives a communicating grey ramus from the superior cervical ganglion of the sympathetic, and from the roots and loops of the plexus a number of branches arise which form two main groups, the superficial and the deep.

Superficial Branches of the Cervical Plexus

The superficial branches are described, according to the direction in which they run, as ascending, transverse, and descending branches. The *ascending branches* are the small occipital and the great auricular nerves. There is only one *transverse branch*, the cervical cutaneous (transverse cervical), and the *descending branches* are distinguished as the supraclavicular nerves and the cervical (hypoglossal) loop.

The ascending branches.—(1) The **small occipital nerve** (fig. 751) arises from the second and third cervical nerves, or from the loop between them, and runs

Fig. 753.—Superficial Branches of the Cervical Plexus. (After Hirschfeld and Leveillé.)



upward and dorsalward to the posterior border of the sterno-mastoid, where it hooks around the lower border of the spinal accessory nerve and then ascends along the posterior border of the muscle to the mastoid process. It pierces the deep cervical fascia and passes across the posterior part of the insertion of the sterno-mastoid into the superficial fascia of the scalp, in which it breaks up into auricular, mastoid, and occipital terminal branches.

(*a*) The **auricular branch** runs upward and slighly forward to reach the integument on the upper median part of the auricle(pinna), which it supplies. (*b*) The **mastoid branch** is distributed to the skin covering the base of the mastoid process. (*c*) The **occipital branches** ramify over the occipitalis muscle and are distributed to the skin of the scalp· they communicate with one another and with the great occipital nerve. The branches of the small occipital nerve anastomose with twigs of the posterior auricular, great auricular, and great occipital nerves (fig. 753).

(2) The **great auricular nerve** arises from the second and third cervical nerves (figs. 751, 752). It accompanies the small occipital to the posterior border of the sterno-mastoid, but at that point it diverges from the small occipital (fig. 753) and runs upward and forward across the sterno-mastoid toward the angle of the mandible. When it is about half-way across the muscle it begins to break up into its terminal branches, which are named, according to the area of their distribution, mastoid, auricular, and facial.

As the nerve ascends obliquely across the sterno-mastoid it is embedded in the deep cervical fascia, is covered by superficial fascia and the platysma, and it lies parallel with and slightly dorsal to the external jugular vein. (*a*) The **mastoid branch** is small, and is distributed to the integument covering the mastoid process. It anastomoses with the posterior auricular and small occipital nerves. (*b*) The **auricular branches** are three or four stout twigs which interlace with the branches of the posterior auricular nerve; they cross the superficial surface of the posterior auricular branch of the facial, and are distributed to the skin on the back of the auricle with the exception of its uppermost part. One or two twigs pass through fissures in the cartilage of the auricle, and are distributed to the integument on the lateral surface of the lobule and the lateral surface of the lower part of the helix and anthelix. (*c*) The **facial branches** pass upward and forward among the superficial lobules of the parotid gland, and supply the skin over that gland and immediately in front of it, and they anastomose in the substance of the gland with the cervico-facial division of the facial nerve. In some cases fine twigs may be traced forward nearly to the angle of the mouth.

Transverse branch of the plexus.—The **superficial cervical cutaneous nerve** (transverse cervical) arises from the second and third cervical nerves (figs. 751, 752), and appears at the posterior border of the sterno-mastoid, a little below the great auricular nerve. It passes transversely across the sterno-mastoid under cover of the integument, platysma, and external jugular vein, and divides into a number of twigs which spread out after the manner of a fan, and, as they approach the middle line, extend from the chin to the sternum (fig. 753).

The upper two or three of these twigs unite, beneath the platysma, with the cervical (inframandibular) branch of the facial and thus form loops. From the terminal branches of the nerve numerous twigs arise which pierce the platysma and end in the skin of the front part of the neck.

The descending or supra-clavicular branches.—These are derived from the third and fourth cervical nerves (figs. 751, 752), and arise under cover of the sterno-mastoid. At their commencements they are usually united with the muscular branches destined for the trapezius. They become superficial at the middle of the posterior border of the sterno-mastoid, and as they pass downward they pierce the deep cervical fascia. They include the following:

(1) The **anterior supra-clavicular (suprasternal) branches** (fig. 753) are small, and cross over the clavicular attachment of the sterno-mastoid to reach the integument over the upper part of the manubrium sterni. They also supply the sterno-clavicular joint. (2) The **middle supra-clavicular (supra-clavicular) nerves** are of considerable size. They cross in front of the middle third of the clavicle under cover of the platysma, and are distributed to the skin covering the upper part of the pectoralis major as low as the third rib. (3) The **posterior supra-clavicular (supra-acromial) branches** (fig. 753) cross the clavicular insertion of the trapezius and the acromion process. They are distributed to the skin which covers the upper two-thirds of the deltoid muscle and they supply the acromio-clavicular joint.

Deep Branches of the Cervical Plexus

The deep branches of the plexus pass lateralward and dorsalward, or ventralward and medialward; therefore they form two series, the lateral and the medial.

The **lateral branches** of the deep series include communicating branches from the second, third, and fourth cervical nerves to the spinal accessory nerve, and muscular branches to the sterno-mastoid and the scalenus medius, levator scapulæ, and trapezius.

The **communicating branches.**—The communicating branch from the second cervical nerve is ultimately distributed to the sterno-mastoid, and those from the third and fourth nerves end in the trapezius.

1. The **nerve to the sterno-mastoid** arises from the second cervical nerve (fig. 753). It pierces the deep surface of the sterno-mastoid, and communicates within the muscle with the spinal accessory nerve.

2. The **nerves to the scalenus medius** (fig. 752) are derived from the third or fourth to the eighth cervical nerves close to their exit from the intervertebral foramina.

3. The **nerves to the levator scapulæ** (fig. 752) are derived from the third and fourth cervical nerves, and occasionally from the second or fifth. They pierce the superficial surface of the levator scapulæ, and supply the upper three divisions of that muscle.

4. The **branches to the trapezius** (fig. 752) are usually in the form of two stout twigs which are given off by the third and fourth cervical nerves. They emerge from under cover of the sterno-mastoid at its posterior border and cross the posterior superior triangle of the neck at a lower level than the spinal accessory nerve (fig. 753). They pass under cover of the trapezius in company with the last-named nerve, and communicate with it to form the **subtrapezial plexus,** from which the trapezius is supplied.

The **medial branches** of the deep series also comprise communicating and muscular branches.

The **communicating branches** (figs. 751, 752) include (1) branches which connect each of the first four cervical nerves with the superior cervical ganglion of the sympathetic; (2) a branch to the vagus; (3) a branch to the hypoglossal; and (4) branches which pass from the second and third cervical nerves to the *descendens cervicalis* (*hypoglossi*). The ultimate distribution of the twigs connected with the sympathetic and the vagus nerves is not known, but the fibres which pass to the hypoglossal nerve pass from it to the thyreo-hyoideus muscle, and to the descendens cervicalis and the latter joins with the branches from the second and third cervical nerves, forming with them the cervical or **hypoglossal loop** [ansa hypoglossi] which lies on the carotid sheath. From this loop the two bellies of the omo-hyoid muscle and the sterno-hyoid and sterno-thyreoid muscles are supplied as described above.

The **muscular branches** supply the rectus capitis lateralis, the longus capitis (rectus capitis anterior major), the rectus capitis anterior (minor), the scalenus anterior, and the diaphragm. The nerve to the latter muscle is the **phrenic.**

1. The **branch to the rectus capitis lateralis** is furnished to that muscle by the first cervical nerve as it crosses the deep surface of the muscle.

2. The **nerve to the rectus capitis anterior** (minor) is given off by the first nerve at the upper part of the loop in front of the transverse process of the atlas.

3. The **longus capitis** (rectus capitis anterior major) receives twigs from the upper four cervical nerves.

4. The **longus colli** receives branches from the second, third, and fourth cervical nerves, and additional branches also from the fifth and sixth nerves.

5. The **phrenic nerve** (fig. 752) springs chiefly from the fourth cervical nerve, but it usually receives a twig from the third and another from the fifth cervical nerve, a small communicating branch from the sympathetic, and, rarely, a branch from the vagus. The twig from the fifth cervical nerve is frequently connected with the nerve to the subclavius. After the union of its roots the phrenic nerve passes downward and medialward on the scalenus anterior (fig. 755). In this part of its course it is crossed by the tendon of the omo-hyoid and by the transverse cervical and transverse scapular (suprascapular) arteries. It is overlapped by the internal jugular vein, and it is covered by the sterno-mastoid muscle. At the root of the neck the left phrenic nerve lies behind the terminal portion of the thoracic duct, and each nerve passes off the anterior border of the scalenus anterior and descends in front of the first part of the subclavian artery and the pleura immediately below that artery; each nerve passes dorsal to the terminus of the subclavian vein, crosses either in front of or dorsal to the internal mammary artery and gains the medial surface of the pleural sac. From the root of the neck the relations of the phrenic nerves differ. The **right phrenic nerve** descends along the medial surface of the right pleural sac and crosses in front of the root of the lung. It is accompanied by the pericardiaco-phrenic artery (comes nervi phrenici), and it is in relation medially, and from above downward, with the right innominate vein, the superior vena cava, and the pericardium, the latter membrane separating it from the wall of the right atrium (auricle). The **left phrenic nerve** descends along the medial surface of the left pleural sac accompanied by the pericardiaco-phrenic (comes nervi phrenici) artery. In the superior mediastinum it lies between the left common carotid and the left subclavian arteries, and it crosses in front of the left vagus, the left superior intercostal vein, and the arch of the aorta. Below the arch of the aorta it crosses in front of the root of the left lung, and then lies along the left lateral surface of the pericardium, which separates it from the wall of the left ventricle.

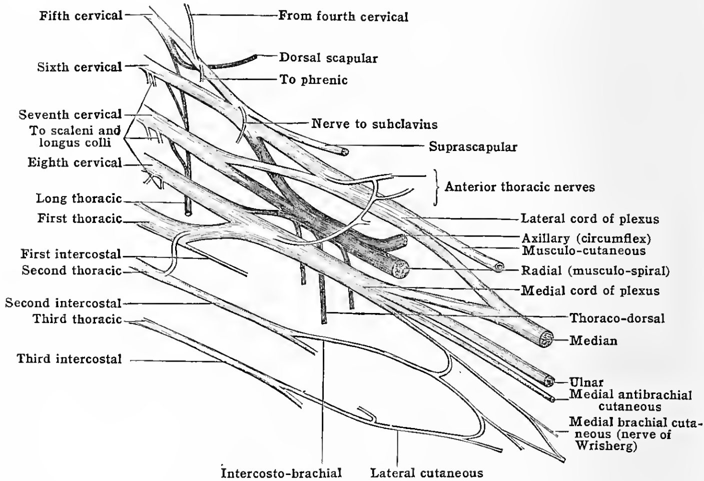
Branches.—Both phrenic nerves distribute branches to the pericardium and to the pleura. The right nerve gives off a branch, **pericardiac,** which accompanies the superior vena cava and supplies the pericardium. Each phrenic nerve divides into numerous terminal **phrenico-abdominal** branches. As a rule, the right phrenic nerve divides into two main terminal branches, an anterior and a posterior. The *anterior* branch runs forward and one of its terminal filaments anastomoses with the phrenic of the opposite side in front of the pericardium; others descend between the sternal and costal attachments of the diaphragm into the abdomen, where some of them supply the diaphragm and others descend in the falciform ligament to the peritoneum on the upper surface of the liver. The *posterior* branch passes through the vena caval opening and ramifies upon the lower surface of the diaphragm, anastomosing with the diaphragmatic plexus of the sympathetic, and its terminal branches supply the muscular fibres of the right half of the diaphragm, the inferior vena cava, and the right suprarenal gland.

The left phrenic nerve divides into several branches. One of the most anterior branches anastomoses with the right phrenic nerve; the others pierce the diaphragm and ramify on its under surface, where they anastomose with filaments of the left diaphragmatic plexus of the sympathetic and supply the left half of the diaphragm and the left suprarenal gland. The left phrenic nerve is considerably longer than the right nerve, partly on account of the lower level of the diaphragm on the left side, and partly on account of the greater convexity of the left side of the pericardium.

THE BRACHIAL PLEXUS

The **brachial plexus** (figs. 751, 754, 755) is formed by the anterior primary divisions of the **four lower cervical nerves** and the greater part of that of the

Fig. 754.—Diagram of a Common Form of Brachial Plexus.
The posterior cord of the plexus is darkly shaded.



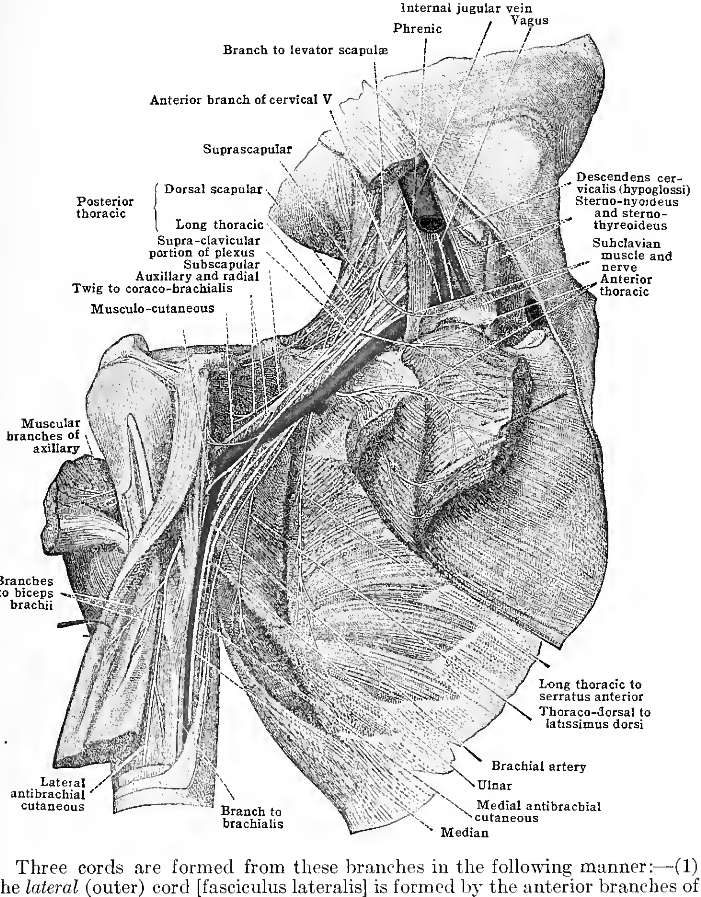
first thoracic nerve. It is usually joined by small twigs from the **fourth cervical** and **second thoracic nerves.**

The anterior primary divisions of the lower four cervical nerves, after passing dorsal to the vertebral artery and between the anterior and posterior parts of the intertransverse muscles, pass into the posterior triangle in the interval between the adjacent borders of the anterior and middle scalene muscles, where the fifth and sixth nerves receive a grey ramus communicans each from the middle cervical sympathetic ganglion, and the seventh and eighth nerves each receive a grey ramus from the inferior cervical sympathetic ganglion. The first thoracic is connected by two rami communicantes with the first thoracic sympathetic ganglion, and it divides into a smaller and a larger branch. The smaller branch passes along the intercostal space as the first intercostal nerve, and the larger branch, after being joined by a twig from the second thoracic nerve, passes upward and lateralward, in front of the neck of the first rib and behind the apex of the pleural sac, into the lower part of the posterior triangle of the neck, where it takes part in the formation of the plexus.

The anterior primary divisions of those cervical nerves that form the brachial plexus may be considered as typically giving off *anterior* and *posterior branches*, except that the fifth and sixth nerves often unite before branching and give off their posterior branches as a common trunk, and the eighth nerve often receives its branch from the first thoracic nerve before giving off its posterior branch.

It is on account of this variation in the point of union of the fifth and sixth cervical nerves and of the eighth cervical and first thoracic nerves that so many different forms of the plexus have been pictured and described. But if the differences in primary branching be borne in mind, the formation of the plexus is always uniform and simple, notwithstanding its different appearances.

Fig. 755.—The Brachial Plexus and its Branches of the Region of the Neck and Shoulder. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



Three cords are formed from these branches in the following manner:—(1) The *lateral* (outer) cord [fasciculus lateralis] is formed by the anterior branches of the fifth, sixth, and seventh nerves; (2) the *medial* (inner) cord [fasciculus medialis], by the anterior branches of the eighth cervical and first thoracic nerves; and (3) the *posterior* cord [fasciculus posterior], by the posterior branches of all of these cervical nerves.

Relations.—The plexus extends from the lateral border of the scalenus anterior, where the roots of its constituent nerves appear, to the lower border of the pectoralis minor, where each of its three cords divides into two terminal branches, and it lies in the posterior triangle, in the root of the neck, and in the axillary fossa. In the posterior triangle and in the root of the neck it is in relation behind with the scalenus medius (figs. 751, 755). In the posterior triangle it is covered superficially by the skin and superficial fascia, the platysma, the supra-clavicular branches of the cervical plexus, and the deep fascia, and it is crossed by the lower part of the external jugular vein, by the nerve to the subclavius, the transverse cervical vein and the transverse scapular (supra-scapular) vein, the posterior belly of the omo-hyoid muscle, and by the transverse cervical artery. At the root of the neck it lies behind the clavicle and the subclavius muscle, and the transverse scapular (suprascapular) artery crosses in front of it. In the axillary fossa the cords are arranged around the axillary artery, the lateral (outer) cord lying lateral to the artery, the medial (inner) cord medial to it, and the posterior cord dorsal to the artery. In this region the posterior relations of the plexus are the fat in the upper part of the fossa and the subscapularis muscle, and it is covered in front by the pectoral muscles and the coraco-clavicular fascia. The lower border of the plexus is in relation in the posterior triangle and at the root of the neck with the pleura and the first rib, and it is overlapped in front by the third part of the subclavian artery. In the axillary fossa the medial cord which forms the lower border of the plexus is overlapped anteriorly by the axillary vein. The upper and lateral border of the plexus has no very important relations.

In gross, the brachial plexus may be formulated as beginning with five nerves and terminating in five nerves, with its intermediate portions displayed in sets of threes. It begins with the fifth, sixth, seventh and eighth cervical and first thoracic nerves; it terminates as a plexus with the formation of the musculocutaneous, radial, axillary, median, and ulnar nerves; in its intermediate portions, first main trunks are formed and these divide into two sets of threes which, by union, give rise to three cords. The **branches from the cords** are three main lateral branches from each and the terminal branches of the plexus. The *lateral branches*, according as they are given off above, below, and dorsal to the clavicle, are grouped as the *supra-clavicular*, the *infra-clavicular* and the *subscapular portions* of the plexus.

The branches of the supra-clavicular portion.—After the roots of the plexus have received communications from the sympathetic, which have already been referred to, they give off a series of muscular branches, viz.—the posterior thoracic nerves (the dorsal scapular and the long thoracic nerve), the suprascapular nerve, a twig to the phrenic, the nerve to the subclavius, and small twigs to the scalene muscles and the longus colli muscle.

The **posterior thoracic nerves** are two in number:—(*a*) the **dorsal scapular** (nerve to the rhomboids) arises principally from the fifth cervical nerve, but it frequently receives a twig from the fourth nerve (fig. 751).

It passes downward and dorsalward, across the middle scalene, parallel with and below the spinal accessory nerve to the anterior border of the levator scapulæ, under which it disappears. It continues its descent under cover of the levator scapulæ and the rhomboids almost to the lower angle of the scapula, lying a little medial to the posterior border of the bone, and it supplies the lower fibres of the levator and the smaller and larger rhomboid muscles.

(*b*) The **long thoracic nerve** (external respiratory nerve of Bell) supplies the serratus anterior.

It usually arises, by three roots, from the fifth, sixth, and seventh cervical nerves. The last is sometimes absent (figs. 751 and 754). The upper two roots traverse the substance of the scalenus medius; the root from the seventh passes in front of that muscle. Twigs are furnished to the superior portion of the serratus anterior by the upper two roots; lower down they unite and are subsequently joined by the root from the seventh when present. The trunk of the nerve passes downward behind the brachial plexus and the first stage of the axillary artery, and runs along the axillary surface of the serratus anterior (magnus), supplying twigs to each of the digitations of that muscle (fig. 755).

The **suprascapular nerve** (fig. 751) supplies the supraspinatus and infraspinatus muscles.

It receives fibres from the fifth and sixth cervical nerves, and occasionally also a twig from the fourth nerve. It is a nerve of considerable size, and it passes downward and dorsalward parallel with the dorsal scapular nerve, at first along the upper border of the posterior belly of the omo-hyoid muscle, then internal to the latter muscle and under cover of the anterior border of the trapezius to the suprascapular notch (fig. 755), where it comes into relation with the transverse scapular (suprascapular) artery. It is separated from the artery at the notch by the superior transverse ligament, the nerve passing through the notch and the artery above the ligament. After entering the supraspinous fossa the nerve supplies branches to the supraspinatus and a branch to the shoulder-joint; then it descends through the great scapular notch between the bone and the inferior transverse ligament to the infraspinous fossa, where it terminates in the infraspinatus muscle.

The **twig to the phrenic** (fig. 751) arises from the fifth cervical nerve close to the point where the latter nerve receives its twig from the cervical plexus.

The nerve to the subclavius (fig. 755) is a small twig which arises from the fifth nerve or from the upper trunk of the plexus, but occasionally it receives additional fibres from the fourth and sixth nerves. It runs downward in front of the lower part of the plexus and the third stage of the subclavian artery and, after giving off sometimes a branch to the phrenic, pierces the posterior layer of the coraco-clavicular fascia, and enters the subclavius at its lower border.

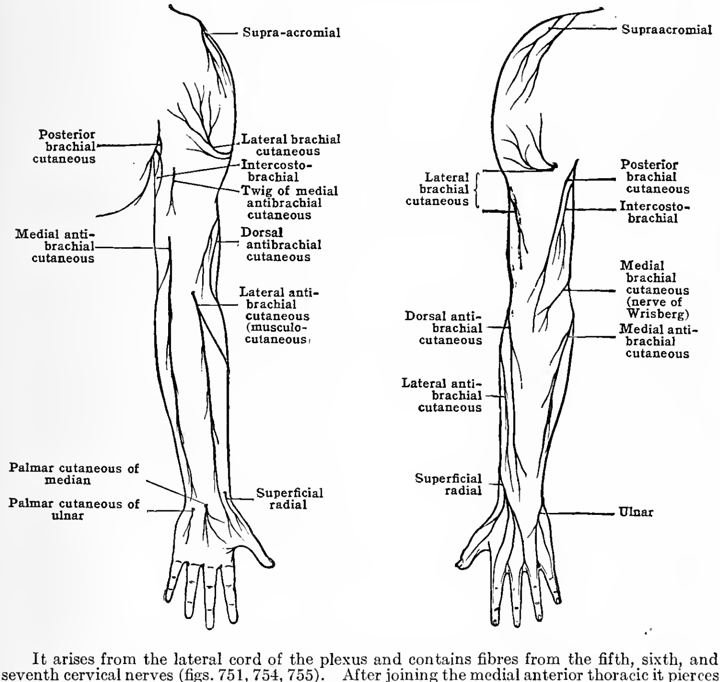
Variety.—In rare cases the entire phrenic nerve may pass *viâ* the nerve to the subclavius in front of the third stage of the subclavian artery.

The *scaleni* and *longus colli* (figs. 751, 754) are supplied by twigs which arise from the lower three or four cervical nerves immediately after their exit from the intervertebral foramina.

The lateral branches of the infra-clavicular portion of the brachial plexus are the anterior thoracic nerves, from the lateral and medial cords respectively, the medial antibrachial (internal) cutaneous and the medial brachial (lesser internal) cutaneous nerves, from the medial cord, and the subscapular nerves and thoraco-dorsal from the posterior cord.

The **lateral anterior thoracic nerve** joins with the medial to form a loop which supplies the pectoralis major and minor.

FIG. 756.—DISTRIBUTION OF CUTANEOUS NERVES ON THE ANTERIOR AND POSTERIOR ASPECTS OF THE SUPERIOR EXTREMITY.



It arises from the lateral cord of the plexus and contains fibres from the fifth, sixth, and seventh cervical nerves (figs. 751, 754, 755). After joining the medial anterior thoracic it pierces the coraco-clavicular fascia and ends in branches that supply the pectoralis major muscle. The **medial anterior thoracic nerve** arises from the medial cord (figs. 751, 754, 755), contains fibres from the eighth cervical and first thoracic nerves, and passes forward between the first stage of the axillary artery and the axillary vein. It unites with a branch from the lateral anterior thoracic, to form a loop which is placed in front of the first stage of the axillary artery; it gives branches to the pectoralis minor, and branches which pass through the latter muscle and end in the pectoralis major. From the loop additional branches are furnished to the pectoralis major.

The **medial brachial (lesser internal) cutaneous nerve, or nerve of Wrisberg** (fig. 754), arises from the medial cord of the brachial plexus and sometimes contains fibres from the eighth cervical and first thoracic nerves, but usually fibres from the first thoracic nerve alone. It runs downward on the medial side of the axillary vein, being separated by that vessel from the ulnar nerve, and it continues downward with a slight inclination dorsalward under cover of the deep fascia on the inner side of the arm. At the middle of the arm it pierces the deep fascia, and near the bend of the elbow it turns somewhat sharply dorsalward to supply the integument which covers the olecranon process (fig. 756).

As it traverses the axilla the nerve of Wrisberg communicates with the intercosto-brachial nerve, forming one, or sometimes two loops (fig. 754). In its course down the arm it gives a few fine twigs to the integument. This nerve may be absent, its place being taken by the intercosto-brachial or by part of the posterior brachial (internal) cutaneous branch of the radial (musculo-spiral) or, rarely, by a branch from the first intercostal nerve.

The **medial antibrachial (internal) cutaneous nerve** (figs. 751 and 754) arises from the medial cord in close relation with the ulnar nerve. It contains fibres from the eighth cervical and first thoracic nerves. At its origin it lies directly on the medial side of the axillary artery (fig. 755), but it soon becomes more superficial and then lies in the groove between the artery and the vein. In the upper two-thirds of the arm it lies in front and to the medial side of the brachial artery. It divides into two branches (volar and ulnar) which supply the medial aspect of the forearm.

At the junction of the middle and lower thirds of the arm this nerve pierces the deep fascia, in company with the basilic vein, and divides into an anterior and a posterior branch. Previous to its division it gives off twigs which pierce the deep fascia and supply the integument of the upper and medial part of the arm. The **volar (anterior) branch** is larger than the ulnar (posterior); it passes in front of or dorsal to the median basilic vein, and divides into several twigs which run down the forearm, supplying the integument covering its anterior and medial aspect as far as the wrist, and anastomosing with the branches of the ulnar nerve. The **ulnar (posterior) branch** passes downward and dorsalward in front of the medial condyle of the humerus, and divides into branches which supply the skin on the postero-medial aspect of the forearm. It anastomoses with the dorsal antibrachial (inferior external) cutaneous branch of the radial (musculo-spiral) nerve and the dorsal branch of the ulnar nerve).

The **subscapular nerves** are branches of the posterior cord (fig. 754). They are three in number, are distinguished as upper, thoraco-dorsal or middle, and lower, and are distributed to the subscapularis, latissimus dorsi, and teres major muscles.

The **upper** or **short subscapular nerve** is derived from the fifth and sixth cervical nerves. It lies in the upper and posterior part of the axillary fossa, and it is distributed exclusively to the subscapularis muscle. It is occasionally double.

The **thoraco-dorsal, middle, or long subscapular nerve** consists mainly of fibres from the seventh and eighth cervical nerves, but it may contain fibres from the fifth or the sixth nerve. It passes behind the axillary artery, accompanies the subscapular artery along the axillary margin of the subscapularis muscle, and ends in the latissimus dorsi (fig. 755).

The **lower subscapular nerve,** carrying fibres from the fifth and sixth cervical nerves, passes behind the subscapular artery, below the circumflex branch (dorsalis scapulæ), and is distributed to the teres major, and furnishes to the subscapularis one or two twigs which enter that muscle near its axillary margin.

The **terminal branches** of the plexus are two from each cord. The posterior cord divides into the axillary (circumflex) and the radial (musculo-spiral) nerves. The lateral cord divides into the musculo-cutaneous nerve, and the lateral root of the median nerve; the medial cord divides into the ulnar nerve, and the medial root of the median nerve, the median nerve as a whole being one of the five terminal branches of the plexus.

The **axillary (circumflex) nerve** is the smaller of the two terminal branches of the posterior cord, and contains fibres from the fifth and sixth cervical nerves (figs. 751 and 754). At the lower border of the subscapularis it passes dorsalward and accompanies the posterior circumflex artery through the quadrilateral space, which is bounded by the teres major, long head of triceps, and subscapularis muscles, and the surgical neck of the humerus, and it divides into a smaller superior and a larger inferior division. Previous to its division it furnishes an articular twig to the shoulder-joint. This twig pierces the inferior part of the articular capsule.

The **superior division** accompanies the posterior circumflex artery around the neck of the humerus, and gives off a number of stout twigs which enter the deltoid muscle (fig. 755). A few fine filaments pierce the deltoid and end in the integument which covers the middle third of that muscle.

The **inferior division** divides into cutaneous and muscular branches. The cutaneous branch (the **lateral brachial cutaneous nerve**) turns around the posterior border of the deltoid, pierces the deep fascia, and supplies the skin covering the lower third of the deltoid and a small area of integument below the insertion of the muscle (fig. 756). One muscular branch is distributed to the teres minor; it swells out into an ovoid or fusiform, reddish, gangliform enlargement before entering the muscle. Other branches supply the lower and posterior part of the deltoid.

The **radial (musculo-spiral) nerve** is the largest branch of the brachial plexus. It contains fibres from the sixth, seventh, and eighth cervical and sometimes from the fifth cervical and first thoracic nerves (figs. 751, 754). It commences at the lower border of the pectoralis minor, as the direct continuation of the posterior cord of the brachial plexus, and passes downward and lateralward in the axillary fossa behind the third part of the axillary artery (fig. 755) and in front of the subscapularis, latissimus dorsi, and teres major muscles. From the lower border of the axillary fossa it descends into the arm, where it lies, at first, on the medial side of the upper third of the humerus, behind the brachial artery and in front of the long head of the triceps; then it runs obliquely downward and lateralward behind the middle third of the humerus, in the groove for the radial nerve (musculo-spiral groove), and between the lateral and medial heads of the triceps. It is accompanied, in this part of its course, by the profunda artery. At the junction of the middle and lower thirds of the humerus it reaches the lateral side of the arm, pierces the external intermuscular septum, and runs downward and forward between the brachio-radialis and extensor carpi radialis longus externally, and the brachialis internally (fig. 758), and it terminates, a short distance above the capitulum, by dividing into deep and superficial terminal branches. In the last part of its course it is accompanied by the anterior terminal branch of the profunda artery.

Branches.—The branches of the radial or musculo-spiral nerve are *cutaneous, muscular, articular*, and *terminal*, but for practical purposes it is best to consider them in association with the situations of their origins. While it is **in the axillary fossa** the radial (musculo-spiral) nerve gives branches to the medial and long heads of the triceps (fig. 758), and a medial cutaneous branch. The branch to the long head of the triceps at once enters the substance of the muscle, that to the medial head breaks into branches which terminate in the muscle at different levels, and one of them, the *ulnar collateral nerve*, accompanies the ulnar nerve to the lower part of the arm. The **posterior brachial (internal) cutaneous branch** crosses the tendon of the latissimus dorsi, passes dorsal to the intercosto-brachial (intercosto-humeral) nerve, pierces the deep fascia, and is distributed to the skin of the middle of the back of the arm below the deltoid.

While it lies behind the middle third of the humerus, the radial nerve gives branches to the lateral and medial heads of the triceps and to the anconeus. The latter branch descends in the substance of the median head of the triceps, close to the bone, and it is accompanied by a small branch of the profunda artery. The **dorsal antibrachial (external) cutaneous branch,** passing down between the lateral and median heads of the triceps, divides near the elbow into its upper and lower branches (fig. 756), each of which perforates either the lateral head of the triceps muscle near its attachment to the humerus or the external intermuscular septum.

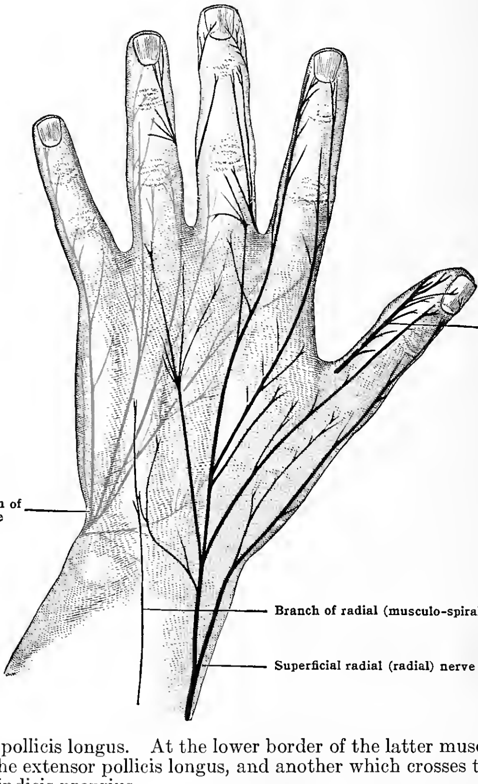
The **upper branch,** much the smaller, pierces the deep fascia in the line of the external intermuscular septum; it accompanies the lower part of the cephalic vein, and supplies the skin over the lower half of the lateral and anterior aspect of the arm. The **lower branch** is of considerable size. It pierces the deep fascia a little below the upper branch, runs behind the external condyle, and supplies the skin of the middle of the back of the forearm as far as the wrist, anastomosing with the medial antibrachial (internal) cutaneous and musculo-cutaneous nerves (fig. 759).

After the radial nerve has pierced the external intermuscular septum it gives branches to the brachio-radialis, extensor carpi radialis longus, and to the lateral portion of the brachialis (fig. 759). From one of these branches an articular filament is distributed to the elbow-joint.

The **terminal branches** of the radial nerve are:—a motor branch, the *deep radial,* to the supinator and extensor muscles of the forearm, and a sensory branch, the *superficial radial*, which supplies the dorsal aspect of the radial half of the hand.

The **deep radial** [ramus profundus] (posterior interosseous) nerve runs downward in the interval between the brachialis and extensor carpi radialis longus. It passes in front of the lateral part of the elbow-joint, and after giving off branches to supply the extensor carpi radialis brevis and supinator, it is crossed in front by the radial recurrent artery (fig. 759). It then runs downward and dorsalward through the substance of the supinator, and enters the interval between the superficial and deep layers of muscles at the back of the forearm, where it comes into relation with the posterior interosseous artery, and accompanies it across

Fig. 757.—A Dissection of the Cutaneous Nerves on the Dorsal Aspect of the Hand and Fingers. (H. St. J. B.)
The branches of the median nerve are shown in black.



the abductor pollicis longus. At the lower border of the latter muscle it gives off a branch to the extensor pollicis longus, and another which crosses this muscle to the extensor indicis proprius.

Continuing distalward as the *dorsal antibrachial interosseous* nerve the deep radial leaves the posterior interosseous artery, dips beneath the extensor pollicis longus, and joins the volar interosseous artery. It accompanies this artery upon the interosseous membrane and upon the back of the radius, passes through the groove for the extensor digitorum communis and extensor indicis proprius to the dorsum of the wrist, and terminates in a gangliform enlargement which gives branches to the carpal articulations. The muscles supplied by the deep radial nerve are the extensor carpi radialis brevis, brachio-radialis (supinator longus), extensor digitorum communis, extensor digiti quinti proprius, extensor carpi ulnaris, extensor indicis proprius, and the extensor muscles of the thumb. The supinator (brevis) receives two twigs, one of which is given off before the nerve pierces the muscle and the other while it is passing through it.

The **superficial radial** (radial) nerve [ramus superficialis n. radialis] is somewhat smaller than the deep radial (posterior interosseous), and is a purely cutaneous nerve. It runs downward under cover of the brachio-radialis, passing in front of the elbow-joint, the radial recurrent artery, and the supinator (brevis). At the lower border of the supinator it approaches the radial artery at an acute angle, and runs parallel to the lateral side of that vessel in the middle third of the forearm, across the pronator teres. At the lower border of the pronator teres it bends dorsalward on the deep surface of the tendon of the brachio-radialis, and appears on the back of the forearm. It pierces the deep fascia and is directed across the dorsal carpal (posterior annular) ligament toward the dorsum of the wrist, where it divides into its terminal branches (fig. 759).

The most lateral of these branches supplies the skin on the radial part of the thenar eminence; the most medial, designated the **ulnar anastomotic branch,** communicates with the dorsal branch of the ulnar nerve. The other terminal branches, the **dorsal digital nerves,** supply to a variable extent the skin on the dorsum of the first digit, both sides of the second and the radial side of the third digit. These branches usually extend to the base of the nail of the first digit, to the distal interphalangeal joint of the second, not quite to the proximal interphalangeal joint of the third, and to the metacarpo-phalangeal joint of the fourth digit.

The **terminal branches of the lateral cord** of the brachial plexus are the musculo-cutaneous and the lateral component of the median nerve. The latter nerve will be described with the medial cord.

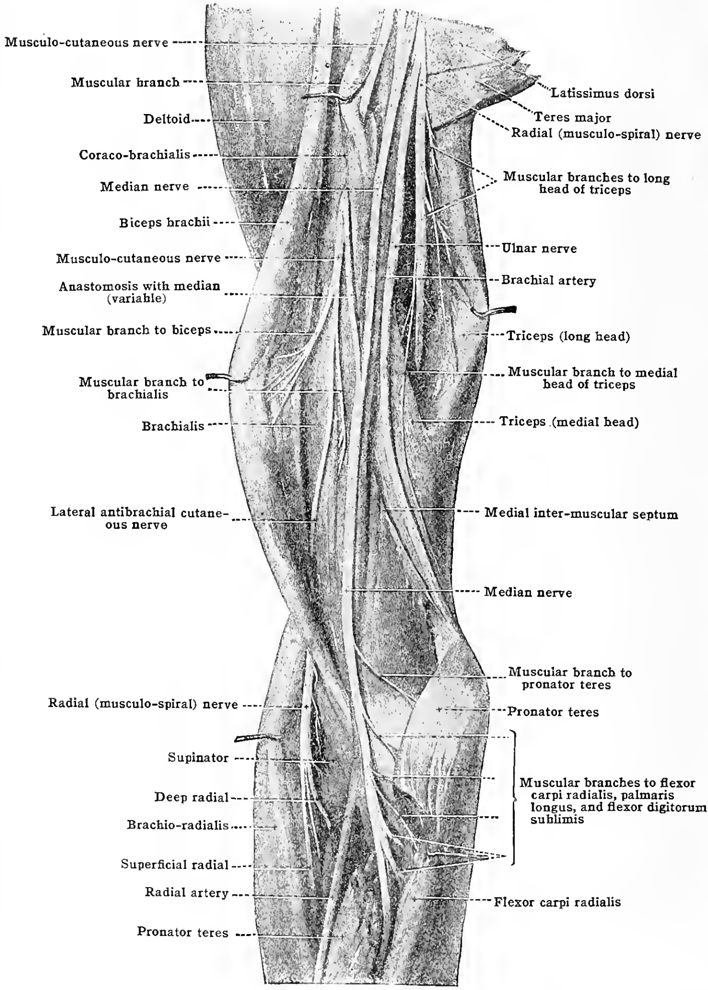
The **musculo-cutaneous nerve** is composed of fibres derived chiefly from the anterior divisions of the fifth and sixth cervical nerves, together usually with some fibres from that of the seventh (figs. 751 and 754). The nerve to the coraco-brachialis usually consists of two or three twigs given off from the nerve close to its origin before it enters the muscle (fig. 755). Sometimes, however, the fibres from the seventh cervical nerve pass directly to this muscle without joining the main trunk. The musculo-cutaneous nerve is placed at first close to the lateral side of the axillary artery (fig. 755), but soon it leaves that vessel and, piercing the coraco-brachialis muscle, it passes obliquely downward and lateralward between the biceps and brachialis muscles. Soon after piercing the coraco-brachialis it gives off **muscular branches** to each head of the *biceps* and to the *brachialis* (fig. 758). It also gives twigs to the *humerus*, to the *nutrient artery*, and gives the chief supply to the *elbow-joint*. Below the branch to the brachialis the cutaneous portion of the nerve forms the **lateral antibrachial cutaneous nerve** (figs. 756, 758). This portion continues downward between the biceps and brachialis, pierces the deep fascia at the lateral border of the former muscle a little above the bend of the elbow, receives a communication from the upper branch of the dorsal antibrachial (upper external) cutaneous branch of the radial (musculo-spiral) nerve, passes dorsal to the median cephalic vein, and divides into an anterior and a posterior branch.

The **anterior branch** runs downward on the lateral and anterior part of the forearm, supplying the integument of that region, and it terminates in the skin covering the middle part of the thenar eminence (fig. 759). A short distance above the wrist, after it has received a communicating twig from the superficial radial nerve, it gives off an articular branch to the carpal joints. This branch pierces the deep fascia and accompanies the radial artery to the dorsum of the wrist. The **posterior terminal branch** is small, and is directed downward and backward in front of the external condyle of the humerus, to be distributed to the skin on the lateral and posterior aspect of the forearm as low as the wrist (fig. 756). It anastomoses with the superficial radial and with the lower branch of the dorsal antibrachial (lower external) cutaneous branch of the radial nerve.

The **terminal branches of the medial cord** of the brachial plexus are the ulnar nerve and the medial component of the median nerve. Neither of these gives any branches in the upper arm, and thus they differ from the other terminal branches of the plexus. They both supply the muscles and joints of the forearm, and the muscles, joints, and integument of the hand.

The **ulnar nerve,** which is the largest branch of the medial cord of the brachial plexus, contains fibres from the anterior divisions of the eighth cervical and first thoracic nerves (figs. 752 and 762). It commences at the lower border of the pectoralis minor and runs downward in the axillary fossa in the posterior angle between the axillary artery and vein. In the upper half of the arm it lies on the medial side of the brachial artery (fig. 755), but at the level of the insertion of the coraco-brachialis it passes backward at an acute angle, and, accompanied by the superior ulnar collateral (inferior profunda) artery, it pierces the internal inter-muscular septum. After passing through the septum it runs downward, in a groove in the medial head of the triceps (fig. 758), to the interval between the olec-

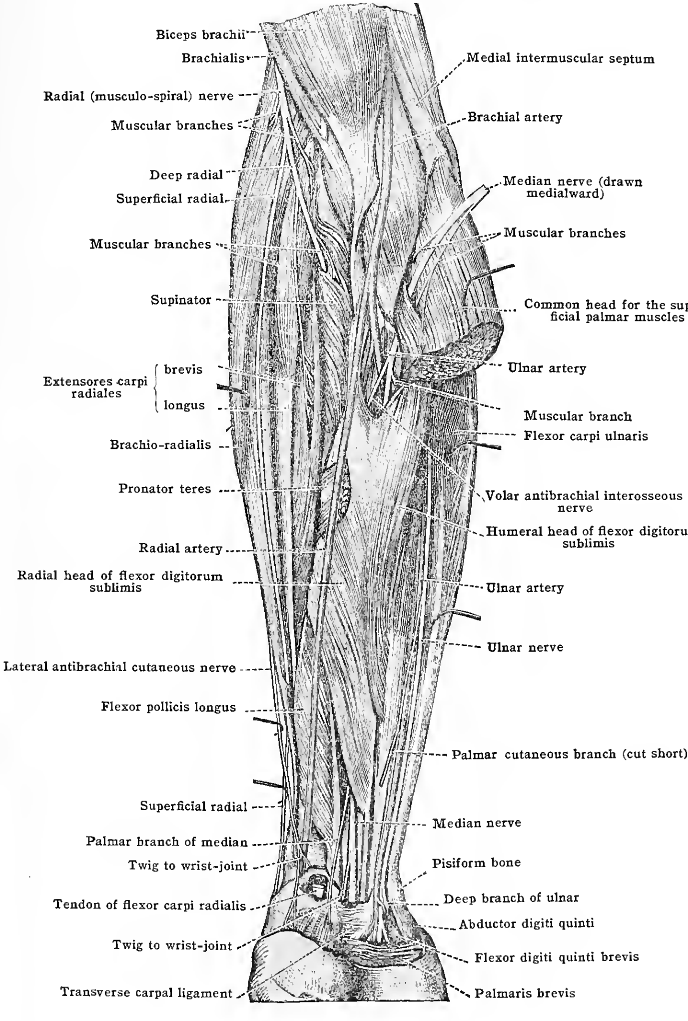
Fig. 758.—Nerves of the Right Upper Arm viewed from in Front. (Spalteholz.)



ranon process and the medial condyle of the humerus, and in this part of its course it is closely bound to the muscle by the deep fascia. Immediately below the medial condyle it passes between the two heads of the flexor carpi ulnaris, along the medial side of the medial collateral ligament of the elbow, and it comes into relation with the dorsal ulnar recurrent artery.

In the upper forearm the ulnar nerve lies on the flexor digitorum profundus, covered by the flexor carpi ulnaris. Near the junction of the upper and middle thirds of the forearm it is joined by the ulnar artery, which accompanies it to its termination, lying throughout on its radial side (fig. 759). In the lower part of the forearm it still rests on the flexor digitorum profundus, but

FIG. 759.—DEEP NERVES OF THE VOLAR SURFACE OF THE FOREARM. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



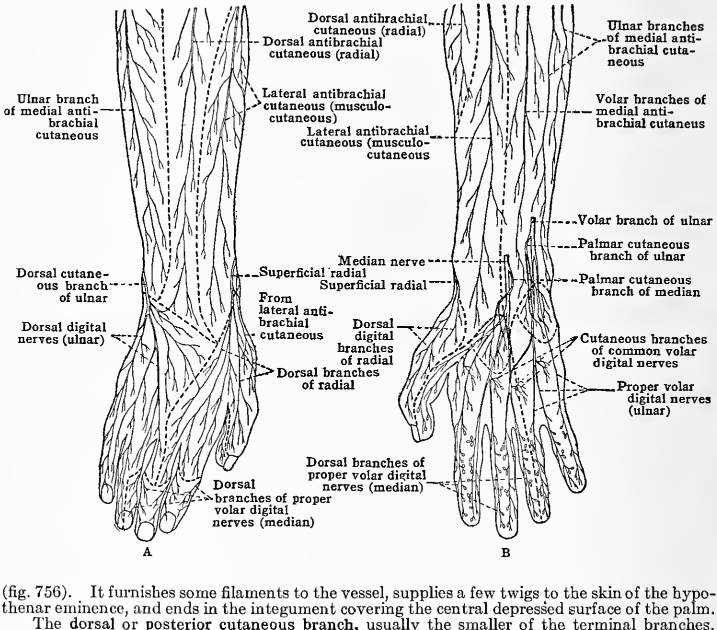
between the flexor carpi ulnaris and flexor digitorum sublimis, and is covered only by skin and fascia. At a variable point in this part of the forearm, usually about 5 to 8 cm. (2 to 3 in.) from the carpus, the nerve divides into its two terminal branches, a dorsal branch to the dorsal aspect of the hand, and a volar branch to the volar aspect.

Branches.—The ulnar resembles the median nerve in not furnishing any branches to the upper arm. As it passes between the olecranon process and the medial condyle it gives off two or three fine filaments to the elbow-joint. In the upper part of the forearm it supplies the flexor carpi ulnaris and the medial portion of the flexor digitorum profundus, and in the lower half it gives off the three cutaneous branches. In the palm of the hand it supplies the integument of the hypothenar eminence, the fifth digit, and half of the fourth digit, and part of the skin of the dorsum. It also supplies the short intrinsic muscles of the hand with the exception of the abductor pollicis, the opponens, the lateral head of the flexor pollicis brevis, and the two lateral lumbricales.

The nerves to the **flexor carpi ulnaris** and to the medial two divisions of the **flexor digitorum profundus** arise from the ulnar nerve in the upper third of the forearm.

Cutaneous branches.—About the middle of the forearm the ulnar nerve gives off two cutaneous branches:—one pierces the fascia and anastomoses with the volar branch of the medial antibrachial (internal) cutaneous nerve, and the other, the **palmar cutaneous branch,** runs downward in front of the ulnar artery (fig. 759) and is conducted by this vessel into the palm

Fig. 760.—Diagrams Illustrating a Common Distribution of Cutaneous Nerves of Forearm. A, dorsum; B, volar aspect.



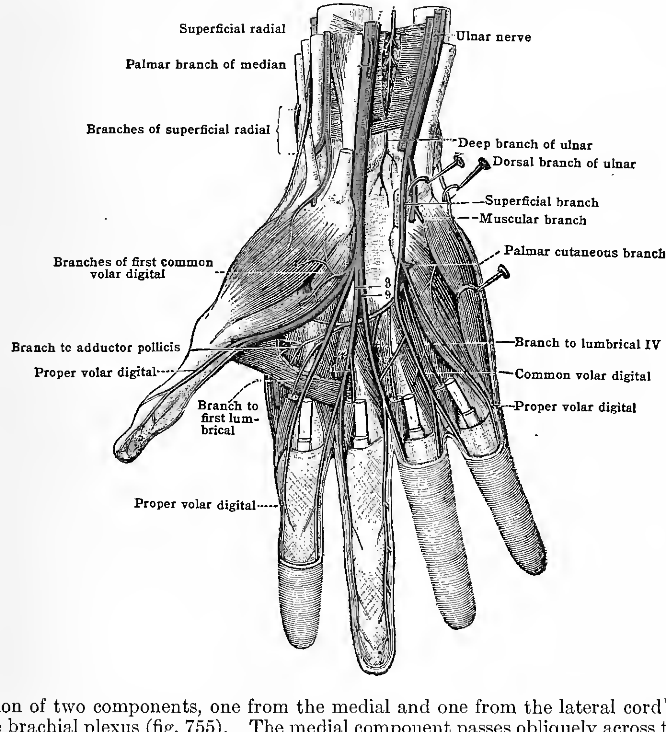
(fig. 756). It furnishes some filaments to the vessel, supplies a few twigs to the skin of the hypothenar eminence, and ends in the integument covering the central depressed surface of the palm.

The **dorsal or posterior cutaneous branch,** usually the smaller of the terminal branches, arises about 5 cm. (2 in.) above the wrist-joint, and passes backward under cover of the flexor carpi ulnaris to reach the dorsal aspect of the wrist (fig. 761), where it gives off delicate branches to anastomose with branches of the medial antibrachial (internal) cutaneous, the dorsal antibrachial (external) cutaneous branch of the radial (musculo-spiral), the lateral antibrachial cutaneous of the musculo-cutaneous nerve, and with branches of the superficial radial, and then divides into five branches, the **dorsal digitals** (fig. 757), which are distributed to the ulnar sides of the third, fourth, and fifth digits and the radial sides of the fourth and fifth digits. These branches usually extend on the fifth digit only as far as the base of the terminal phalanx, and on the fourth digit as far as the base of the second phalanx. The more distal parts of these digits are supplied by palmar digital branches of the ulnar nerve.

The **volar branch,** the other terminal branch of the ulnar nerve, continues its course between the flexor carpi ulnaris and flexor digitorum sublimis, on the medial side of the ulnar artery, to the wrist, where, on the lateral side of the pisiform bone, it divides into a **superficial** and a **deep branch** (figs. 759 and 761). The latter accompanies the deep branch of the ulnar artery into the interval between the abductor digiti quinti and flexor digiti quinti brevis, and then passes through the fibres of the opponens digiti quinti to reach the deep surface of the flexor tendons and their synovial sheaths. It supplies the abductor and opponens digiti quinti, the flexor digiti quinti brevis, the third and fourth lumbricales, all the interossei, the adductors of the thumb, and the medial head, and occasionally the lateral head, of the flexor pollicis brevis. The **superficial branch** gives off a branch to supply the palmaris brevis muscle, an anastomosing branch to the median nerve, and then divides into two branches, the **proper volar digital branch,** which is distributed to the medial side of the fifth digit on its volar aspect, and the **common volar digital branch,** which passes underneath the palmar aponeurosis and divides into two branches, which supply the contiguous margins of the fourth and fifth digits. These branches usually supply also the dorsal surface of the second and third phalanges of the same digits.

The **median nerve** contains fibres of the sixth, seventh, and eighth cervical nerves and of the first thoracic, and sometimes of the fifth cervical nerve. The trunk is formed a little below the lower margin of the pectoralis minor, by the

FIG. 761.—NERVES OF THE PALMAR SURFACE OF THE HAND. (Testut.)
The transverse carpal (anterior annular) ligament, superficial palmar arch, the flexor tendons of the digits, and the proximal portions of the lumbrical muscles have been removed.



union of two components, one from the medial and one from the lateral cord of the brachial plexus (fig. 755). The medial component passes obliquely across the third part of the axillary artery, and in the upper part of the trunk the fibres of the two components are felted together. From its commencement the median nerve runs almost vertically through the lower part of the axillary fossa and through the arm and forearm to the hand.

In the fossa it lies lateral to the axillary artery and it is overlapped, on its lateral side, by the coraco-brachialis muscle. In the upper half of the arm it lies along the lateral side of the brachial artery, and it is overlapped by the medial border of the biceps. At the middle of the arm it passes in front of the brachial artery, and then it descends, on the medial side of the artery, to the elbow. In the upper part of the antecubital fossa it is still at the medial side of the brachial artery, but separated from it by a small interval, and in the lower part of the fossa it lies along the medial side of the ulnar artery. In case of the high division of the brachial artery, when the radial and the ulnar arteries lie together in the upper arm, the median nerve may pass between them and then one or the other of the arteries will be superficial to the nerve. As it leaves the antecubital fossa it passes between the two heads of the pronator teres, and it crosses in front of the ulnar artery (fig. 759), from which it is separated by the deep head of the pronator. In the forearm it passes vertically downward, accompanied by the median (comes nervi mediani) artery. In the upper two-thirds of this region it lies deeply, between the flexor digitorum sublimis and the flexor digitorum profundus, but in the lower third it becomes more superficial, and is placed beneath the deep fascia, between the flexor carpi radialis on the radial side and the palmaris longus and flexor digitorum sublimis tendons on the ulnar side. It crosses beneath the transverse carpal (anterior annular) ligament, in front of the flexor tendons, and in the palm at the lower border of the ligament it enlarges and divides into three branches, the **common volar digital nerves** (fig. 760).

Branches.—The median nerve does not supply any part of the upper arm. In front of the elbow-joint it furnishes one or two filaments to that articulation. In the forearm it supplies all the superficial anterior muscles (with the exception of the flexor carpi ulnaris) directly from its trunk, and it supplies the deep muscles (with the exception of the ulnar half of the flexor digitorum profundus) by its volar (anterior) interosseous branch. Thus in general it supplies the pronator and flexor muscles of the forearm (radial side). In the hand it supplies the group of short muscles of the thumb, which are placed on the radial side of the tendon of the flexor pollicis longus, the two lateral lumbricales, the integument covering the central part of the palm and ulnar aspect of the thenar eminence, and the palmar aspect of the first, second, third, and radial half of the fourth digits. It also sends twigs to the dorsal aspect of these digits.

The **nerve to the pronator teres** usually arises a little above the bend of the elbow, and pierces the lateral border of the muscle (figs. 759 and 761). It may arise in a common trunk with the following nerves:—

The nerves to the **flexor carpi radialis, palmaris longus**, and **flexor digitorum sublimis** arise a little lower down, and pierce the pronator-flexor mass of muscles to end in the respective members of the group for which they are destined (fig. 758).

The **volar (anterior) interosseous nerve** arises from the median at the level of the bicipital tubercle of the radius (fig. 759), and runs downward, on the interosseous membrane, accompanied by the volar (anterior) interosseous artery. It passes under cover of the pronator quadratus, and pierces the deep surface of that muscle, which it supplies. The volar interosseous nerve also furnishes a twig to the front of the wrist-joint, and supplies the flexor digitorum profundus and the flexor pollicis longus. The nerve to the former muscle arises from the volar interosseous near its commencement; it supplies the outer two divisions of the muscle, and it communicates within the substance of the muscle with twigs derived from the ulnar nerve.

It also supplies a branch to the interosseous membrane which runs downward upon, or in, the membrane, supplying it and giving branches to the volar (anterior) interosseous and nutrient arteries and to the periosteum of the radius, the ulna, and the carpus.

The **palmar cutaneous branch** arises immediately above the transverse carpal (anterior annular) ligament and passes between the tendons of the flexor carpi radialis and the palmaris longus (fig. 759). It then crosses the superficial surface of the transverse carpal ligament, and is distributed to the integument and fascia on the central, depressed surface of the palm. It also supplies a few twigs to the medial border of the thenar eminence; these twigs communicate with the musculo-cutaneous and superficial radial nerves.

The three **common volar digital nerves** pass in the palm of the hand dorsal to the superficial palmar arch and its digital branches, while the **proper volar digitals,** branches of these nerves, lie on the volar side of the digital arteries.

The **first** of the common volar digital nerves gives off a branch to supply the abductor pollicis, the opponens, and the superficial head of the flexor pollicis brevis, and joins by a delicate branch with the deep branch of the ulnar nerve. It then divides into three **proper volar digitals** (fig. 761). The lateral of these passes obliquely across the long flexor tendon of the thumb and runs along the radial border of the thumb to its extremity. It gives numerous branches to the pulp of the thumb, and a strong twig which passes to the dorsum to supply the matrix of the nail. The second of these proper volar digitals supplies the medial side of the volar aspect of the thumb and gives off a twig to the matrix of the thumb nail. The third supplies the radial side of the second digit and gives a twig to the first lumbrical muscle.

The **second** common volar digital sends a twig to the second lumbrical muscle, and divides a little above the metacarpo-phalangeal articulation into two **proper volar digitals,** which respectively supply the adjacent sides of the second and third digits.

The **third** common volar digital communicates with the ulnar nerve, often gives a branch to the third lumbrical muscle, and divides into two **proper volar digitals** which supply the adjacent sides of the third and fourth digits.

As the proper volar digitals pass along the margins of the fingers they give off twigs for the innervation of the skin on the dorsum of the second and third phalanges and the matrix of their nails. Each of the nerves terminates in filaments to the pulp of the finger.

Table Showing Relation of Cervical and Thoracic Nerves to Branches of Brachial Plexus

Nerves Contributing.	Nerves, Branches of Plexus.

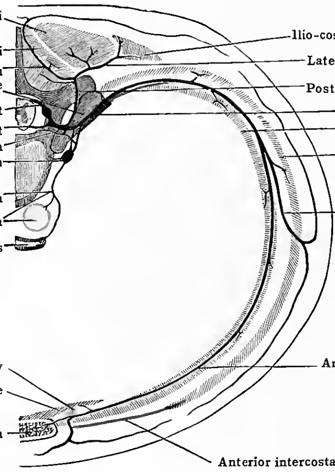
2. THE THORACIC NERVES

The **anterior primary divisions of the thoracic nerves,** with the exception of the first, retain, in the simplest form, the characters of anterior primary divisions of the typical spinal nerve. They do not form plexuses, but remain distinct from each other. Each divides into an easily recognisable lateral or dorsal and anterior or ventral branch (figs. 762 and 763), and they are not distributed to the limbs. The first, second, and last thoracic nerves, on account of their peculiarities, require separate description. The remainder are separable into two groups, an upper and a lower. The **upper group** consists of four nerves, the third to the sixth inclusive, which are distributed entirely to the thoracic wall. The **lower group** contains five nerves, the seventh to the eleventh inclusive, which are distributed partly

Fig. 762.—Diagram of the Distribution of a Typical Thoracic Nerve.



to the thoracic and partly to the abdominal wall. The upper group is therefore purely thoracic in distribution, and the lower thoraco-abdominal.

The **first thoracic nerve** is connected with the first thoracic sympathetic ganglion, and it frequently is joined by a small branch with the second nerve. It is distributed chiefly to the upper limb. Opposite the superior costo-transverse ligament of the second rib it divides into a larger and a smaller branch; the larger passes upward and lateralward, between the apex of the pleura and the neck of the first rib, and on the lateral side of the superior intercostal artery, to the root of the neck, where it joins the brachial plexus. The smaller branch continues along the intercostal space, below the first rib and between the intercostal muscles in which, as a rule, all its fibres terminate.

However, the smaller branch may give off a lateral cutaneous branch which connects with the medial brachial (lesser internal) cutaneous nerve and with the intercosto-brachial nerve in the axillary fossa; and occasionally it terminates in an anterior cutaneous branch at the anterior extremity of the first intercostal space.

The **second thoracic nerve,** as it lies between the pleura and the superior costo-transverse ligament of the third rib, gives a branch to the first nerve, then it pierces the posterior intercostal membrane and passes between the external and internal intercostal muscles in the second intercostal space. In the dorsal part of the space it sends branches backward, through the external intercostal muscle, to supply the second levator costæ and the serratus posterior superior, and then it divides into a *lateral* and an *anterior* branch. The two branches run forward together to the mid-axillary line, where the lateral branch pierces the external intercostal muscle and passes between two digitations of the serratus anterior (magnus) into the axillary fossa; the anterior branch enters the substance of the internal intercostal muscle.

The **lateral branch**, the **intercosto-brachial** (*intercosto-humeral*), may divide into a small anterior and a large posterior division, or the anterior division may be absent. In either case the lateral branch anastomoses with the medial brachial (lesser internal) cutaneous nerve, and usually with the lateral branch of the third intercostal nerve; it also anastomoses with the lateral branch of the first nerve, if the latter is present. After forming these junctions it passes out of the axillary fossa, pierces the deep fascia, and supplies the integument in the upper and posterior half of the arm. It also gives off a few filaments which terminate in the skin over the axillary border of the scapula. The size of the intercosto-brachial nerve and the extent of its distribution are usually in inverse proportion to the size of the other cutaneous nerves of the upper arm, especially the middle brachial (lesser internal) cutaneous. When the latter nerve is absent, the intercosto-brachial usually takes its place.

The course and distribution of the **anterior branch,** when it is present, being similar to the course and distribution of the anterior branches of the next four nerves, do not require a separate description.

The **thoracic intercostal nerves** (upper group).—The third, fourth, fifth, and sixth thoracic nerves, in the posterior parts of the intercostal spaces, give **muscular branches** to the levatores costarum, the first to the fourth also giving branches to the serratus posterior superior. They pass forward a short distance between the external and internal intercostals, giving twigs to these muscles, and divide into two branches, lateral and anterior.

The **lateral cutaneous branches** continue forward between the intercostal muscles, and, near the mid-axillary line, pierce the external intercostals and serratus anterior (magnus) and divide into two branches, posterior and anterior. The *posterior branches* pass backward over the latissimus dorsi to supply the skin in the lower part of the scapular region. The *anterior branches,* in the four nerves, increase in size from above downward. They pass around the lateral border of the great pectoral muscle and are distributed to the integument over the front of the thorax and mamma, sending filaments, the *lateral mammary branches,* into the latter organ. The lowest two nerves also supply twigs to the upper digitations of the external oblique muscle.

The **anterior branches** run obliquely forward and medialward through the substance of the internal intercostal muscles, reaching the deep surface of these muscles at the extremity of the costal cartilages (fig. 762). They continue forward between these muscles and the pleura, pass in front of the internal mammary artery, turn abruptly ventralward a short distance from the sternum, pierce the internal intercostals, the anterior intercostal membrane, and the pectoralis major, and give off three sets of terminal branches. One set supplies the transverse thoracic muscle and the back of the sternum. A second set, cutaneous, runs mesially. The third set passes laterally over the pectoralis major, supplying the skin in that region, and, in the female, the mammary gland through the **medial mammary branches.** The anterior branches in their course supply the intercostal and subcostal muscles and give filaments that supply the ribs, the periosteum, and the pleura.

The thoraco-abdominal nerves (lower group).—The relations of the posterior portions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves to the thoracic wall are similar to those of the upper thoracic intercostal nerves. Each divides in a similar manner into a *lateral* and an *anterior* branch, but these branches are distributed partly to the abdominal and partly to the thoracic wall, and the smaller muscular branches have also different distributions.

The **lateral branches,** *lateral cutaneous nerves of the abdomen,* pierce the external intercostal muscles and pass through or between the digitations of the external oblique into the subcutaneous tissue, where they divide in the typical way into anterior and posterior branches. The *posterior branches* pass backward over the latissimus dorsi. The *anterior branches* give filaments to the digitations of the external oblique and extend forward, medialward and downward to the outer border of the sheath of the rectus.

The **anterior branches** pass forward between the external and internal intercostal muscles, to the ends of the intercostal spaces; there they insinuate themselves between the interdigitating slips of the diaphragm and the transversus abdominis and enter the abdominal wall. The seventh, eighth, and ninth nerves, in their transit from the thoracic to the abdominal wall, pass behind the upturned ends of the eighth, ninth, and tenth rib-cartilages respectively. Having entered the abdominal wall the nerves run forward between the transversus abdominis and the internal oblique muscles to the outer border of the rectus abdominis, where they pierce the posterior lamella of the internal oblique aponeurosis and enter the sheath of the rectus. In the sheath they pass through the substance of the rectus. Finally they turn directly forward, pierce the anterior part of the sheath, and become **anterior cutaneous nerves of the abdomen.**

The muscular branches.—Muscular branches from all the thoraco-abdominal nerves are distributed to the levatores costarum, the intercostal muscles, the transversus abdominis, the internal oblique, and to the rectus abdominis, and the ninth, tenth, and eleventh nerves gives branches also to the serratus posterior inferior. Branches are also distributed from a variable number of the lower nerves to the costal portions of the diaphragm.

The last thoracic nerve.—The anterior primary division of the last thoracic nerve is distributed to the wall of the abdomen and to the skin of the upper and front part of the buttock. It appears in the thoracic wall immediately below the last rib, where it communicates with the sympathetic cord and gives off a communicating branch to the first lumbar nerve. It passes from the thorax into the abdomen beneath the lateral lumbo-costal arch (external arcuate ligament), accompanied by the subcostal artery, and it runs across the upper part of the quadratus lumborum dorsal to the kidney and to the ascending or the descending colon according to the side considered. At the lateral border of the quadratus lumborum it pierces the aponeurosis of attachment of the transversus abdominis muscle and divides, between the transversus and the internal oblique muscle, into a *lateral* and an *anterior* branch. It gives branches to the transversus abdominis, the quadratus lumborum, and the internal oblique muscles.

The **anterior branch** passes forward, between the internal oblique and the transversus abdominis, to which it supplies twigs. It enters the sheath of the rectus, turns forward through that muscle, and terminates in branches which become cutaneous midway between the umbilicus and the symphysis. Before it becomes cutaneous it supplies twigs to the transversus abdominis, the internal oblique, the rectus abdominis, and the pyramidalis muscles.

The **lateral branch** pierces the internal oblique; it supplies the lowest digitation of the external oblique, and then pierces the latter muscle from 2.5 to 8 cm. (1 to 3 in.) above the iliac crest, and descends in the superficial fascia of the anterior part of the gluteal region, crossing the iliac crest about 2.5 cm. (1 in.) behind its anterior extremity and reaching as far down as the level of the great trochanter. Occasionally this branch is absent and its place is taken by the iliac branch of the ilio-hypogastric. In such cases, however, the branch from the last thoracic to the first lumbar nerve is larger than usual.

THE LUMBO-SACRAL PLEXUS

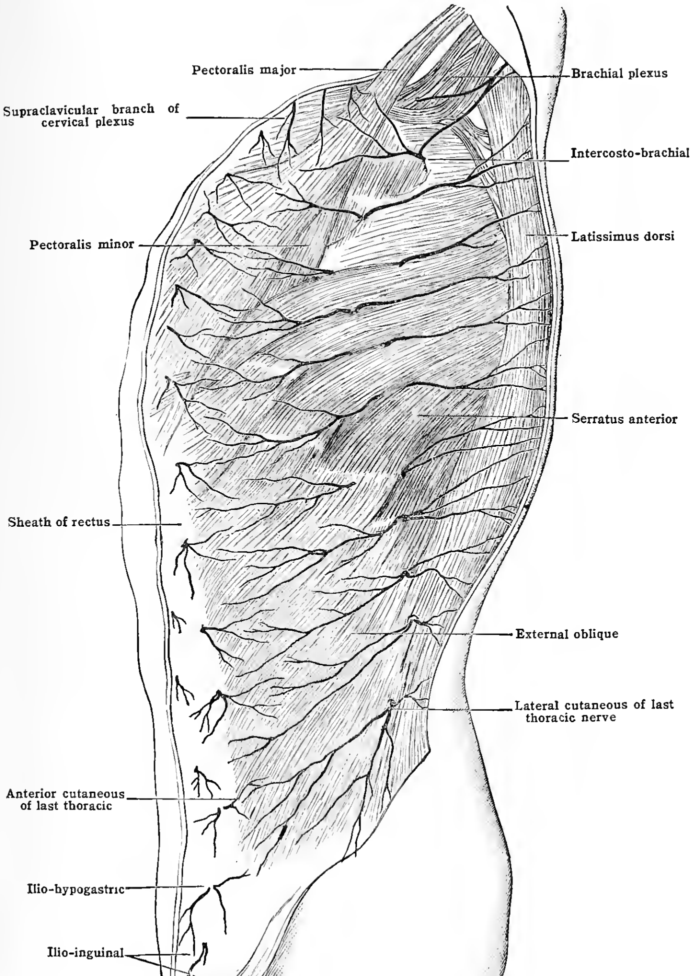
The lumbo-sacral plexus is formed by the union of the anterior primary divisions of the lumbar, sacral, and coccygeal nerves. In about 50 per cent. of cases it receives a branch from the twelfth thoracic nerve. Its components are distributed to the lower extremity in a manner homologous and similar to the distribution of the parts of the brachial plexus to the upper extremity; the lumbar nerves are distributed similarly to the nerves formed from the anterior (medial and lateral) cords of the brachial plexus, and the sacral nerves are distributed in a manner similar to the distribution of the nerves from the posterior cord of the brachial plexus.

Partly for convenience of description and partly on account of the differences in position and course of some of the nerves arising from it, this plexus is subdivided into four parts—the lumbar, sacral, pudendal, and coccygeal plexuses. These plexuses overlap so that there is no definite line of demarcation between them. However, they will be considered separately.

3. *THE LUMBAR NERVES*

The anterior primary divisions of the five lumbar nerves increase in size from the first to the last. Each lumbar nerve is connected by one or two long, slender rami with a lumbar sympathetic ganglion. The first three nerves and the greater part of the fourth enter into the formation of the lumbar plexus, and the smaller

FIG. 763.—CUTANEOUS NERVES OF THE THORAX AND ABDOMEN, VIEWED FROM THE SIDE. (After Henle.)



part of the fourth and the fifth nerve commonly unite to form the lumbo-sacral cord which takes part in the formation of the sacral plexus (figs. 764, 765). When the fourth nerve enters into the formation of both lumbar and sacral plexuses, it may be called the *furcal nerve*, but this name is also applied to any of the nerves that enter into the formation of both plexuses, so there may be one or more furcal nerves.

THE LUMBAR PLEXUS

Although the **lumbar plexus** is ordinarily formed by the first three lumbar nerves and a part of the fourth, yet it is subject to considerable variation in the manner of its formation.

Owing to this variation three general classes of plexuses may be found, **proximal or prefixed, ordinary,** and **distal or post-fixed.** The basis of classification is the relation of the nerves of the limb to the spinal nerves which enter into their formation. The intermediate or slighter degrees of variation may consist only of changes in the size of the portions contributed by the different spinal nerves to a given peripheral nerve, for a given nerve may receive a larger share of its fibres from a more proximal spinal nerve, and a smaller share from a more distal nerve, or *vice versâ*. However, in the more marked degrees of variation the origin of a given peripheral nerve may vary in either direction to the extent of one spinal nerve. The more extreme types of the plexuses are sometimes associated with abnormal conditions of the vertebral column. It has been suggested that when the prefixed or proximal condition occurs, it indicates that the lower limb is placed a segment more proximal than in the ordinary cases, and when the distal condition is present, that the limb is arranged a segment more distal. Three types each of the proximal and the distal classes and one type of the ordinary class have been described by Bardeen. His statistics are made use of in the compilation of the following tables, in which are shown the range of variation and the common composition of each class of plexus:—

Composition of the Nerves of the Lumbar Plexus
Range of Variation

Nerve.	Proximal.	Ordinary.	Distal.
Lateral (external) cutaneous	12 T, 1, 2, 3 L.	1, 2, 3, 4 L.	1, 2, 3, 4 L.
Femoral (anterior crural) ...	12 T, 1, 2, 3, 4 L.	1, 2, 3, 4 L.	1, 2, 3, 4, 5 L.
Obturator..................	1, 2, 3, 4 L.	1, 2, 3, 4 L.	2, 3, 4, 5 L.
Furcal....................	3 or 3, 4 L.	4 L.	4, 5 or 5 L.

Common Composition

Nerve.	Proximal.	Ordinary.	Distal.
Lateral (external) cutaneous	1, 2 L.	1, 2, 3 L.	2, 3 L.
Femoral (anterior crural) ..	1, 2, 3, 4 L.	2, 3, 4 L.	2, 3, 4, 5, L.
Obturator................	1, 2, 3, 4 L.	2, 3, 4 L.	2, 3, 4 L.
Furcal...................	4 L.	4 L.	4 L.

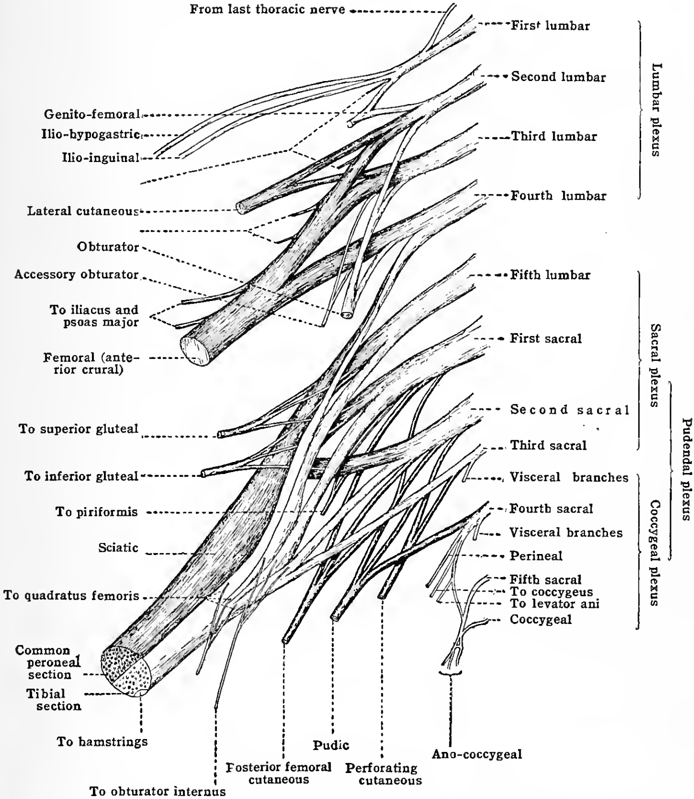
The lumbar plexus lies in the posterior part of the psoas muscle (fig. 765), in front of the transverse processes of the lumbar vertebræ and the medial border of the quadratus lumborum, and its terminal branches are distributed to the lower part of the abdominal wall, the front and medial part of the thigh, the external genital organs, the front of the knee, the medial side of the leg, and the medial side of the foot.

The first and second of the lumbar nerves give collateral *muscular branches* to the quadratus lumborum muscle, and the second and third nerves give similar branches to the psoas. The remaining branches of the plexus are *terminal branches*. The first lumbar nerve, after it has been joined by the branch from the last thoracic nerve, divides into three terminal branches, the ilio-hypogastric nerve, the ilio-inguinal nerve, and a branch which joins the second nerve. The fibres of this latter branch pass mainly into the genito-femoral (genito-crural) nerve, but occasionally some of them enter the femoral (anterior crural) and obturator nerves. The remaining nerves divide into anterior or ventral and posterior or dorsal divisions. The **anterior divisions** form a portion of the genito-femoral (genito-crural) nerve and the obturator nerve, and the **posterior divisions** enter the lateral (external) cutaneous and femoral (anterior crural) nerves.

All the terminal branches of the plexus are formed in the substance of the psoas muscle; four of them, the ilio-hypogastric, the ilio-inguinal, the lateral (external) cutaneous, and the femoral (anterior crural), leave the muscle at its lateral border. The genito-femoral (genito-crural) passes through its anterior surface, and the obturator through its medial border.

Terminal branches.—The **ilio-hypogastric nerve** springs from the first lumbar nerve, after the latter has been joined by the communicating branch from the last thoracic nerve, as it is in about 50 per cent. of the cases, and it thus contains fibres of both the last thoracic and the first lumbar nerves. It pierces the lateral border of the psoas and crosses in front of the quadratus lumborum (fig. 765), and behind the kidney and the colon. At the lateral border of the quadratus it pierces the aponeurosis of origin of the transversus abdominis and enters the areolar tissue between the transversus and the internal oblique, where it frequently communicates with the last thoracic and with the ilio-inguinal

Fig. 764.—Diagram of a Common Form of Lumbo-sacral Plexus. (Modified from Paterson.)



nerve, and it divides into an iliac and a hypogastric branch, which correspond, respectively, with the lateral and anterior branches of a typical spinal nerve.

The **anterior cutaneous (hypogastric) branch** passes forward and downward, between the transversus abdominis and the internal oblique muscles, giving branches to both; it communicates with the ilio-inguinal nerve, and, near the anterior superior spine of the ilium, it pierces the internal oblique muscle and continues forward beneath the external oblique aponeurosis toward the middle line. About 2.5 cm. (1 in.) above the subcutaneous inguinal ring it pierces the aponeurosis of the external oblique, becomes subcutaneous, and supplies the skin above the symphysis.

The **lateral cutaneous (iliac) branch** pierces the internal and external oblique muscles, emerging through the latter above the iliac crest at the junction of its anterior and middle thirds (fig. 769). It is distributed to the integument of the upper and lateral part of the thigh, in the neighborhood of the gluteus medius and tensor fasciæ latæ muscles (fig. 768).

The **ilio-inguinal nerve** arises principally from the first lumbar nerve, but it frequently contains fibres of the last thoracic nerve. It emerges from the lateral border of the psoas, at a lower level than the ilio-hypogastric nerve, and passes across the quadratus lumborum (figs. 765, 766). As a rule, it is below the level of the inferior end of the kidney, but it passes dorsal to the ascending or the descending colon according to the side considered, and crosses the posterior part of the inner lip of the iliac crest; it then runs forward on the upper part of the iliacus, pierces the transverus abdominis near the anterior part of the crest, and communicates with the anterior cutaneous (hypogastric) branch of the ilio-hypogastric nerve. A short distance below the anterior superior spine it passes through the internal oblique muscle, and then descends in the inguinal canal to the subcutaneous inguinal (external abdominal) ring, through which it emerges into the thigh on the lateral side of the spermatic cord (fig. 763). It is distributed to the skin of the upper and medial part of the thigh, in the male to the root of the penis and to the skin of the root of the scrotum through the **anterior scrotal nerves** (fig. 768), and in the female to the mons veneris and labium majus through the **anterior labial nerves.**

Not uncommonly the ilio-inguinal nerve is blended with the ilio-hypogastric nerve and separates from the latter between the transversus abdominis and the internal oblique muscles. It may be replaced by branches of the genito-femoral (genito-crural) nerve, or it may replace that nerve or the lateral cutaneous nerve.

The **genito-femoral (genito-crural) nerve** is connected with the first and second lumbar nerves, but the majority of its fibres are derived from the second nerve. It passes obliquely forward and downward through the psoas and emerges from the anterior surface of that muscle, close to its medial border, at the level of the lower border of the third lumbar vertebra. After emerging from the substance of the psoas it runs downward on the anterior surface of the muscle (fig. 765), to the lateral side of the aorta and the common iliac artery, passes behind the ureter and divides into two branches, an external spermatic or genital, and a lumbo-inguinal or crural (fig. 766). Occasionally it divides in the substance of the psoas, and then the two branches issue separately through the anterior surface of the muscle.

The **external spermatic (genital) branch** runs downward on the psoas muscle, external to the external iliac artery; it gives a branch to the psoas, and at Poupart's ligament it turns around the inferior epigastric artery and enters the inguinal canal, accompanying the spermatic cord in the male or the round ligament in the female. It supplies the cremaster muscle, and gives twigs to the integument of the scrotum (fig. 766) or the labium majus.

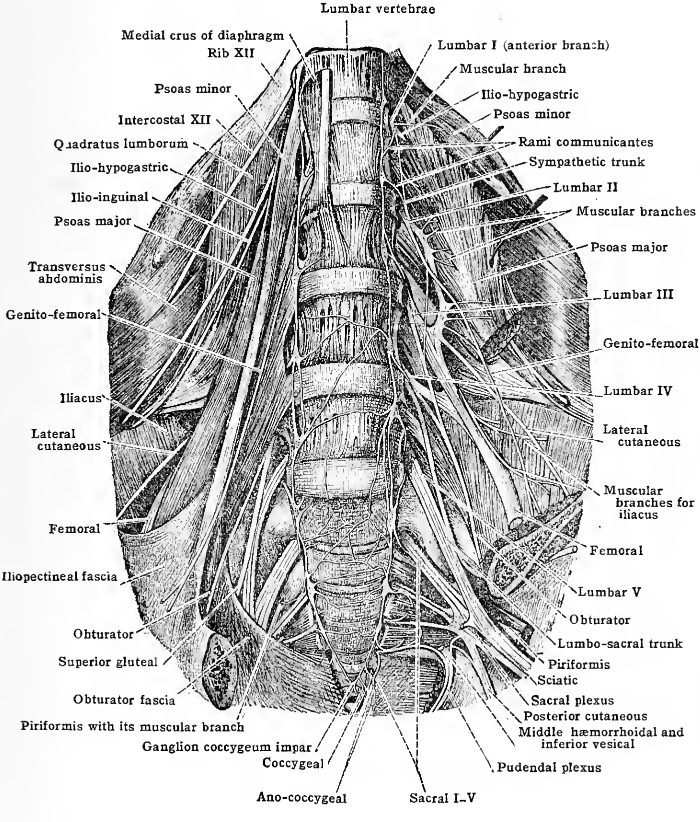
The **lumbo-inguinal (crural) branch** passes downward along the external iliac artery and beneath Poupart's ligament into the thigh, which it enters to the lateral side of the femoral artery. A short distance below Poupart's ligament it pierces the fascia lata or passes through the fossa ovalis (saphenous opening) and supplies the skin in the middle of the upper part of the thigh. A short distance below Poupart's ligament it sometimes sends branches to the anterior branch of the lateral cutaneous nerve, and about the middle of the thigh it often joins with the cutaneous branches of the femoral (anterior crural) nerve.

The **lateral cutaneous nerve** receives fibres from the dorsal branches of the anterior primary divisions of the second and third lumbar nerves, and frequently some fibres from the first lumbar (fig. 769). It emerges from the lateral border of the psoas and passes obliquely across the iliacus dorsal to the iliac fascia, and dorsal to the cæcum on the right side and the sigmoid colon on the left side, to a point immediately below the anterior superior spine of the ilium, where it passes below Poupart's ligament into the lateral angle of the femoral trigone (Scarpa's triangle). Leaving the trigone at once it passes through, behind, or in front of the sartorius and divides into two branches, anterior and posterior, which enter the deep fascia (fig. 766).

The **posterior branch** of the lateral cutaneous nerve breaks up into several secondary branches which become subcutaneous, and they supply the integument of the lateral part of the thigh, from the great trochanter to the level of the middle of the femur. The **anterior branch** runs downward in a canal in the deep fascia, for three or four inches, before it becomes subcutaneous. It usually divides into two branches, a lateral and a medial. The *lateral branch* supplies the skin of the lower half of the lateral side of the thigh, and the *medial branch* is distributed to the skin of the lateral side of the front of the thigh as far as the knee (fig. 766). Its lower filaments frequently unite with the cutaneous branches of the femoral (anterior crural), and with the patellar branch of the saphenous nerve in front of the patella, forming with them the patellar plexus.

The **femoral (anterior crural) nerve** is the largest terminal branch of the lumbar plexus. It is formed chiefly by fibres of the dorsal branches of the anterior primary divisions of the second, third, and fourth lumbar nerves, but it sometimes receives fibres from the first nerve also (figs. 765 and 769). It emerges from the lateral border of the psoas a short distance above Poupart's ligament, and descends in the groove between the psoas and the iliacus, behind Poupart's ligment, into

FIG. 765.—LUMBO-SACRAL PLEXUS. (After Toldt, 'Atlas of Human Anatomy,' Rebman, London and New York.)



the femoral trigone (Scarpa's triangle), where it lies to the lateral side of the femoral artery (fig. 767), from which it is separated by some of the fibres of the psoas. In this situation it is flattened out and it divides into two series of terminal branches, the superficial and the deep. In general, they supply the muscles and skin on the anterior aspect of the thigh.

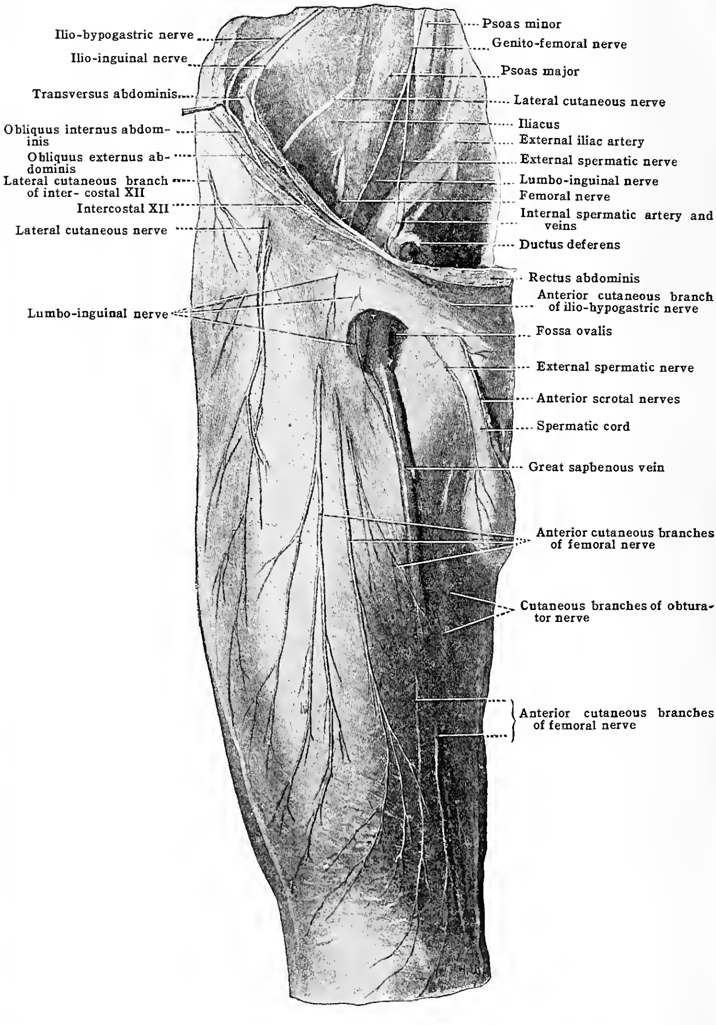
Branches.—The branches of the femoral nerve are collateral and terminal.

The **collateral branches** are twigs of supply to the iliacus, and a branch to the femoral artery; they are given off before the nerve enters the femoral trigone.

The **terminal branches** form two groups, the superficial and the deep.

The **superficial terminal branches** are two muscular branches, the nerve to the pectineus, and the nerve to the sartorius, and two anterior cutaneous branches.

Fig. 766.—Cutaneous Nerves of the Right Thigh. (Spalteholz.)
(The iliac fascia has been removed, the fascia lata retained.)



The **nerve to the pectineus** passes medially and downward behind the femoral sheath and in front of the psoas to the anterior surface of the pectineus, in which it terminates.

The **nerve to the sartorius** accompanies the middle cutaneous nerve; it leaves the latter nerve above the sartorius and ends in the upper part of the muscle.

The anterior (**middle and internal**) **cutaneous nerves** are best described separately. The **middle cutaneous nerve** soon divides into two branches, medial and lateral. The lateral branch pierces the sartorius and both branches become cutaneous about the junction of the upper and middle thirds of the thigh (figs. 766, 768). They descend along the medial part of the front of the thigh to the knee, supplying the skin in the lower two-thirds of the medial part of the front of the thigh, and their terminal filaments take part in the formation of the patellar plexus. About the middle of the thigh the middle cutaneous is often joined by a twig with the lumbo-inguinal nerve (crural branch of the genito-crural nerve). The **medial or internal cutaneous nerve** runs downward and medialward along the lateral side of the femoral artery, to the apex of the femoral trigone (Scarpa's triangle), where it crosses in front of the artery and divides into an anterior and a posterior terminal branch. Before this division takes place, however, two or three collateral branches are given off from the trunk. The highest of these passes through the fossa ovalis (saphenous opening), or it pierces the deep fascia immediately below the opening, and supplies the skin as low as the middle of the thigh. The lowest pierces the deep fascia at the middle of the thigh and it descends in the subcutaneous tissue, supplying the skin on the medial side of the thigh from the middle of the thigh to the knee (figs. 768, 769). This nerve frequently varies in size inversely with the cutaneous branches of the obturator and saphenous nerves. The **anterior branch** of the internal cutaneous nerve passes vertically downward to the junction of the middle and lower thirds of the thigh, where it pierces the deep fascia. It still continues downward for a short distance, then it turns lateralward and passes to the front of the knee, where it enters into the patellar plexus.

The **posterior branch** descends along the dorsal border of the sartorius, and it gives off a branch which passes beneath that muscle to unite with twigs from the saphenous and from the superficial division of the obturator nerve, forming with them the **subsartorial plexus** which lies on the roof of the adductor (Hunter's) canal. At the medial side of the knee the nerve pierces the deep fascia and it descends to the middle of the calf (figs. 766, 768).

The **deep terminal branches** of the femoral nerve are six in number, one cutaneous branch, the *saphenous*, and five *muscular branches*. The branches radiate from the termination of the trunk of the femoral nerve, and they are arranged in the following order from medial to lateral:—the saphenous nerve, the nerve to the vastus medialis, the nerve to the articularis genu (subcrureus), the nerve to the vastus intermedius (crureus), the nerve to the vastus lateralis, and the nerve to the rectus femoris.

The **saphenous nerve** passes down through Scarpa's triangle along the lateral side of the femoral artery. At the apex of the triangle it enters the adductor (Hunter's) canal and descends through it, lying first to the lateral side, then in front, and finally to the medial side of the artery (fig. 767). After emerging from the lower end of the canal, accompanied by the superficial branch of the genu suprema (anastomotic) artery, it passes between the dorsal border of the sartorius and the anterior border of the tendon of the gracilis, and, becoming superficial, it enters into relationship with the great saphenous vein and descends with it along the inner border of the upper two-thirds of the tibia (fig. 768). It crosses the medial surface of the lower third of the tibia, passes in front of the internal malleolus, and runs forward along the medial border of the foot to the ball of the great toe.

While it is in the adductor (Hunter's) canal it gives off a twig to the subsartorial plexus. Before it passes from under cover of the sartorius it gives off an infra-patellar branch, which pierces the sartorius just above the knee and passes outward to the patellar plexus. After it becomes superficial it supplies the integument on the medial side of the leg and foot, and it anastomoses, in the foot, with the medial dorsal cutaneous branch of the superficial peroneal (musculo-cutaneous) nerve.

The **nerve to the vastus medialis** accompanies the saphenous nerve in the femoral trigone (Scarpa's triangle), lying to its outer side. At the upper end of the adductor canal it passes beneath the sartorius, external to the roof of the canal, and enters the medial surface of the vastus medialis. It sends a twig down to the knee-joint.

The **nerve to the articularis genu (subcrureus)**, usually a terminal branch of the femoral, frequently arises from the nerve to the vastus intermedius. It passes between the vastus medialis and the vastus intermedius to the lower third of the thigh, where it supplies the articularis genu and sends a branch to the knee-joint.

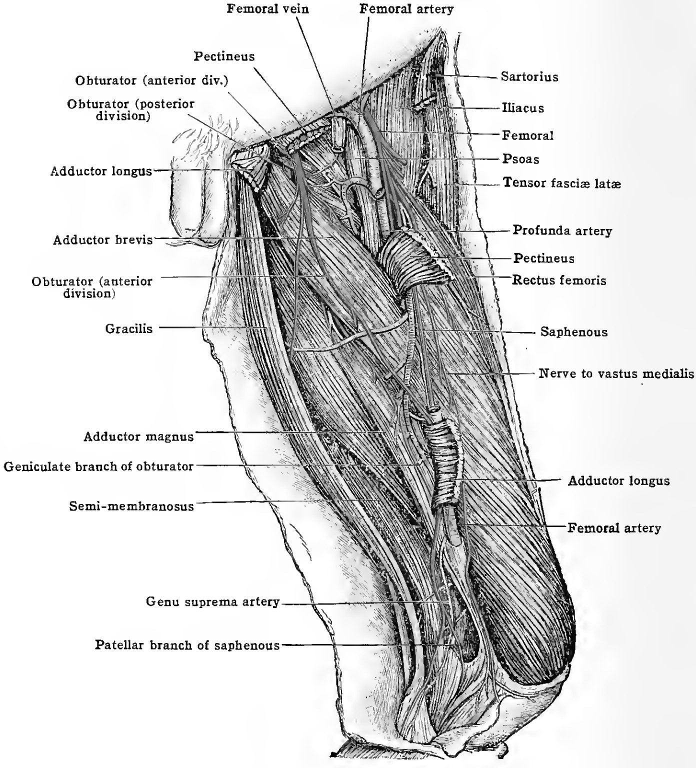
The **nerve to the vastus intermedius (crureus)** is represented by two or three branches which enter the upper part of the muscle. One of them frequently sends a twig to the knee-joint.

The **nerve to the vastus lateralis** passes downward behind the rectus and along the anterior border of the vastus lateralis accompanied by the descending branch of the lateral circumflex artery. It also sends a branch to the knee-joint.

The **nerve to the rectus femoris** (fig. 767) enters the deep surface of that muscle, having previously given off a twig to the hip-joint which accompanies the ascending branch of the external circumflex artery.

The **obturator nerve** contains fibres from the anterior primary divisions of the second, third, and fourth lumbar nerves, but its largest root is derived from the third nerve (figs. 765, 769). It sometimes receives fibres from the first and third lumbar nerves. It emerges from the medial border of the psoas at the dorsal part of the brim of the pelvis, where it lies in close relation with the lumbo-sacral trunk of the plexus, from which it is separated by the ilio-lumbar artery. Immediately after its exit from the psoas it pierces the pelvic fascia, crosses the lateral side of the internal iliac vessels and the ureter, and runs forward in the extraperitoneal fat, below the obliterated hypogastric artery and along the upper part of the medial surface of the obturator internus to the upper part of the obturator foramen, where it passes through the obturator canal below the so-called horizontal ramus of the pubis and above the obturator membrane, into the upper part of the thigh. It is accompanied in the pelvis and the obturator canal by the obturator artery, which lies at a lower level than the nerve, and it divides

Fig. 767.—Femoral and Obturator Nerves. (Ellis.)



in the obturator canal into two branches, an anterior and a posterior, which supply the adductor group of muscles, the hip and knee-joints, and the skin on the medial aspect of the leg.

The **anterior branch** of the obturator has a twig joining it with the accessory obturator nerve, if that nerve is present, and then descends behind the pectineus and adductor longus and in front of the obturator externus and adductor magnus muscles (fig. 767). Its branches are:—

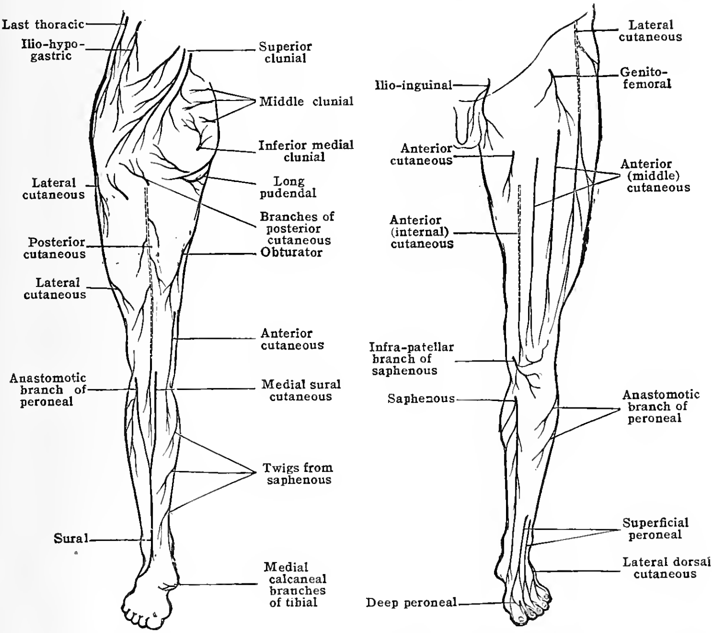
1. A **twig** to the accessory obturator nerve if the latter is present.
2. An **articular branch** to the hip-joint.
3. **Muscular branches** to the gracilis, adductor longus, and, usually, to the adductor brevis.
4. Two **terminal branches**, of which one is distributed to the femoral artery and the other communicates with the subsartorial plexus. The subsartorial branch is occasionally longer

than usual, and it then descends, along the dorsal border of the sartorius, to the medial side of the knee, where it enters the subcutaneous tissue, and, proceeding downward, supplies the skin on the medial side of the leg as far as the middle of the calf. Twigs join it with the saphenous.

The **posterior branch** of the obturator (fig. 767) pierces the upper part of the obturator externus and passes downward between the adductor brevis and adductor magnus. Its branches are:—

1. **Muscular branches** to the obturator externus, to the oblique fibres of the adductor magnus and to the adductor brevis when the latter is not entirely supplied by the anterior branch. The branch to the obturator externus is given off in the obturator canal.
2. An **articular branch** to the knee-joint which appears in some cases to be the continuation of the trunk of the posterior branch (fig. 767). It either pierces the lower part of the adductor

Fig. 768.—Distribution of Cutaneous Nerves on the Posterior and Anterior Aspects of the Inferior Extremity.



magnus, or it passes through the opening for the femoral artery. In the popliteal space it descends on the popliteal artery to the back of the joint, where it pierces the posterior ligament, and its terminal filaments are distributed to the crucial ligaments and the structures in their immediate neighbourhood. This branch is not uncommonly absent. Occasionally the posterior branch of the obturator nerve also supples a twig to the hip-joint.

The **accessory obturator nerve** arises from the third or fourth or from the third and fourth lumbar nerves, in the angles between the roots of the femoral (anterior crural) and obturator nerves. It is present in about twenty-nine per cent. of all cases (Eisler). It is often closely associated with the obturator nerve to the level of the brim of the pelvis, but instead of passing through the obturator foramen, it descends along the medial border of the psoas, crosses the anterior part of the brim of the pelvis, passes beneath the pectineus, and terminates in three main branches. One of these branches joins the anterior division of the obturator nerve, another supplies the pectineus, and the third is distributed to the hip-joint.

The Lumbo-sacral Trunk

The trunk of the plexus usually formed by the union of the smaller part of the fourth and the entire fifth lumbar nerves is called the **lumbo-sacral trunk** (figs. 765, 769). Sometimes the larger part of the fourth nerve may help to form the trunk. It may receive fibres from the third lumbar nerve or be formed entirely from the fifth. At its formation it is situated on the ala of the sacrum under cover of the psoas. It descends into the pelvis, and, as it crosses the anterior border of the ala of the sacrum, it emerges from beneath the psoas at the medial side of the obturator nerve, from which it is separated by the ilio-lumbar artery. It passes behind the common iliac vessels and unites with the first and second sacral nerves, forming with them the upper trunk of the sacral plexus.

4. *SACRAL NERVES*

The anterior primary divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina and they diminish in size progressively from above downward. The first sacral is the largest of the spinal nerves, the second is slightly smaller than the first, while the third and fourth are relatively small. The fifth sacral nerve is still smaller than the fourth; it enters the pelvis between the sacrum and the coccyx. The anterior divisions of these nerves enter into the formation of three parts of the lumbo-sacral plexus, the sacral, pudendal, and coccygeal.

Sacral Plexus

The **sacral plexus** shows in its formation variations similar to those of the lumbar plexus; hence there are also seven types of this plexus, three of them belonging to the prefixed or proximal class, three to the postfixed or distal class, and one to the ordinary class. The following tables show the range of variation and the common arrangement in these classes:—

Composition of the Nerves of the Sacral Plexus
Range of Variation

Nerve.	Proximal.	Ordinary.	Distal.
Furcal	3 or 3, 4 L.	4 L.	4, 5 or 5 L.
Common peroneal (external popliteal)	3, 4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.	4, 5 L. 1, 2, 3 S.
Tibial (internal popliteal)	3, 4, 5 L. 1, 2, S.	4, 5, L. 1, 2, 3 S.	4, 5 L. 1, 2, 3, 4, S.
Posterior femoral cutaneous (small sciatic)	5 L. 1, 2, 3 S.	5 L.1, 2, 3, 4 S.	5 L. 1, 2, 3, 4 S.

Common Composition

Nerve.	Proximal.	Ordinary.	Distal.
Furcal	4 L.	4L.	4L.
Common peroneal (external popliteal	4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.	4, 5 L. 1, 2 S.
Tibial (internal popliteal).	4, 5 L. 1, 2 S.	4, 5 L. 1, 2, 3 S.	4, L. 1, 2, 3, 4 S.
Posterior femoral cutaneous (small sciatic)	1, 2, 3 S.	1, 2, 3 S.	2, 3 S.

The ordinary type of sacral plexus is commonly formed by the smaller part of the anterior division of the fourth lumbar nerve and the entire anterior division of the fifth lumbar nerve, together with the first and parts of the second and third sacral nerves.

The plexus lies in the pelvis on the anterior surface of the piriformis (fig. 765) and behind the pelvic fascia and the branches of the hypogastric (internal iliac) artery. It is also dorsal to the coils of intestine, the lower part of the ilio-pelvic colon lying in front of the left plexus, and the lower part of the ileum in front of the right plexus.

The branches given off by this plexus are:—visceral, cutaneous, and muscular.

Visceral branches are given off from the second, third, and fourth sacral nerves to the pelvic viscera.

The visceral branches correspond to white rami communicantes, through not joining the sympathetic trunk. The branches from the second and fourth sacral nerves are inconstant.

Cutaneous branches.—(*a*) The **posterior femoral cutaneous (small sciatic) nerve** arises partly from the anterior and partly from the posterior branches of the anterior primary divisions of the first, second, and third sacral nerves. It lies on the back of the plexus (figs. 765, 769), leaves the pelvis at the lower border of the piriformis, and descends in the buttock between the gluteus maximus and the posterior surface of the sciatic nerve (fig. 770). At the lower border of the gluteus maximus it passes behind the long head of the biceps femoris, and descends, immediately beneath the deep fascia, through the thigh and the upper part of the popliteal space (fig. 740). At the lower part of the popliteal region it perforates the deep fascia, and it terminates in branches which are distributed to the skin of the calf.

Branches of the small sciatic.—1. **Perineal branches** are distributed in part to the skin of the upper and medial sides of the thigh on its dorsal aspect. One of the branches, known as the **long pudendal nerve**, runs forward and medialward in front of the tuberosity of the ischium to the lateral margin of the anterior part of the perineum, where it perforates the fascia lata and Colles' fascia and enters the anterior compartment of the perineum. In the perineum twigs join it with the superficial perineal nerves, and its terminal filaments are distributed to the skin of the scrotum in the male, and to the labium majus in the female.

2. **Inferior clunial** (gluteal) **branches**, two or three in number, are given off beneath the gluteus maximus; they turn around the lower border of this muscle and are distributed to the skin of the lower and lateral part of the gluteal region.

3. **Femoral cutaneous branches** are given off as the nerve descends through the thigh. They perforate the deep fascia and are distributed to the skin of the back of the thigh, especially on the medial side.

In case of the separate origin of the tibial (internal popliteal) and common peroneal (external popliteal) nerves, the posterior femoral cutaneous (small sciatic) also arises from the sacral plexus in two parts. The *ventral portion* descends with the tibial nerve below the piriformis and gives off the perineal branches and medial femoral branches, while the *dorsal portion* passes through that muscle with the common peroneal nerve, and furnishes the gluteal and lateral femoral branches.

(*b*) The **inferior medial clunial (perforating cutaneous) nerve** arises from the posterior portion of the second and third sacral nerves (figs. 765, 769). It perforates the lower part of the sacro-tuberous (great sciatic) ligament, turns around the inferior border of the gluteus maximus, and is distribtued to the skin over the lower and medial part of that muscle. It is sometimes associated at its origin with the pudic nerve. It is not always present. Its place is sometimes taken by a small nerve (the *greater coccygeal perforating nerve* of Eisler), arising from the third and fourth or fourth and fifth sacral nerves, and sometimes it is represented by a branch of the posterior femoral cutaneous.

Muscular branches of the sacral plexus.—(*a*) One or two small **nerves to the piriformis** pass from the posterior divisions of the first and second sacral nerves.

(*b*) The **superior gluteal nerve** receives fibres from the posterior branches of the fourth and fifth lumbar, and the first sacral nerves. It passes out of the pelvis through the great sciatic foramen, above the upper border of the piriformis, and it is accompanied by the superior gluteal artery. As soon as it enters the buttock it divides into two branches, an upper and a lower.

1. The **upper branch** is the smaller. It accompanies the upper branch of the deep division of the superior gluteal artery below the middle curved line of the ilium, and it ends entirely in the gluteus medius (fig. 770).

2. The **lower branch**, larger than the upper, passes forward across the middle of the gluteus minimus, with the lower branch of the gluteal artery; it supplies the gluteus medius and the gluteus minimus, and it ends in the medial and posterior part of the tensor fasciæ latæ.

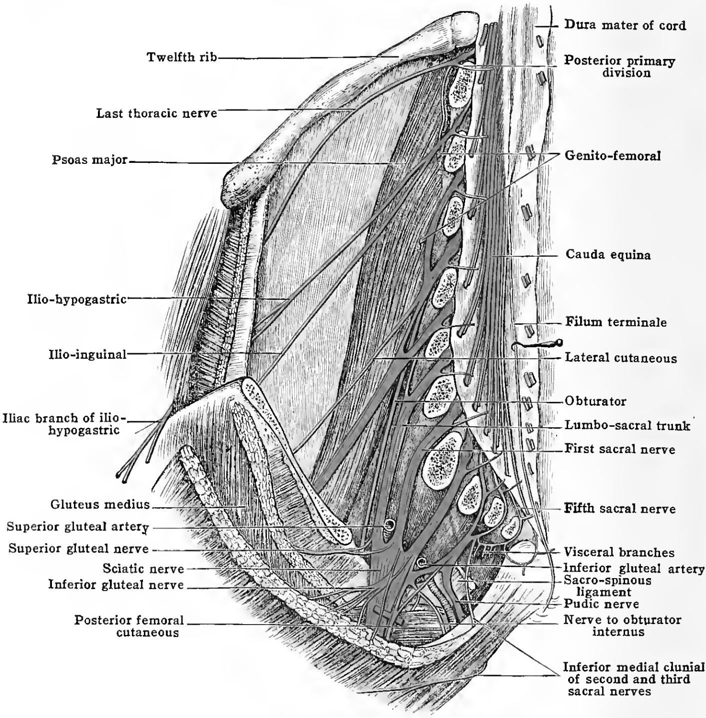
(*c*) The **inferior gluteal nerve** is formed by fibres from the posterior branches of the fifth lumbar, and the first and second sacral nerves. It passes through the great sciatic foramen, below the piriformis, and divides into a number of branches which end in the gluteus maximus (figs. 765, 769).

(*d*) The **nerve of the quadratus femoris** is formed by the anterior branches of the fourth and fifth lumbar and the first and second sacral nerves. It lies on the front of the plexus and issues from the pelvis below the piriformis. In the buttock it lies at first between the sciatic nerve and the back of the ischium, and, at a lower level, between the obturator internus with the gemelli and the ischium. It terminates in the anterior surface of the quadratus femoris, having previously given off a branch to the hip-joint and another to the inferior gemellus.

(*e*) The **nerve of the obturator internus** is formed by the anterior branches of the fifth lumbar, and the first and second sacral nerves (figs. 765, 769). It leaves the pelvis below the piriformis, and crosses the spine of the ischium on the lateral side of the internal pudic artery and on the medial side of the sciatic nerve. It gives a branch to the gemellus superior, and turns forward through the small sciatic foramen into the perineum, where it terminates in the inner surface of the obturator internus.

The **sciatic nerve** [n. ischiadicus].—The sciatic is not only the largest nerve of the sacral plexus, but it is also the largest nerve in the body. Its terminal branches are chiefly muscular, though some of its fibres are cutaneous. Although it is referred to as one trunk, it consists in reality of peroneal (lateral) and tibial (medial popliteal) portions, which are bound together by a sheath of fibrous tissue as far as the upper end of the popliteal space. In about 10 per cent. of the cases the two parts remain separate, and in such cases the peroneal (lateral popliteal)

Fig. 769.—A Dissection of the Lumbar and Sacral Plexuses, from Behind.
(The anterior crural nerve is placed between the external cutaneous and obturator nerves.)

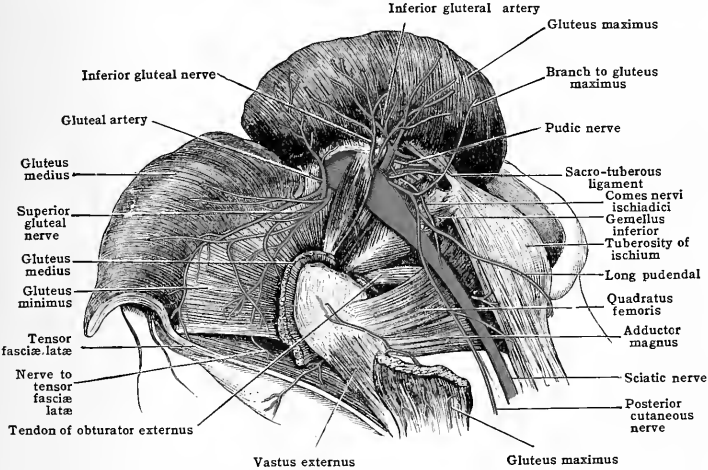


part usually pierces the piriformis. The peroneal portion of the nerve consists of fibres derived from the dorsal branches of the anterior primary divisions of the fourth and fifth lumbar and the first and second sacral nerves, while the tibial part is formed by the fibres from the anterior branches of the fourth and fifth lumbar, and the first, second, and third sacral nerves (figs. 765, 769). The common trunk leaves the pelvis by passing through the great sacro-sciatic foramen, usually below the piriformis, and descends through the buttock, running midway between the tuber ischii and the great trochanter (fig. 770). Passing down the thigh, the trunk terminates at the upper angle of the popliteal space by dividing into the common peroneal (external politeal) and the tibial (internal popliteal) nerves (fig. 771).

The relation of the trunk to the piriformis muscle is more or less unique. It may pass either above or below the muscle, it may split and pass around the muscle, or the muscle may be split and surround the nerve. Again, there may be a splitting of both the muscle and the nerve, in which case any possible combination of the four parts may occur; a portion of the nerve may be above and a portion between the parts of the muscle, or a portion may be below and a portion between. The trunk of the nerve lies deeply in the thigh, and it is covered posteriorly by the skin and fascia, the gluteus maximus and the long head of the biceps femoris. Anteriorly it is in relation, from above downward, with the following structures:—the posterior surface of the ischium and the nerve to the quadratus femoris, the gemellus superior, obturator internus, gemellus inferior, quadratus femoris, and adductor magnus muscles.

Muscular branches of the sciatic are given off at the upper part of the thigh to the semitendinosus, to the long head of the biceps femoris, to the semimembranosus,

Fig. 770.—A Dissection of the Nerves in the Gluteal Region.
(The gluteus maximus and gluteus medius have been divided near their insertions, and thrown upward.)



and to the adductor magnus, and, about the middle of the thigh, a branch is furnished to the short head of the biceps.

The branch to the **short head of the biceps femoris** is derived from the peroneal (lateral popliteal) portion of the nerve, while all the other muscular branches are given off by the tibial (medial popliteal) part. The **semitendinosus** receives two branches, one which enters it above and another which passes into it below its tendinous intersection. The nerve to the **long head of the biceps** descends along the sciatic trunk and enters the middle of the deep surface of the muscle. The nerves to the **semimembranosus** and **adductor magnus** arise by a common trunk which divides into three or four branches. One branch ends in the adductor, and the others are distributed to the semimembranosus. The branch to the adductor magnus supplies only those fibrés of the muscle which begin from the tuberosity of the ischium and descend vertically to the medial condyle of the femur.

At the apex of the popliteal space the two component parts of the common trunk of the sciatic become distinct. The **tibial nerve** (internal popliteal), formed by fibres from the anterior branches of the fourth and fifth lumbar and first, second, and third sacral nerves, passes vertically through the popliteal space, descends through the leg to a point midway between the medial malleolus and the most prominent part of the medial tubercle of the os calcis, where it divides into its terminal branches, the *lateral plantar* and the *medial plantar* nerves. The part of the nerve from the point of bifurcation to the lower border of the popliteus muscle is sometimes called the *internal popliteal;* the part of the nerve in the dorsum of the leg being then designated the *posterior tibial nerve.*

In the upper part of the popliteal space the tibial nerve lies relatively superficially, being covered dorsally by the skin and fascia, while in the lower part of the space it is overlapped by the heads of the gastrocnemius and is crossed by the plantaris. In the upper part of the space it lies in front of the posterior femoral cutaneous (small sciatic) nerve and to the lateral side of the vein and artery; at the middle of the space it is dorsal and in the lower part of the space it is medial to both of them.

The branches given off by the tibial nerve *in the popliteal space* are articular, cutaneous, and muscular.

The **articular branches** are usually three in number, a superior and an inferior internal articular and an azygos articular. They accompany the corresponding arteries, and, after piercing the ligaments, are distributed in the interior of the joint. The superior branch is often wanting.

The **cutaneous branch,** *the medial sural cutaneous* (tibial communicating) nerve, descends between the heads of the gastrocnemius, beneath the deep fascia, to the middle of the calf, where it pierces the fascia and unites with the peroneal anastomotic branch of the lateral sural cutaneous to form the sural (external saphenous) nerve, through which its fibres are distributed to the skin of the lower and dorsal part of the leg and the lateral side of the foot.

The **muscular branches** are distributed to both heads of the gastrocnemius, to the plantaris, soleus, and popliteus.

The *nerve to the soleus* is relatively large, and passes between the lateral head of the gastrocnemius and the plantaris before it reaches its termination (fig. 771). The *nerve to the popliteus* descends on the posterior surface of the muscle, turns around its lower border, and is distributed on its anterior aspect. In addition to supplying the popliteus, it gives articular branches to the knee and superior tibio-fibular joints, a branch to the tibia which accompanies the medullary artery, and a long, slender twig which gives filaments to the anterior and posterior tibial arteries, and it descends as the *interosseous crural nerve* on the interosseous membrane to the inferior tibio-fibular joint. It also gives branches to the interosseous membrane and to the periosteum of the lower part of the tibia.

Relations.—In the upper part of the leg the tibial nerve is placed deeply, under the gastrocnemius and soleus, but in the lower half it is merely covered by the deep fascia, which is thickened between the medial maleolus and the calcaneus to form the lacinate (internal annular) ligament, and the termination of the nerve lies either under cover of this ligament, or under the attachment of the abductor hallucis. The anterior relations of the nerve are, from above downward, the tibialis posterior, the flexor digitorum longus, the lower part of the tibia, and the posterior ligament of the ankle-joint. For a short distance after its commencement the nerve lies to the medial side of the posterior tibial artery; then it crosses behind the artery and runs downward along its lateral aspect.

The **branches** *of the lower part of the tibial nerve* (below the popliteal space) are likewise muscular, cutaneous, and articular. They are supplied to the deep muscles of the dorsum of the leg, to the fibula, to the skin of the heel and foot, and to the ankle-joint. Several of the terminal branches are important enough to receive special names and special treatment.

The **muscular branches** pass from the upper part of the nerve to the tibialis posterior, flexor digitorum longus, soleus, and flexor hallucis longus. The **fibular branch** arises with the nerve to the flexor hallucis longus, and accompanies the peroneal artery. It supplies the periosteum and gives filaments which accompany the medullary artery.

The **articular branches** arise from the lower part of the nerve, immediately above its terminal branches, and they pass into the ankle-joint through the deltoid ligament.

The **medial calcaneal (calcaneo-plantar cutaneous) nerves** arise from the trunk of the tibial nerve in the lower part of the leg. They pierce the laciniate (internal annular) ligament, and are distributed to the integument of the medial side and plantar surface of the heel and the adjoining part of the sole of the foot (fig. 771).

Terminal branches of tibial nerve.—The **medial plantar nerve** is the larger of the two terminal branches of the tibial nerve. It commences under cover of the lower border of the laciniate (internal annular) ligament, or under the posterior border of the abductor hallucis, and passes forward, accompanied by the small internal plantar artery, in the inter-muscular septum between the abductor hallucis and the flexor digitorum brevis. At the middle of the length of the foot it becomes superficial, in the interval between the two muscles, and divides into four sets of terminal branches (fig. 772):—

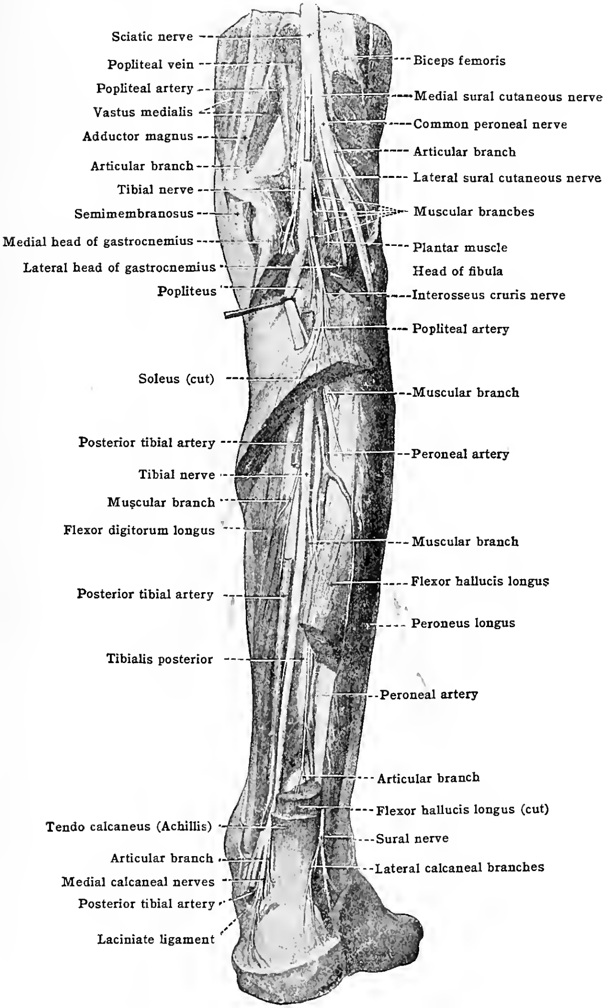
(*a*) **Muscular branches** pass from the trunk of the nerve to the abductor hallucis and the flexor digitorum brevis.

(*b*) **Articular branches** are distributed to the talo-navicular (astragalo-sacphoid) and the naviculari-cuneiform joint.

(*c*) **Plantar cutaneous branches** are supplied to the skin of the medial part of the sole.

(*d*) The **digital branches** are four in number, the first, a **proper plantar digital,** the second, third, and fourth, the **common plantar digitals.** Near the bases of the

Fig. 771.—Muscle Nerves of the Right Leg, viewed from Behind. (Spalteholz.) The semitendinosus, semimembranosus, biceps femoris, gastrocnemius, plantaris, soleus, and flexor hallucis longus have been wholly or in part removed.

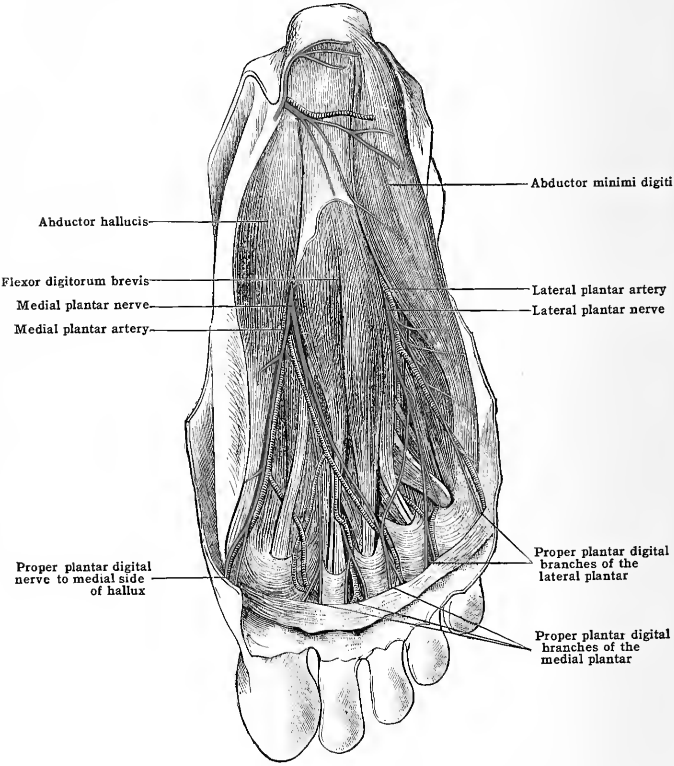


metatarsal bones, the second, third and fourth common plantar digital divide into **proper plantar digital nerves.**

The first proper plantar digital nerve becomes subcutaneous farther back than the others, and, after sending a branch to the flexor hallucis brevis, passes to the medial side of the great toe. The second (common digital) nerve gives a twig to the first lumbrical and bifurcates to supply the adjacent sides of the first and second toes. The third supplies the adjacent sides of the second and third toes, and the fourth, after connecting with the superficial branch of the lateral plantar nerve, divides to supply the adjacent sides of the third and fourth toes. All the proper digital nerves run along the sides of the toes and lie below the corresponding arteries; they supply the joints of the toes, and each gives off a dorsal branch to the skin over the second and terminal phalanges and to the bed of the nail. All of them give fibres terminating in numerous Pacinian corpuscles.

The **lateral plantar nerve** is the smaller of the two terminal branches of the tibial nerve. It commences at the lower border of the laciniate (internal annular)

Fig. 772.—Superficial Nerves in the Sole of the Foot. (Ellis.)



ligament, or under cover of the origin of the abductor hallucis, and passes forward and lateralward to the base of the fifth metatarsal bone, where it divides into a superficial and a deep branch (fig. 772). As it runs forward and lateralward it it is superficial to the tendon of the flexor hallucis longus and to the quadratus plantæ (flexor accessorius), and deep to the flexor digitorum brevis. At its termination it lies in the interval between the flexor digitorum brevis and abductor digiti quinti.

Branches.—From the trunk of the lateral plantar nerve muscular, superficial and deep, and articular branches are given off.

The **muscular branches** arise from the commencement of the nerve and are distributed to the abductor digiti quinti and quadratus plantæ.

The **articular branches** supply the calcaneo-cuboid joint.

The **superficial branch** supplies muscular filaments to the flexor digiti quinti brevis, the opponens, the third plantar and fourth dorsal interosseous muscles, and divides into two **common plantar digital nerves**, each of which subdivides to form **proper plantar digital nerves.**

The lateral of the two common branches supplies the lateral side of the fifth digit; the medial connects with the lateral digital branch of the medial plantar nerve (fig. 772) and divides into proper plantar digital nerves for the adjacent sides of the fourth and fifth digits. The digital branches of the superficial division of the lateral plantar, like those of the medial plantar, supply the skin of the toes and the beds of the nails, and their fibres terminate in numerouos Pacinian corpuscles.

The **deep branch** passes forward and medialward into the deep part of the sole with the plantar arterial arch. It runs deep to the quadratus plantæ, the long flexor tendons and the lumbricals, and the oblique adductor of the great toe. It lies, therefore, immediately beneath the bases of the metatarsal bones and it supplies the following muscular and articular branches:—

Muscular branches to the lateral three lumbricals, the interossei of the medial three intermetatarsal spaces, and the transverse and oblique adductor muscles of the great toe.

Articular branches to the intertarsal and to the tarso-metatarsal joints and not uncommonly to the metatarso-phalangeal joints also. Filaments from the deep branch frequently pass through the interosseous spaces and join with the interosseous branches of the deep peroneal (anterior tibial) nerve.

The common peroneal (external popliteal) nerve.—At the apex of the popliteal space, where the two component parts of the sciatic trunk usually become distinct, the lateral portion receives the name *common peroneal nerve.* It descends along the posterior border of the biceps femoris, which forms the upper part of the lateral boundary of the space (fig. 771). It leaves the space at the lateral angle, crosses the plantaris, the lateral head of the gastrocnemius, the popliteus, and the inferior external artery, and descends behind the upper part of the soleus, to the neck of the fibula, where it turns forward between the peroneus longus and the bone, and breaks up into its three terminal branches, the recurrent articular, the superficial peroneal (musculo-cutaneous), and the deep peroneal (anterior tibial) nerves (fig. 773).

Upper branches.—While it is in the popliteal space the common peroneal (external popliteal) nerve gives off two articular branches and a cutaneous branch.

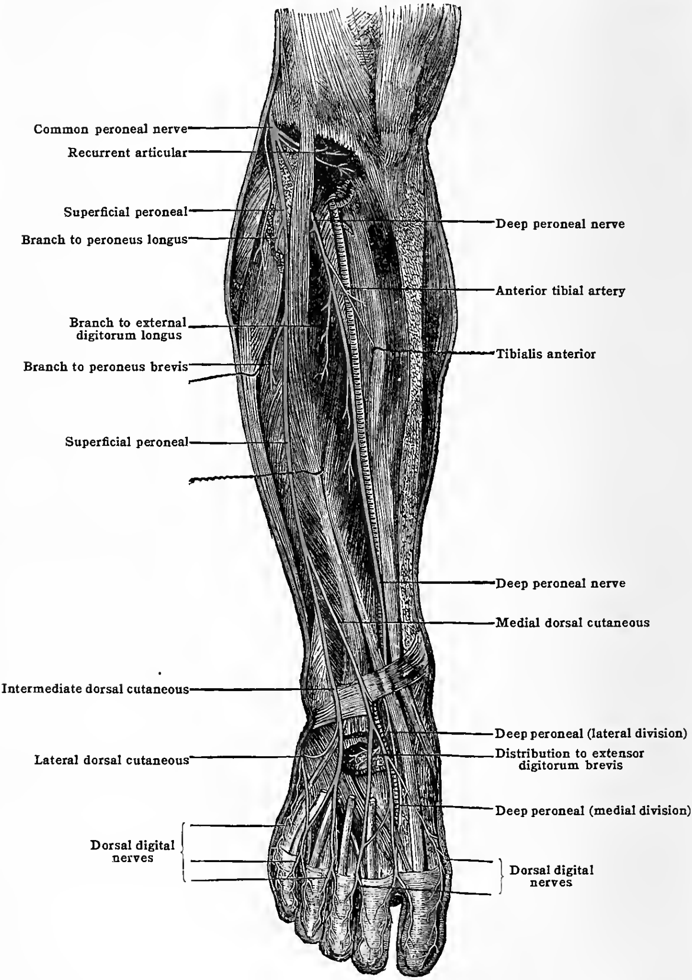
The **superior articular branch** accompanies the superior external articular artery. The lateral head of the gastrocnemius, and it joins the inferior external articular artery behind the tendon of the biceps femoris. Both the upper and lower articular branches pierce the ligaments and are distributed in the interior of the knee joint.

The **cutaneous branch** (*communicans fibularis*), *lateral sural cutaneous*, is extremely variable both as to the number of its branches and as to the place of its anastomosis with the medial sural cutaneous. Leaving the common peroneal (external popliteal) in the popliteal space, it descends between the deep fascia and the lateral head of the gastrocnemius to the middle of the calf, where it pierces the fascia and unites with the medial sural cutaneous to form the sural (external saphenous) nerve. In its course it may give off no branches; or it may give off several, some of which supply the skin of the dorsum of the leg, while one of them, the peroneal anastomotic branch, unites with the medial sural cutaneous to form the sural (short saphenous) nerve. The junction of the peroneal anastomotic branch with the medial sural cutaneous may take place at any point between the popliteal space and the lower third of the leg.

The **sural (external or short saphenous) nerve** is formed by the union of the lateral sural cutaneous nerve either directly, or through a connecting branch, the peroneal anastomotic, with the medial sural cutaneous (fig. 771). It descends along the lateral border of the tendo Achillis, giving branches to the lower and lateral part of the leg, and **lateral calcaneal** branches to the lateral side of the heel. It passes dorsal to the lateral malleolus, turns forward across the lateral surface of the cruciate (external annular) ligament, and becomes the **lateral dorsal cutaneous nerve.** Continuing along the lateral side of the foot it divides into two branches, the **dorsal digitals,** one of which supplies the lateral side of the fifth digit, while the other anastomoses with or takes the place of a branch of the superficial peroneal (musculo-cutaneous) nerve, which is distributed to the adjacent sides of the fourth and fifth digits (fig. 773).

The terminal branches of the common peroneal.—(1) The **recurrent articular nerve** passes medialward, around the neck of the fibula, and through the upper part of the attachment of the extensor digitorum longus. At the medial border of the fibula it becomes associated with the anterior tibial recurrent artery, with which it ascends through the upper part of the tibialis anterior to the head of the

FIG. 773.—DISTRIBUTION OF THE SUPERFICIAL AND DEEP PERONEAL NERVES ON THE ANTERIOR ASPECT OF THE LEG AND ON THE DORSUM OF THE FOOT. (Hirschfeld and Leveillé.)



tibia and the knee-joint. It supplies the tibialis anterior, the superior tibiofibular joint, and the knee-joint.

(2) The **superficial peroneal (musculo-cutaneous) nerve** arises from the common peroneal between the peroneus longus and the neck of the fibula and descends in the intermuscular septum between the long and short peronei on the

lateral side, and the extensor digitorum longus on the medial side. It gives off muscular and cutaneous branches in its descent, and at the junction of the middle and lower thirds of the leg it pierces the deep fascia and divides into a *medial* and a *lateral branch* (fig. 773).

Muscular branches are given off from the superficial peroneal to the peroneus longus and peroneus brevis before the nerve pierces the deep fascia.

Cutaneous branches pass from the trunk of the superficial peroneal to the skin of the lower part of the front of the leg.

The **medial dorsal cutaneous** (internal cruciate branch of the superficial peroneal), passes downward and medialward across the transverse and the cruciate (anterior annular) ligament of the ankle and subdivides into two branches. The *medial branch* passes to the medial side of the great toe; it also supplies twigs to the skin of the medial side of the foot, and it anastomoses with the deep saphenous nerve and with the medial terminal branch of the deep peroneal (anterior tibial) nerve. The *lateral branch* passes to the base of the cleft between the second and third toes and divides into two dorsal digital branches which supply the adjacent sides of the cleft.

The **lateral branch (intermediate dorsal cutaneous)** of the superficial peroneal, in separating from the medial, crosses in front of the cruciate ligament and divides into two dorsal digital branches, which pass beneath the dorsal venous arch. The medial of these branches supplies the adjacent sides of the third and fourth toes (fig. 773). The lateral branch communicates with the sural (external saphenous) nerve and is distributed to the adjacent sides of the fourth and fifth toes. This latter branch is frequently replaced by the sural nerve.

(3) The **deep peroneal (anterior tibial) nerve** springs from the end of the common peroneal (external popliteal) nerve between the peroneus longus muscle and the neck of the fibula. It passes forward and medialward through the upper part of the origin of the extensor digitorum longus, to the interval between that muscle and the tibialis anterior; then it descends, in the anterior compartment of the leg, to the ankle, where it divides into a medial and a lateral terminal branch (fig. 773).

In the upper part of the leg the deep peroneal nerve lies between the extensor digitorum longus and tibialis anterior and lateral to the anterior tibial artery. In the middle of the leg it is in front of the artery and between the extensor hallucis longus and tibialis anterior; then it crosses beneath the extensor hallucis, and in the lower third of the leg it is again to the lateral side of the artery, but between the extensor hallucis longus and the extensor digitorum longus.

Branches furnished from the trunk of the deep peroneal are muscular, articular, and terminal.

The **muscular branches** supply the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius.

Articular filaments are given to the ankle-joint and the inferior tibio-fibular articulation.

Terminal branches.—The **medial terminal branch** passes downward along the side of the dorsalis pedis artery and divides into two dorsal digital branches which supply the adjacent sides of the first and second toes. It also gives filaments to the periosteum of the adjacent bones, to the metatarso-phalangeal and interphalangeal articulations, a twig to the dorsal interosseous muscle of the first space, and a perforating twig which connects with the lateral plantar nerve. The **lateral terminal branch** passes lateralward, beneath the extensor digitorum brevis, and it ends in a gangliform enlargement from which branches are distributed to the extensor digitorum brevis, the tarsal joints, and to the three lateral intermetatarsal spaces. The latter branches supply the neighbouring bones, periosteum, and joints. They give off perforating twigs, which pass through the spaces and anastomose with branches of the lateral plantar nerve, and the most medial also gives a twig to the second dorsal interosseous muscle.

THE PUDENDAL PLEXUS

The **pudendal plexus**, like the parts of the lumbo-sacral plexus already described, varies in its formation. The accompanying tables show the extreme range of variation and the common method of formation of the large nerve of this plexus in each of the three classes.

COMPOSITION OF THE NERVES OF THE PUDENDAL PLEXUS

Range of Variation

Nerve.	Proximal.	Ordinary.	Distal.
Pudic nerve........................	1, 2, 3, 4, 5 S.	1, 2, 3, 4 S.	2, 3, 4, 5 S.

Common Composition

Nerve.	Proximal.	Ordinary.	Distal.
Pudic nerve........................	2, 3 S.	2, 3, 4 S.	3, 4 S.

The pudendal plexus is commonly formed by parts of the anterior divisions of the second, third, and fourth sacral nerves. It lies in the lower part of the back of the pelvis, and gives off visceral, muscular, and terminal branches.

Visceral branches (pelvic splanchnics) arise from the third and fourth sacral nerves especially, and enter branches of the sympathetic plexus. They are distributed both directly (their afferent or sensory fibres terminating in the pelvic viscera) and by their visceral efferent fibres terminating in the ganglia of the sympathetic plexus to the pelvic viscera (figs. 765, 791). The **middle hæmorrhoidal nerves** pass to the rectum, the **inferior vesical nerves** to the bladder, and, in the female, the **vaginal nerves** to the vagina (see Sympathetic System).

Muscular branches are given by the fourth sacral nerve to the coccygeus, levator ani, and sphincter ani externus (fig. 765).

The nerves to the two former muscles pass into the pelvic surfaces of the muscles, but that to the last-named muscle, called the **perineal branch,** passes backward between the levator ani and the coccygeus, or through the posterior fibres of the latter muscle, into the posterior part of the ischio-rectal fossa, and, in addition to supplying the sphincter ani, it gives cutaneous filaments to the skin between the anus and the coccyx.

Terminal branches.—The **pudic nerve** [n. pudendus] rises usually from the anterior primary divisions of the second, third, and fourth sacral nerves (fig. 765). It emerges from the pelvis below the piriformis, crosses the spine of the ischium, lying to the medial side of the internal pudic artery (fig. 769), and accompanies the artery, through the small sciatic foramen, into Alcock's canal in the obturator fascia on the lateral wall of the ischio-rectal fossa, where it terminates by dividing into three branches, the inferior hæmorrhoidal, the perineal, and the dorsal nerve of the penis.

The **inferior hæmorrhoidal nerves** frequently arise independently from the third and fourth sacral nerves, pierce the medial wall of Alcock's canal, and pass forward and medialward through the ischio-rectal fat to supply the sphincter ani externus and adjacent skin. They anastomose with branches of the perineal nerve.

The **perineal nerve** runs forward for a short distance in Alcock's canal and divides into a deep and a superficial branch. The *deep branch* breaks up into filaments, one or two of which pierce the medial wall of the canal and pass medialward to the anterior fibres of the sphincter and levator ani. The remaining part of the nerve pierces the base of the uro-genital trigone (triangular ligament), and enters the superficial pouch of the urethral triangle, where it is distributed to the bulb of the urethra, and to the transversus perinei, bulbocavernosus, and ischiocavernosus. It also sends some sensory filaments to the mucous membrane of the urethra. The *superficial branch* almost at once divides into medial and lateral branches, the *posterior scrotal* (*labial*) nerves.

Both branches pass through the wall of Alcock's canal into the anterior part of the ischio-rectal fossa, then they pierce the base of the uro-genital trigone, and enter the superficial pouch of the urethral triangle. The lateral branch usually passes below the transversus perinei, and the medial branch above the muscle or through its fibres. The lateral branch connects with the long pudendal nerve, and with the inferior hæmorrhoidal nerve, and both branches end in terminal filaments which anastomose and which are distributed to the skin of the scrotum and the anterior part of the perineum in the male, and to the labium majus in the female.

The **dorsal nerve of the penis** runs forward in Alcock's canal above the internal pudic artery. It pierces the base of the uro-genital trigone, continues forward between the layers of the trigone, embedded in the fibres of the constrictor urethræ, and it gradually passes to the lateral side of the internal pudic artery. A short distance below the pudic arch it pierces the anterior layer of the uro-genital trigone, gives a branch to the corpus cavernosum penis, passes forward between that structure and the bone, and turns downward on the dorsum of the penis, passing between the layers of the fundiform (suspensory) ligament and along the outer side of the dorsal artery of the penis. It supplies the skin of the dorsum of the penis, and, having given branches to the prepuce, it breaks up into terminal filaments which are distributed to the glans penis.

The **dorsal nerve of the clitoris** is much smaller than the dorsal nerve of the penis to which it corresponds. Is is distributed to the clitories.

THE COCCYGEAL PLEXUS

This plexus is frequently, and with some reason, considered as a subdivision of the pudendal plexus, and sometimes it is described with the coccygeal nerves. It is formed chiefly by the anterior division of the fifth sacral nerve and the coccygeal nerve, but it receives a small filament from the anterior division of the fourth sacral nerve (figs. 765, 769). These constituents unite to form plexiform cords lying on either side of the coccyx. From these cords arise the **ano-coccygeal nerves,** which pierce the sacro-tuberous (great sacro-sciatic) ligament and supply the skin in the neighbourhood of the coccyx.

III. THE DISTRIBUTION OF THE CUTANEOUS BRANCHES OF THE SENSORY AND MIXED CRANIAL AND SPINAL NERVES

The cutaneous filaments of the sensory and mixed nerves are distributed to definite regions of the surface of the body which are known as 'cutaneous areas.' Each cutaneous area has one special nerve of supply and the central part of the area receives that nerve alone, but wherever the borders of two areas meet they reciprocally overlap, therefore each margin of every cutaneous area has two nerves of supply, its own nerve and that of an adjacent area, and of these, sometimes one and sometimes the other preponderates.

The Cutaneous Areas of the Scalp

The limits of the cutaneous areas in the scalp region are indicated in figs. 774, 776, but in general terms it may be said that the skin of the scalp in front of the pinna is supplied by four cutaneous nerves, viz., the mesial part by the supratrochlear and the supra-orbital branches of the ophthalmic division of the trigeminus, and the lateral part by the temporal branch of the maxillary division, and the auriculo-temporal branch of the mandibular division of the same nerve.

The portion of the scalp behind the pinna also receives four cutaneous nerves; laterally it is supplied by the great auricular and small occipital branches of the cervical plexus which contain filaments from the second and third cervical nerves, and medially it receives the great and smallest occipital nerves which are derived from the internal branches of the posterior primary divisions of the second and third cervical nerves respectively.

The Cutaneous Areas of the Face

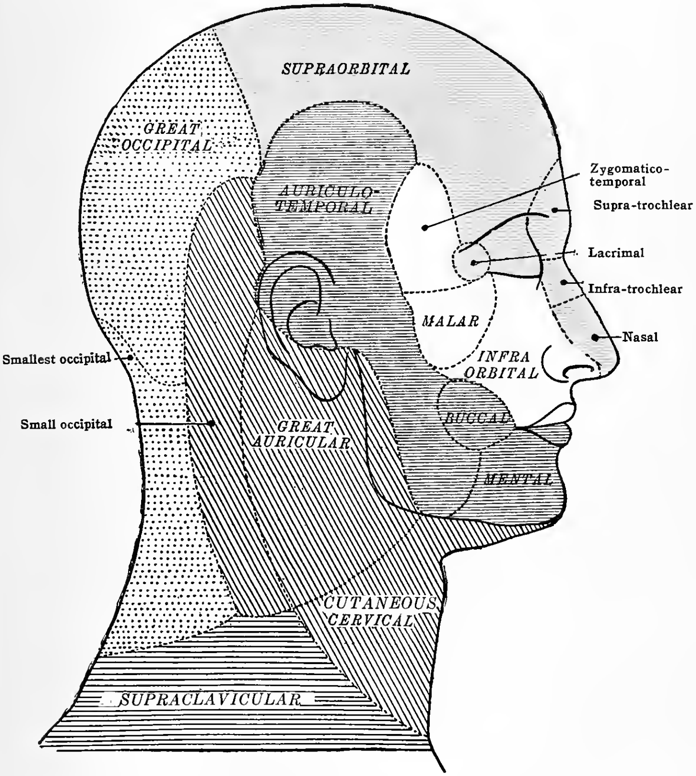
With the exception of the skin over the posterior part of the masseter muscle, the whole of the skin of the face is supplied by the branches of the trigeminus. The nose is supplied medially by the supratrochlear, the infratrochlear, and the nasal branches of the ophthalmic division, and laterally by the infra-orbital branch of the maxillary division. The upper eyelid is supplied by the supratrochlear, the supra-orbital, and the lacrimal branches of the ophthalmic division; the lower eyelid by the infratrochlear branch of the ophthalmic division and by the infra-orbital and the zygomatico-facial (malar) branches of the maxillary division. The skin over the upper jaw and the zygomatic (malar) bone is supplied by the infra-orbital and zygomatico-facial branches of the maxillary division, that over the buccinator by the buccal branch of the mandibular division, and that over the lower jaw, from in front backward, by the mental, buccal, and auriculo-temporal branches of the mandibular division, except a small part near the posterior border which receives its supply from the great auricular nerve.

The Cutaneous Areas of the Auricle (Pinna)

The upper two-thirds of the outer surface of the pinna are supplied by the auriculo-temporal branch of the mandibular division of the trigeminus, and the lower third by twigs of the great auricular nerve. The lower three-fourths of the cranial surface of the pinna are supplied by the great auricular nerve, and the upper fourth by the small occipital nerve. The posterior surface of the external auditory meatus receives filaments from the auricular branch of the vagus.

Fig. 774.—Diagram of the Cutaneous Nerve Areas of the Head and Neck.
Red—ophthalmic division of trigeminus. White—maxillary division of trigeminus.
Blue—mandibular division of trigeminus.

Dotted shading—Posterior primary divisions of cervical nerves.
Oblique shading—Ascending and transverse superficial branches of cervical plexus.
Transverse shading—Descending superficial branches of cervical plexus.
It must be remembered that the boundaries of each area are not distinct; wherever two areas meet they overlap.



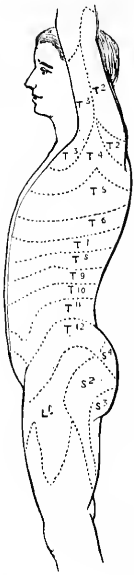
The Cutaneous Areas of the Neck

The skin over the anterior part of the neck is supplied by the superficial cervical branch of the cervical plexus, which contains fibres from the second and third cervical nerves, and in the lower part of its extent, by the anterior supra-clavicular nerves (suprasternal branches), which convey twigs of the third and fourth cervical nerves (fig. 774). The lateral part of the neck receives filaments from the second, third, and fourth cervical nerves by way of the great auricular, small occipital, and middle supraclavicular (supra-clavicular) branches of the cervical plexus, and posteriorly the skin of the neck is supplied by the small occipital nerve and by the medial branches of the posterior primary divisions of the cervical nerves from the second to the sixth inclusive (fig. 776).

The Cutaneous Areas of the Trunk

The skin over the ventral aspect of the trunk as far down as the third rib is supplied by the anterior supra-clavicular (suprasternal) and middle supra-clavicular (supra-clavicular) branches of the cervical plexus, which contain filaments from the third and fourth cervical nerves (fig. 776). From the third rib to the lower part of the abdominal wall the skin receives the anterior cutaneous branches, and the anterior divisions of the lateral cutaneous branches of

Fig. 775.—Diagram of the Cutaneous Areas of the Side of the Body and Part of the Limb. (After Head.)



the thoracic nerves except the first, second, and twelfth (fig. 776). The skin over the lower and anterior part of the abdominal wall is supplied by the ilio-hypogastric branch of the first lumbar nerve.

The cutaneous supply of the lateral aspects of the body is derived from the lateral branches of the anterior primary divisions of the thoracic nerves from the second to the eleventh, and the skin over the dorsal aspect of the body is supplied laterally by the posterior divisions of the lateral branches of the thoracic nerves from the third to the eleventh, and medially by the posterior primary divisions of the thoracic nerves, in the upper half by their medial branches and in the lower half principally by their lateral branches.

THE CUTANEOUS AREAS OF THE LIMBS

The areas of skin of the upper and lower limbs which are supplied by the branches of the brachial, lumbar, and sacral plexuses are indicated in fig. 776, and the spinal nerves which contribute to each nerve area are noted. The question of the skin areas supplied by any given spinal nerve is one of great clinical importance, in connection with the diagnosis of injuries of nerves and of pathological conditions affecting them. Therefore, considerable attention has been directed to the matter and it has been found that the areas which become hypersensitive when certain spinal nerve-roots are irritated, or anæsthetic when the roots are destroyed, do

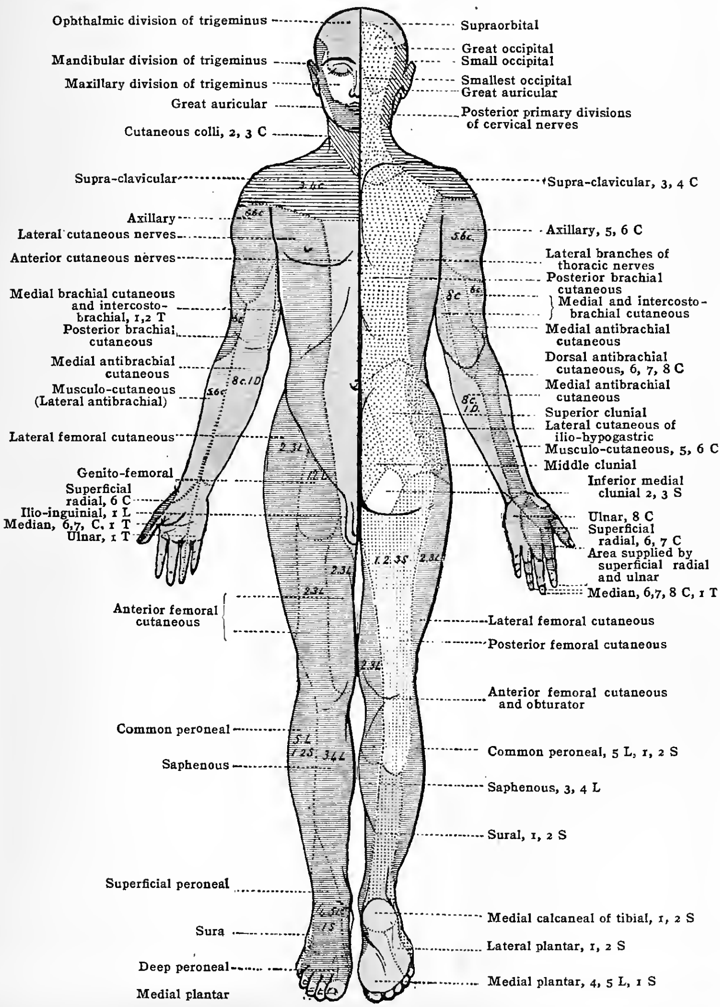
FIG. 776.—DIAGRAM SHOWING AREAS OF DISTRIUTION OF CUTANEOUS NERVES.

HEAD:—

RED—Ophthalmic division of trigeminus. White—maxillary division of trigeminus. Blue—mandibular division of trigeminus. Dotted area—Posterior primary divisions of cervical nerves. Oblique and transverse shading—Branches of cervical plexus.

BODY AND LIMBS:—

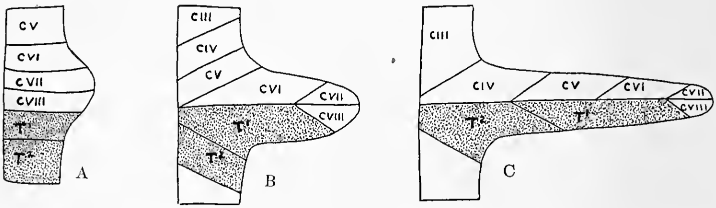
RED—Anterior branches of anterior primary divisions. Blue—Posterior branches of anterior primary divisions. Two colours in one area indicate that the area is supplied by two sets of nerves, and it should be remembered that wherever two nerve areas approach each other they overlap. The dotted blue area of the posterior femoral cutaneous (small sciatic) indicates that the nerve comes from the posterior as well as from the anterior parts of the anterior primary divisions of the sacral nerves, but it supplies a flexor area. The area of the inferior medial cluneal nerve is left uncoloured, because its true nature is uncertain. Dotted shading—posterior primary divisions. The numbers and initial letters refer to the respective spinal nerves from which the nerves are derived.



not correspond exactly with the regions to which the fibres of the roots can apparently be traced by dissection. Moreover, it has been discovered, partly by clinical observations on the human subject and partly by experiment on monkeys, that the nerves of the limbs have a more or less definite segmental distribution. To understand clearly this segmental arrangement the reader must remember that in the embryonic stage when no limbs are present the body is formed of a series of similar segments, each of which is provided with its own nerve. At a later stage when the limbs grow outward, each limb is formed by portions of a definite number of segments which fuse together into a common mass of somewhat wedge-like outline. Each rudimentary limb possesses a dorsal and a ventral surface. The dorsal surfaces of both the upper and the lower limbs are originally the extensor surfaces, and the ventral surfaces the flexor surfaces, but, as the upper limb rotates lateralward and the lower limb rotates medianward as development proceeds, in the adult, the extensor surface of the upper limb becomes the posterior surface, and the extensor surface of the lower limb, the anterior surface. The preaxial border of the upper limb is the radial or thumb border, and the postaxial border, the ulnar or little finger border. The preaxial border of the lower limb is the tibial or great toe border, and the postaxial border, the fibular or little toe border. As projections of the segments of the body grow out to form the limb-buds and limbs each projection carries with it the whole or part of the nerve of the segment to which it belongs, and therefore the number of body segments which take part in a limb is indicated by the number of spinal nerves which pass into it. If these facts are remembered it will naturally be expected (1) that the highest spinal nerves passing into a limb will be associated with its preaxial portion and the lowest with its post-

FIG. 777.—DIAGRAMS A, B, AND C, ILLUSTRATING STAGES IN THE PROJECTION OF THE LIMB-BUDS FOR THE UPPER EXTREMITY, AND THE DRAWING OUT OF THE NERVES OF THE CORRESPONDING BODY SEGMENTS FOR THE CUTANEOUS AREAS OF THE PREAXIAL AND POSTAXIAL BORDER OF THE LIMB.

Postaxial border shaded.



axial portion; (2) that only the nerves of those segments forming middle or central portions of the limbs will extend to the tips of the limbs; (3) that the highest and lowest segments in each limb area will take a smaller part in the formation of the limb that the middle segments; and (4) that, consequently, the highest and lowest nerves will pass outward into the limb for a shorter distance than the middle nerves. Observers are not yet in perfect agreement as to the exact distribution of each nerve, but the diagrams in figs. 775 to 781 show the embryonic derivation of the cutaneous areas and the adult dorso-ventral segmental arrangement in the projected portions of both the upper and lower limbs as assumed from clinical observations. In the upper parts of the lower limbs, the original segmental distributuion appears to be masked. This may be due (1) partly to the fact that the areas recognisable by clinical phenomena do not correspond exactly with the areas to which definite dorsal root-fibres are distributed, but rather to definite segments of the grey substance of the spinal cord with which the root-fibres are connected; (2) partly to the overlapping of segments and the acquired preponderance of one nerve over another in the overlapping areas, and (3) partly to the fact that in the lower limb there has been a greater amount of shifting of parts to result in the fixed flat position of the sole of the foot; (4) and partly to the incompleteness of the data which are at our disposal in the case of the human subject. Sherrington has proved that in the monkey the sensory areas of the limbs are arranged in serial correspondence with the spinal nerves, the middle nerves of each limb series passing to the distal extremity while the higher and lower nerves are limited to the proximal regions. Thorburn's observations, which differ from Head's, are, especially as regards the upper limb, in close conformity with the results obtained by Sherrington's experiments on monkeys.

Each limb may be divided into its preaxial and postaxial borders by a line drawn longitudinally along the middle of both its anterior and posterior surfaces (compare figs. 777 and 779) The cutaneous nerves to the preaxial border are from the cephalic portion of the limb plexus. and those to the postaxial are from the caudal components of the plexus. Thus the thumb and index finger are cephalad.

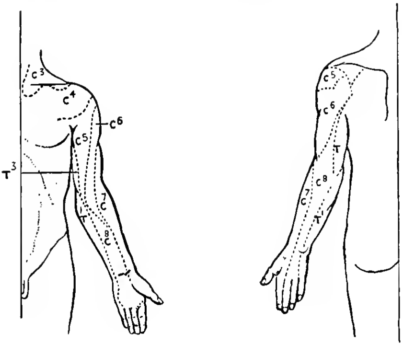
THE CUTANEOUS AREAS OF THE UPPER LIMB

A line passing along the middle of both the anterior and posterior surfaces of the upper extremity to the tip of the middle finger (fig. 779) separates the preaxial from the postaxial border and passes longitudinally along the area of the cutaneous fibres derived from the seventh cervical nerve.

The skin over the upper third of the deltoid muscle is supplied by the posterior supra-clavicular (supra-acromial) and middle supra-clavicular (supra-clavicular) nerves, which are branches of the cervical plexus containing fibres of the third and fourth cervical nerves, and that over the lower two-thirds by the axillary (circumflex) nerve which conveys fibres of the fifth and sixth cervical nerves (fig. 776).

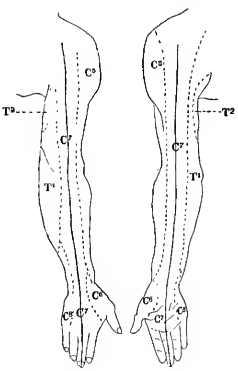
The skin over the lateral surface of the upper arm is supplied externally by the axillary (circumflex) nerve above, and below by the superior branch of the dorsal antibrachial cutaneous,

FIG. 778.—DIAGRAM OF THE CUTANEOUS AREAS OF THE UPPER EXTREMITY. (Modified from Head.)



the external cutaneous branch of the radial (musculo-spiral) nerve. The former contains filaments of both the fifth and sixth cervical nerves, and the latter filaments of the sixth alone. The skin of the medial side of the upper arm is supplied by the medial antibrachial cutaneous (internal cutaneous) nerve with fibres of the eighth cervical and first thoracic nerves, and by the medial brachial cutaneous (lesser internal cutaneous) and intercosto-brachial (intercosto-humeral) nerves which are derived from the first and second thoracic nerves. The dorsal side of the upper arm is supplied, laterally, by the fifth and sixth cervical nerves through the axillary

FIG. 779.—DIAGRAM OF THE CUTANEOUS AREAS OF THE UPPER EXTREMITY.
The solid middle lines are drawn to separate preaxial (radial) borders from postaxial borders. (After Thorburn, modified.)



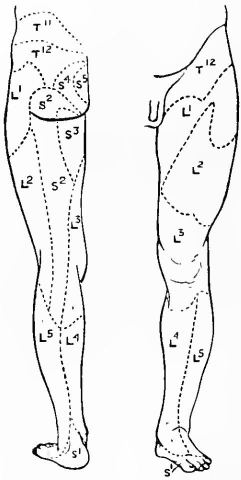
(circumflex) nerve and by the dorsal antibrachial cutaneous; the middle portion, by the seventh cervical nerve through the posterior brachial cutaneous, the internal cutaneous branch of the radial (musculo-spiral) nerve; and the medial portion by the first and second thoracic nerves through the medial brachial cutaneous (lesser internal cutaneous) nerve, and the intercosto-brachial (intercosto-humeral) nerve (fig. 776).

The front of the forearm is divided into three areas, a lateral which is supplied by the fifth, sixth, and possibly the seventh cervical nerves, through the musculo-cutaneous branch of the brachial plexus; a middle which is supplied by the seventh cervical nerve as above, and a medial area supplied by the eighth cervical and first thoracic nerve through the medial antibrachial cutaneous (internal cutaneous) nerve. On the dorsal side of the forearm there are three areas: —(1) a lateral supplied by fibres of the fifth and sixth cervical nerves through the musculo-cutaneous nerve; (2) a middle, which receives fibres of the seventh, and probably some from the sixth and eighth cervical nerves through the lower branch of the dorsal antibrachial cutaneous of the radial (inferior external cutaneous branch of the musculo-spiral nerve), and (3) a medial which receives the eighth cervical and first thoracic nerves through the medial antibrachial cutaneous (figs. 776, 779).

The palm of the hand is supplied by the sixth, seventh, and eighth cervical nerves through the superficial radial (radial) nerve, and through the median and ulnar nerves. The superficial radial supplies the radial side of the thumb by its palmar cutaneous branch. The remainder of the palm and the palmar aspects of the fingers are supplied by the median and ulnar nerves through their palmar cutaneous and digital branches, the median supplying three and a half digits and the ulnar the remaining one and a half (figs. 776 and 779).

The dorsal aspect of the hand is supplied by the sixth, seventh, and eighth cervical nerves, which reach it through the superficial radial(radial) and through the median and ulnar nerves. The superficial radial supplies the lateral part of the dorsum and the lateral three and a half digits, except the lower portions of the second, third, and half of the fourth digits, which receive twigs from the median nerve; the ulnar nerve supplies the ulnar half of the dorsum of

Fig. 780.—Diagram of the Cutaneous Areas of the Lower Extremity. (After Head.)



the hand, including the medial one and a half digits. The areas supplied by definite spinal nerves, according to the observations of Head and Thorburn, are shown in figures 778 and 779 respectively.

The Cutaneous Areas of the Lower Extremity

The segmental arrangement of the cutaneous areas of the lower extremity is not so well retained as in the upper, due largely to a greater amount of developmental shifting of the parts. Both of the lines separating the areas of the lumbar (cephalic) and the sacral (caudal) parts of the lumbo-sacral plexus lie on the dorsal aspect of the limb. The nerves from the lumbar part of the plexus are distributed to the entire anterior and the medial and lateral surfaces of the limb and to the muscles of the anterior and medial portions of the thigh and the anterior portion of the leg, whereas the cutaneous nerves from the sacral part of the plexus are confined to a narrow strip along the dorsal aspect of the limb (fig. 781). However, the muscular distribution of the sacral part is as much expanded as its cutaneous area is contracted; it supplies the muscles in the dorsal portions of the hip, thigh and knee, the whole of the dorsal part of the leg and ankle and the plantar muscles of the foot.

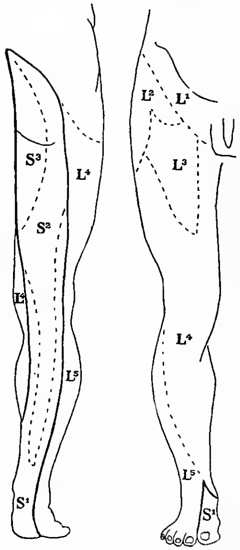
There are six cutaneous areas in the region of the buttock, three upper and three lower. Of the upper areas the lateral is supplied by the anterior primary divisions of the last thoracic and first lumbar nerves through the iliac branches of the last thoracic and the ilio-hypogastric nerves; the middle upper area receives the lateral divisions of the posterior primary branches of the upper three lumbar nerves, and the medial upper area is supplied by twigs from the lateral branches of the posterior primary divisions of the upper two or three sacral nerves (figs. 776, 780).

Of the lower three areas, the lateral receives filaments from the second and third lumbar nerves through the lateral femoral cutaneous (external cutaneous) branch of the lumbar plexus; the middle area is supplied by the first, second, and third sacral nerves through the posterior femoral cutaneous (small sciatic) nerve; and the medial area by the second and third sacral nerves through the medial inferior clunial (perforating cutaneous) branch of the sacral plexus (fig. 776).

On the back of the thigh there are three areas. According to Head, the medial and lateral areas are supplied by the second and third lumbar nerves, the former through the lateral femoral cutaneous (external cutaneous) branch of the lumbar plexus, and the latter through the anterior cutaneous branches of the femoral (internal cutaneous branch of the anterior crural) nerve. The middle area receives twigs from the first, second, and third sacral nerves through the posterior femoral cutaneous (small sciatic), a branch of the sacral plexus.

The front of the thigh is supplied by the first, second, and third lumbar nerves, and, according to Head, there are five cutaneous areas. The lateral area receives twigs of the second and third lumbar nerves through the lateral (external) cutaneous nerves. There are two medial areas, an upper and a lower. The former is supplied by the lumbo-inguinal (crural) branch of the genito-femoral (genito- crural), which conveys twigs of the first and second lumbar nerves; the latter receives fibres of the second and third lumbar nerves through one of the an-

Fig. 781.—Diagram of the Cutaneous Areas of the Lower Extremity (After Thorburn, modified.)



terior (middle) cutaneous branches of the femoral (anterior crural) nerve. The small upper and medial area is supplied by the first lumbar nerve through the ilio-inguinal, and the lower medial area receives twigs of the second and third lumbar nerves through one of the anterior cutaneous branches (internal cutaneous) of the femoral (anterior crural) nerve (fig. 776).

The front of the knee is supplied by the second, third, and fourth lumbar nerves through the anterior (middle and internal) cutaneous and saphenous (long saphenous) branches of the femoral (fig. 776).

Of the skin over the region of the popliteal space, the medial portion receives fibres from the second, third, and fourth lumbar nerves through the anterior (internal) cutaneous branch of the femoral (anterior crural) nerve and through the superficial division of the obturator nerve; the middle and lateral portion receives twigs of the first three sacral nerves through the posterior cutaneous (small sciatic) nerve (fig. 776).

The skin over the front and medial side of the leg is supplied by the fourth lumbar nerve through the saphenous nerve, and the skin of the front and lateral side receives nerve-fibres from the fifth lumbar nerves through the sural cutaneous (fibular communicating) branch of the common peroneal (external popliteal) nerve.

In the skin of the back of the leg four areas can be distinguished, a medial, two middle, upper and lower, and a lateral area. The medial area is supplied by the fourth lumbar nerves through an anterior cutaneous branch (internal cutaneous) of the femoral (anterior crural) nerve and the superficial branch of the obturator nerve. The upper middle area is supplied by the second, and third sacral nerves through the posterior femoral cutaneous (small sciatic) nerve, and the lower middle area by the first sacral nerve through the sural (external saphenous) nerve. The lateral area is supplied by the fifth lumbar nerve through the lateral sural cutaneous (fibular communicating) branch of the common peroneal (external popliteal) nerve (fig. 776, 780, 781).

The skin of the dorsum of the foot is supplied principally by the fifth lumbar and by the first sacral nerves; the majority of the nerve-fibres travel by the superficial peroneal(musculocutaneous) nerve, but the adjacent sides of the first and second toes are supplied by the femoral (anterior crural) nerve and the side of the dorsum of the little toe is supplied through the sural (external saphenous).

The skin of the region of the heel is supplied by the first sacral nerve, the medial surface and medial part of the under surface by the medial calcaneal branches of the tibial (calcaneoplantar) nerve and the posterior, external, and lower aspects by the sural (external saphenous) nerve (fig. 776).

The sole of the foot in front of the heel receives cutaneous fibres from the fifth lumbar and the first sacral nerves; the medial area, which includes the medial three and a half digits, being supplied by the medial plantar nerve which conveys fibres of the fifth lumbar and the first sacral nerves; and the lateral area by the fifth lumbar nerve through the lateral plantar nerve.

The medial side of the foot is supplied by the first sacral and fourth lumbar nerves through the saphenous nerve and the lateral side by the fifth lumbar nerve through the sural (external saphenous) nerve.

The skin of the scrotum and penis is supplied by the first lumbar nerve through the ilio-inguinal nerves, and by the second and third sacral nerves through the perineal and dorsal penile branches of the pudendal (pudic) nerve.

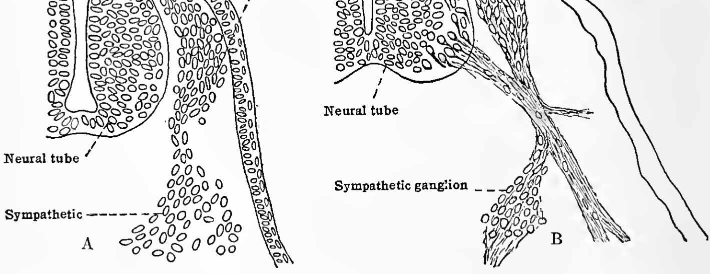
The cutaneous areas of the lower extremity which have been demarcated by Head and Thorburn are shown in fig. 780. These do not conform wholly with each other nor with the areas given in more detail in fig. 776, due probably to individual differences in subject and observer and to the difficulties coincident with the overlapping of the areas. Fig. 781 is more general in character and is considered more approximately correct.

The homology of the parts of the plexuses of the upper and lower extremities is not well carried out in the distribution of the nerves. The radial and great sciatic nerves are similar to the extent that the one arises from the posterior cord of the brachial plexus and the other from the sacral plexus, and that the one is distributed to the dorsal aspect of the arm and the other to the dorsal surface of the lower extremity, but the great sciatic supplies the sole of the foot, and the plantar muscles, whereas the radial does not supply the palm of the hand and the palmar muscles.

THE SYMPATHETIC SYSTEM

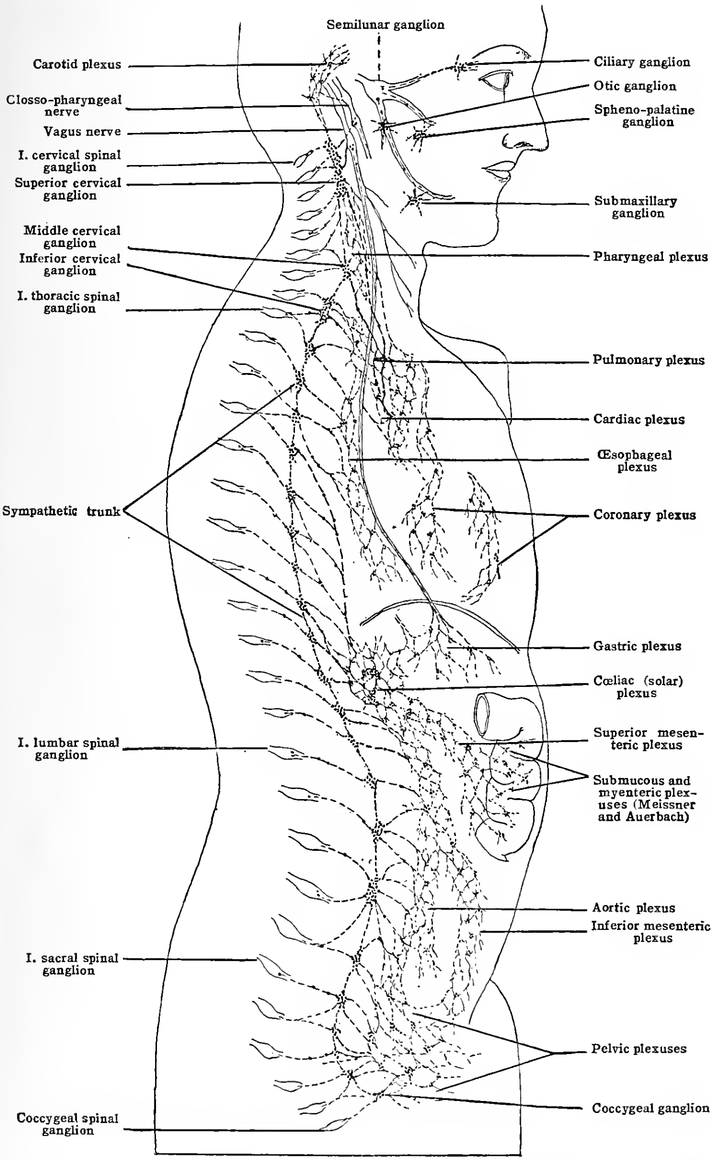
The so-called sympathetic system is that portion of the peripheral nervous system which is especially concerned in the distribution of impulses to the

FIG. 782.—DIAGRAM SHOWING TWO STAGES OF THE MIGRATION OF THE PRIMITIVE GANGLIA FROM THE GANGLION CREST; A. THE DIVISION OF THE PRIMITIVE GANGLIA INTO SPINAL AND SYMPATHETIC PORTIONS, AND B. THE FORMATION OF THE NERVES.



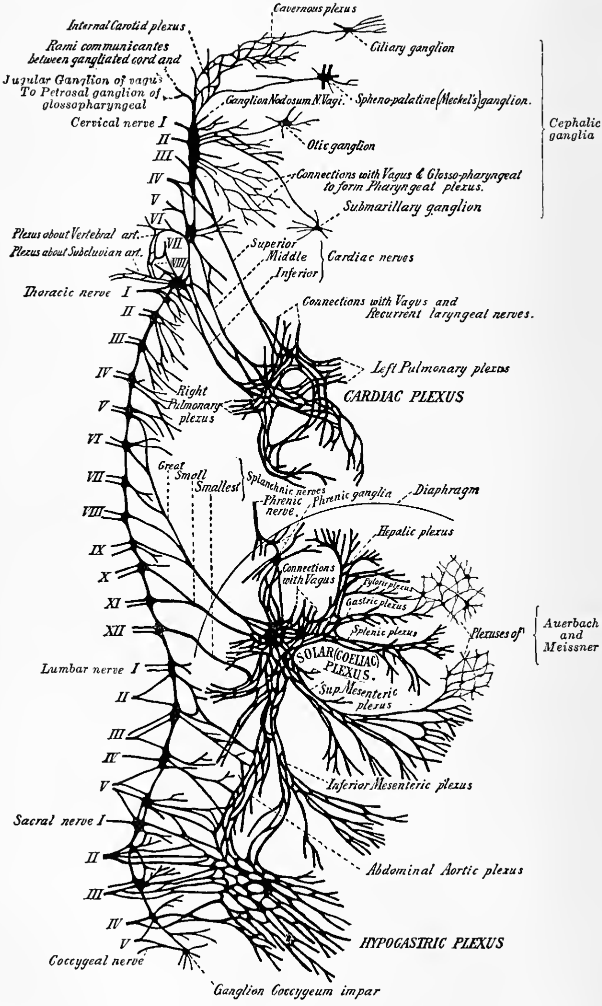
glandular tissues, to the muscle of the heart and blood-vessels, and to the non-striated muscular tissue of the body wherever found. Since these tissues are most

Fig. 783.—Diagram Showing the Chief Paths of Migration of the Cells from the Ganglia of the Spinal and Cranial Nerves to form the Adult Sympathetic System (After Schwalbe, modified.)



abundant in and largely comprise the viscera or splanchnic organs of the body, the largest and most evident of the structures comprising the sympathetic system are found either in or near the cavities containing the viscera. However, the

Fig. 784.—Scheme showing General Plan of the Coarser Portions of the Sympathetic Nervous System and its Principal Communications with the Cerebro-spinal System. (After Flower, modified.)



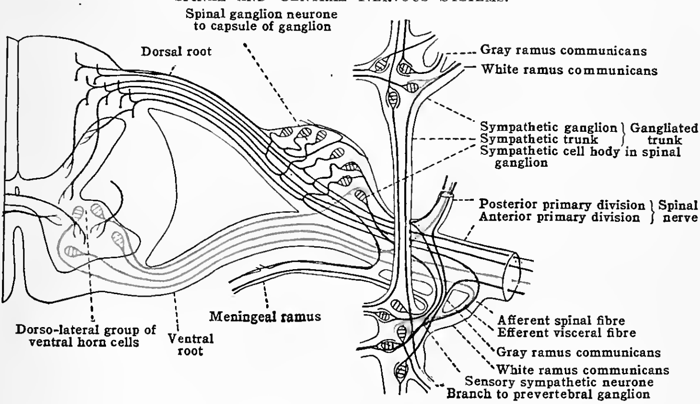
finer divisions of the system ramify throughout the whole body, supplying vaso-motor fibres to the blood-vessels throughout their course, controlling the glands of the skin, and supplying pilo-motor fibres for the hairs, forming intrinsic plexuses within the walls of the viscera, and it is claimed that a few of its neurones convey inpulses toward the central system (sensory sympathetic neurones). While it is very probable that certain of the simpler reflexes of the splanchnic organs may be mediated by the sympathetic system alone, yet the sympathetic is by no means independent of the cranio-spinal system, but is rather, both anatomically and functionally merely a part of one continuous whole. Throughout, it shares its domain of termination with cranio-spinal fibres, chiefly of the sensory variety, and most of its rami and terminal branches carry a few cranio-spinal fibres toward their areas of distribution. Likewise the cranio-spinal nerves carry numerous sympathetic fibres gained by way of rami connecting the two systems.

Like the cranio-spinal system, the sympathetic consists of cell-bodies, each of which gives off one axone. In addition, the cell-bodies give off numerous dichotomously branched dendrites by which their receptive surfaces are increased, and they are accumulated into ganglia, large and small. The larger ganglia have more or less constant positions, shapes, and arrangements, while the smaller, some of which are microscopic, are scattered throughout the body in a seemingly more indefinite manner. The axones or fibres arising in these ganglia are given off in trunks and rami which associate the ganglia with each other or with the cranio-spinal system, or which pass from the ganglia to be distributed directly upon their allotted elements.

The **sympathetic fibres** arising from the ganglia are, for the most part, either totally non-medullated or partially medullated. Some fibres are completely medullated near their cells of origin, but lose their medullary sheaths before reaching their terminations. Some of them possess complete medullary sheaths throughout, but in no cases are the sheaths as thick or well developed as is the rule with the cranio-spinal fibres. Thus, nerve-trunks and rami in which sympathetic fibres predominate appear greyish in colour and more indefinite, as distinguished from those of the cranio-spinal nerves, which always appear a glistening white, due to light being reflected from the emulsified myelin of the sheaths of their fibres.

Origin of the sympathetic system.—Not only must the cranio-spinal and sympathetic systems be considered anatomically continuous and dependent, but also the neurones of the two systems have a common origin, namely, the ectoderm of the dorsal mid-line of the embryo. The cells of the ganglion crest (see p. 754) become arranged in segmental groups and soon separate into two varieties:—those which will remain near the spinal cord and develop into the spinal ganglia, and those which, during the growth processes, migrate and become displaced further into the periphery and form the sympathetic ganglia.

Fig. 785.—Scheme showing the Connection between the Sympathetic and the Cranio-spinal and Central Nervous Systems.



In the development of the sympathetic system the migration from the vicinity of the central system occurs to varying extents, so that in the adult the cells comprise three general groups of ganglia situated different distances away from the central nerve axis.—(1) A large portion of the cells remain near the central system and form a linear series of ganglia which, with the trunks connecting them, become two *gangliated nerve trunks* extending along each side, proximal to and parallel with the vertebral column; (2) a still larger portion of the cells migrate further toward the periphery and are accumulated into ganglia which assume an intermediate position and which, with the rami associating them with each other and with other structures, form a series of great *prevertebral* *plexuses;* (3) still other cells wander even further away from the locality of their origin and invade the very walls of the organs innervated by the sympathetic system. The latter cells occur as numerous small terminal ganglia, most of which are microscopic and which, with the twigs connecting them, form the most peripheral of the sympathetic plexuses. Examples of these are the intrinsic ganglia of the heart and pancreas and the *plexuses of Auerbach* and *Meissner* in the walls of the digestive canal. Small, straggling ganglia may be found scattered between these three general groups. In the head, the gangliated trunks and great prevertebral plexuses are represented by the ciliary, sphenopalatine, otic and submaxillary ganglia and the plexuses associated with these. The supporting tissue of the sympathetic system accumulates early and is probably all of mesodermic origin.

Construction of the sympathetic system.—The sympathetic ganglia may be considered as relays in the pathways for the transmission of impulses from the region in which they arise to the tissues in which they are distributed; the cells composing the ganglia are the cell-bodies of the neurones interposed in the various neurone chains performing this function. A fibre arising from a cell-body in a given ganglion may pass out of the ganglion and proceed directly to its termination upon a smooth muscle-fibre or gland-cell, or it may pass through a connecting trunk to another ganglion and there terminate about and thus transmit the impulse to another cell, which, in its turn, may give off the fibre which bears the impulse to the appropriate tissue-element. Fibres arising in given ganglia may pass uninterrupted through other ganglia and proceed to their respective destinations. On the other hand, several neurones may be involved in the transmission of a given impulse when sent from a region distant from the tissue to which it is distributed.

Communication between the central nervous system and the sympathetic is established through both efferent and afferent fibres. In the region of the spinal cord both varieties of fibres pass from one system to the other by way of the **rami communicantes,** delicate bundles of fibres connecting the nearby sympathetic trunk with the respective spinal nerves (fig. 785).

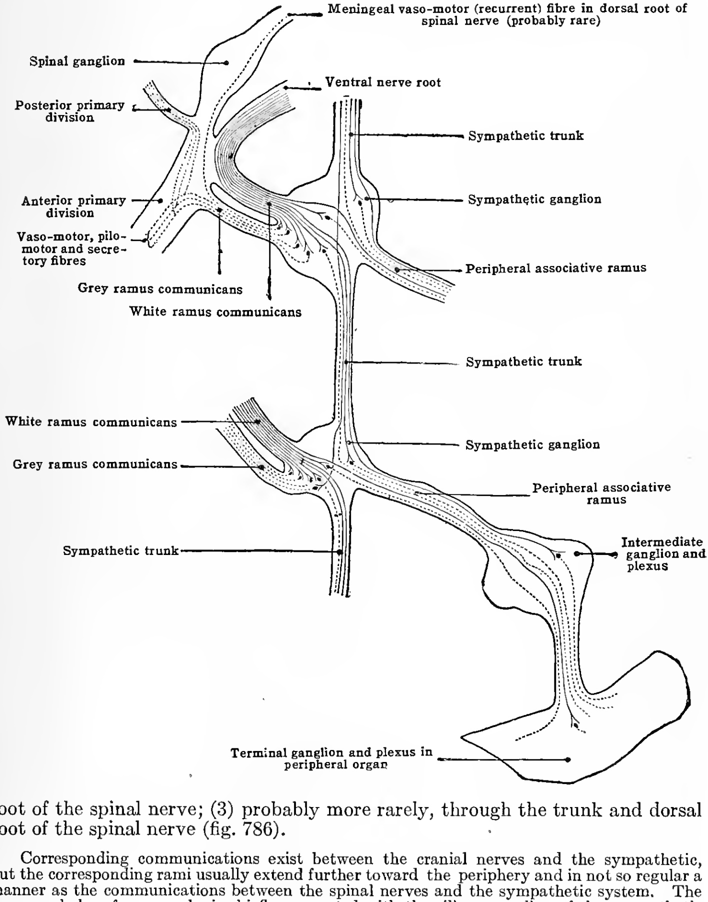
The efferent fibres of the rami arise in the ventral horn (dorso-lateral cell-group chiefly) of the spinal cord, emerge through the ventral roots, enter the rami, and terminate chiefly about the cells of the nearest sympathetic ganglion; some, however, may pass through or over the ganglion of the sympathetic cord and terminate about cells in more distant ganglia. Since these fibres transmit impulses from the central to the sympathetic system, they are known as **visceral efferent fibres.** They are of smaller size than is the average for the cranio-spinal efferent or motor fibres of the ventral root. The **visceral afferent fibres** are of two varieties:—(1) Peripheral processes of the spinal ganglion-cells which run outward in the nerve-trunk, enter the rami communicantes, pass through the various connecting trunks and terminal rami of the sympathetic and terminate in the tissues supplied by these rami. Such are merely sensory fibres of the cranio-spinal type which collect impulses in the domain of the sympathetic and convey them to the central system by way of the sympathetic nerves and the dorsal roots of the spinal nerves. (2) Afferent sympathetic fibres proper. The actual existence of these has not been long established, and their relative abundance is as yet uncertain. They consist of fibres arising in the sympathetic ganglia which enter the spinal ganglia by way of the rami commnicantes and the cranio-spinal nerve-trunk and terminate in arborisations about the spinal ganglion-cells (fig. 785). The afferent impulses transmitted by these sympathetic fibres are borne into the spinal cord or brain by way of the cranio-spinal fibres of the dorsal roots. These sensory sympathetic fibres must necessarily either receive the impulses they bear from sympathetic neurones having both peripheral and central processes or they themselves must be axones or central processes of neurones having also processes terminating in the peripheral tissues. Doubtless the variety of visceral afferent fibres first mentioned greatly predominates.

The thoracic and the lumbar spinal nerves are connected with the sympathetic trunk (gangliated cord) by two rami communicantes. Most of both the visceral efferent and also the visceral afferent fibres (which arise in the spinal ganglia) pass by way of a separate ramus. Both these varieties being of the cranio-spinal type, and, therefore, medullated, they give the ramus a white appearance meriting the name **white ramus communicans.** Fibres of the sympathetic type predominate in the second ramus and thus it is the **grey ramus communicans.** The latter consists of:—(1) afferent sympathetic fibres and (2) of sympathetic fibres which join the primary divisions of the spinal nerves and course in them to their allotted tissues (fig. 785).

In the sacral region, most of the visceral efferent fibres pass over the ganglia of the sympathetic trunk and terminate in the more peripheral ganglia of the plexuses of this region. This is especially true for the fibres passing from the second, third, and fourth sacral nerves. In the cervical region white rami are not in evidence, a fact probably explicable as due to an arrangement by which at least most of the visceral efferent fibres arising in the cervical segments of the spinal cord pass downward in these segments and join the sympathetic through the white rami of the upper thoracic nerves; others may enter the cervical portion of the gangliated cord through the spinal accessory or eleventh cranial nerve, rather than through individual white rami, while others pass into the nerves of the brachial plexus to terminate in the minute ganglia of the plexuses upon the blood-vessels of the limb. All the spinal nerves are joined by grey rami communicantes from the sympathetic trunk.

Vaso-motor fibres to the meninges and intrinsic blood-vessels of the spinal cord pass to the spinal nerves by way of the grey rami. Thence they may reach the meninges by one of three ways:—(1) through the delicate recurrent or meningeal branch of the spinal nerve (fig. 785); (2) through the trunk and ventral

FIG. 786.—DIAGRAM SUGGESTING THE ORIGIN, COURSE AND CONNECTIONS OF SYMPATHETIC NERVE-FIBRES.



root of the spinal nerve; (3) probably more rarely, through the trunk and dorsal root of the spinal nerve (fig. 786).

Corresponding communications exist between the cranial nerves and the sympathetic, but the corresponding rami usually extend further toward the periphery and in not so regular a manner as the communications between the spinal nerves and the sympathetic system. The mesencephalon, for example, is chiefly connected with the ciliary ganglion of the sympathetic by fibres which are sent through the oculo-motor nerve and which enter this ganglion by way of its short root and terminate about its cells. Visceral efferent fibres from the rhombencephalon pass outward to the sympathetic in the roots of the facial, glosso-palatine, glosso-pharyngeal, vagus, and spinal accessory nerves, all of which have more or less irregularly disposed communicating rami. The ganglia of origin of the vagus, more than perhaps any other nerve, both receive impulses from visceral efferent fibres and give origin to sympathetic fibres. Likewise twigs of other cranial nerves, especially of the trigeminus, connect with (pass through) the small sympathetic ganglia of the head. The meningeal branches given by certain of the cranial nerves contain vaso-motor fibres, and these correspond to the sympathetic fibres in the recurrent branches and in the roots of the spinal nerves.

It is known that spinal ganglia and certain of the ganglia of the cranial nerves contain cell-bodies of sympathetic neurones—cell-bodies which, during the period of the migration peripheralward, remained within the confines of these ganglia (fig. 785). These cell bodies receive efferent impulses from ventral root fibres and send their axones further into the periphery just as if in the sympathetic ganglion. Their relative abundance is not known. It is supposed that the ganglia of the vagus, glosso-pharyngeus, trigeminus and the geniculate ganglion contain a considerable proportion of such sympathetic cell-bodies.

From the above it may be seen that the ganglia and connecting trunks and rami of the sympathetic system may be divided as follows:—(1) The two **sympathetic gangliated trunks** lying proximal to and parallel with the vertebral column; (2) the **great prevertebral plexuses,** of which there are roughly four, one in the head, one in the thorax, one in the abdomen, and one in the pelvic cavity (fig. 784), each of which is subdivided; (3) the numerous **terminal ganglia and plexuses** situated either within or close to the walls of the various organs; (4) the **trunks** and **rami** associating the ganglia with each other and thus contributing to the plexuses, or connecting the ganglia with other nerves or with the organs with whose innervation they are concerned. The trunks and rami may be divided into—(*a*) the *rami communicantes,* or *central branches,* connecting the sympathetic with the cranio-spinal and central systems; (*b*) *associative trunks,* best considered as those which associate sympathetic ganglia situated on the same side of the body; (*c*) *commissural branches,* or those which associate ganglia situated on opposite sides of the mid-line of the body, such as the transverse connecting branches between the sympathetic trunk in the lumbo-sacral region (fig. 787), or all the associating trunks between the ganglia of plexuses occupying the mid-region of the body; (*d*) *terminal* or *peripheral branches,* or those which pass from the ganglia to their final distribution apparently uninterrupted by other ganglia.

THE SYMPATHETIC TRUNKS

The sympathetic gangliated trunks, or gangliated cords, of the sympathetic system are two symmetrical trunks with ganglia interposed in them at intervals of varying regularity, and extending vertically, one on each side of the ventral aspect of the vertebral column, from the second cervical vertebra to the first piece of the coccyx. Upon the coccyx the two trunks unite and terminate in a single medial ganglion, the **ganglion coccygeum impar.** The various ganglia are connected with the cranio-spinal nerves by the rami communicantes. Morphologically, each trunk might be expected to possess thirty-one ganglia, one for each spinal nerve, but, owing to the fusion of adjacent ganglia in certain regions, especially in the cervical, there are in the adult only twenty-one or twenty-two ganglia in each trunk. These occur as *three cervical ganglia, ten or eleven thoracic ganglia, four lumbar and four sacral ganglia,* and the *ganglion coccygeum impar,* which is common to both trunks.

In the cervical region the sympathetic trunks lie in front of the transverse processes of the vertebræ, from which they are separated by the longus capitis (rectus capitis anticus major) and longus colli; in the thoracic region they lie at the sides of the bodies of the vertebræ and on the heads of the ribs; in the lumbar region they are placed more ventrally with reference to the spinal nerves and more in front of the bodies of the vertebræ and along the anterior borders of the psoas muscles; in the pelvis the ganglia lie between and ventral to the openings of the sacral foramina. In the lower lumbar and sacral region one ganglion may send rami communicantes to two spinal nerves and one spinal nerve may be connected with two ganglia. The ganglia of the trunks throughout give off associative branches to the ganglia of the prevertebral plexuses and branches to the nearby viscera and blood-vessels. These branches may appear either white or grey according to the predominance of medullated or non-medullated fibres in them. In the lumbo-sacral region commissural or transverse branches between the ganglia of the two trunks are especially abundant. In trunks having a whiter appearance, the greater part of the medullated fibres producing it are sensory and visceral motor fibres from the spinal nerves which have passed through the sympathetic ganglia without termination. The nerve trunks connecting the ganglia of the sympathetic trunks all contain three varieties of fibres:—(1)

visceral motor fibres which have entered them in the white rami communicantes from the spinal nerves of higher or lower levels, and which are coursing in them to terminate in other ganglia, either in the trunks above or below or in ganglia not belonging to the trunks; (2) fibres arising in sympathetic ganglia of a higher or lower level and passing upward or downward to terminate in other ganglia of the trunk or to issue from the trunk and proceed to more peripheral ganglia or to ganglia of the opposite trunk (both associative and commissural fibres); (3) afferent fibres or sensory fibres arising either in the spinal ganglia, or sensory sympathetic fibres arising in sympathetic ganglia and coursing in the trunk to pass into spinal ganglia above or below by way of the grey rami communicantes.

THE CEPHALIC AND CERVICAL PORTIONS OF THE SYMPATHETIC TRUNK

The cephalic portion of the sympathetic system consists of numerous small ganglia and of numerous plexuses connected with the internal carotid nerve, the ascending branch given off by the superior cervical sympathetic ganglion. The cephalic ganglia are all relatively small. There are four considered in the ordinary macroscopic dissections, namely, the ciliary or ophthalmic, the spheno-palatine or Meckel's ganglion, the otic, and the submaxillary. To these may be added a portion of the superior cervical sympathetic ganglion, the sympathetic portions of the nodosal, petrous, geniculate and semilunar ganglia, and the various small ganglia dispersed in the plexuses. These ganglia with their roots or communicating branches have been described in their relations with the divisions of the trigeminus and with the oculo-motor, glosso-palatine, vagus and facial nerves.

The internal carotid nerve, the **ascending branch** from the superior cervical sympathetic ganglion, may be regarded as an upward prolongation of the primitive sympathetic trunk.

It arises from the upper end of the superior cervical ganglion and passes through the carotid canal into the cranial cavity. It divides into two branches which subdivide to form a coarse plexus, the *internal carotid plexus*, which partly surrounds the internal carotid artery before the latter enters the cavernous sinus (fig. 787 and 788). It passes with the artery to the cavernous sinus, where it forms the finer meshed *cavernous plexus*.

The **internal carotid plexus** supplies offsets to the artery and receives branches from the tympanic plexus through the inferior carotico-tympanic nerve and from the spheno-palatine ganglion through the great deep petrosal nerve. It also communicates by fine branches with the semilunar (Gasserian) ganglion and with the abducens nerve.

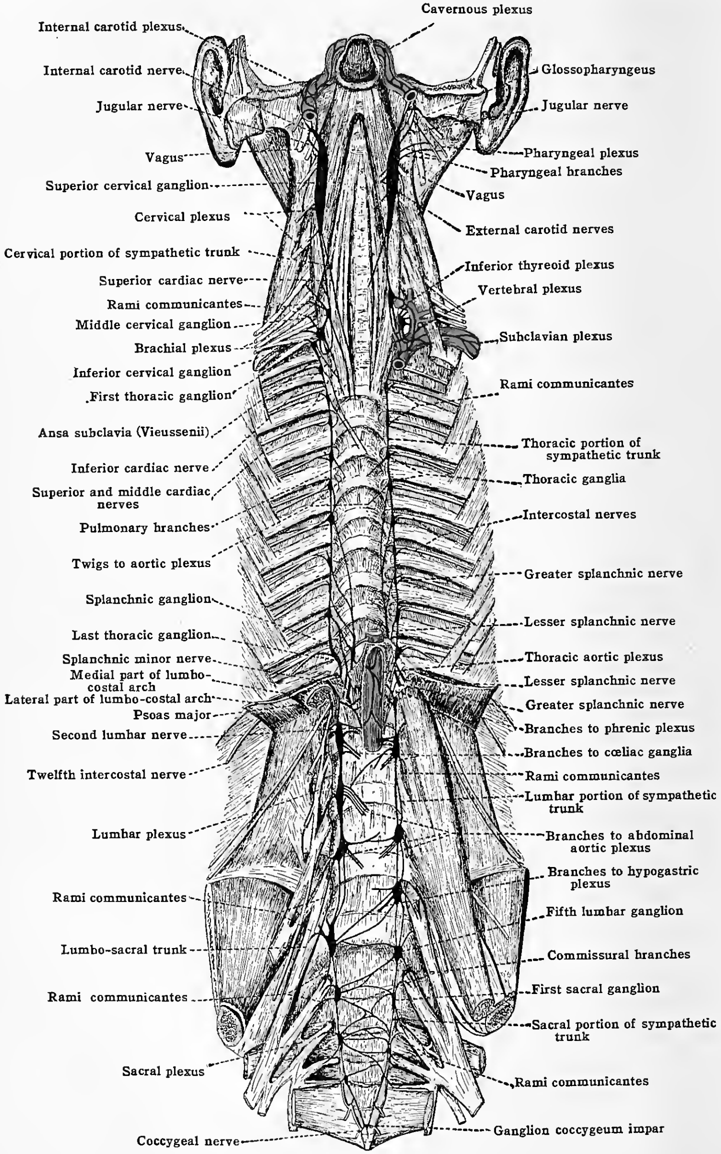
The **cavernous plexus** gives branches of communication to the oculo-motor and trochlear nerves and to the opthalmic division of the trigeminus. According to Toldt and Spalteholz, it communicates with the **tympanic plexus** through the superior carotico-tympanic (small deep petrosal) nerve. It also communicates with the ciliary ganglion through the **long root** *of the ciliary ganglion* and usually through a separate *sympathetic root* of this ganglion. These branches may pass through the superior orbital (sphenoidal) fissure either separately or with the naso-ciliary (nasal) nerve.

The cavernous plexus also gives branches to the carotid artery and filaments of the plexus accompany small branches of the artery to the hypophysis (pituitary body) and to the dura mater on the sphenoid bone.

The *terminal branches* of the cavernous plexus consist of delicate filaments that anastomose freely, forming fine plexuses, and pass from the cavernous plexus along the terminal divisions of the internal carotid artery and their branches. These fine plexuses take the name of the artery on which they lie. The four larger of them are the plexuses of the anterior and middle cerebral arteries, the plexus of the chorioid artery, and the ophthalmic plexus.

The **cervical portion of the sympathetic cord** extends upward along the great vessels of the neck. No white rami communicantes connect it directly with the spinal cord, but instead it receives visceral efferent fibres from the upper thoracic spinal nerves through the sympathetic trunk, and probably also from the cervical spinal cord through the spinal acessory nerve and the connections with the vagus. It sends **grey rami communicantes** to each of the cervical nerves. It extends from the subclavian artery to the base of the skull, lying dorsal to the sheath of the great vessels and in front of the longus capitis and longus colli, which separate is from the transverse processes of the cervical vertebræ (fig. 787). It usually

Fig. 787.—Showing the Sympathetic Trunks in their Relation to the Vertebral Column, to the Spinal Nerves, and to each Other. (Modified from Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



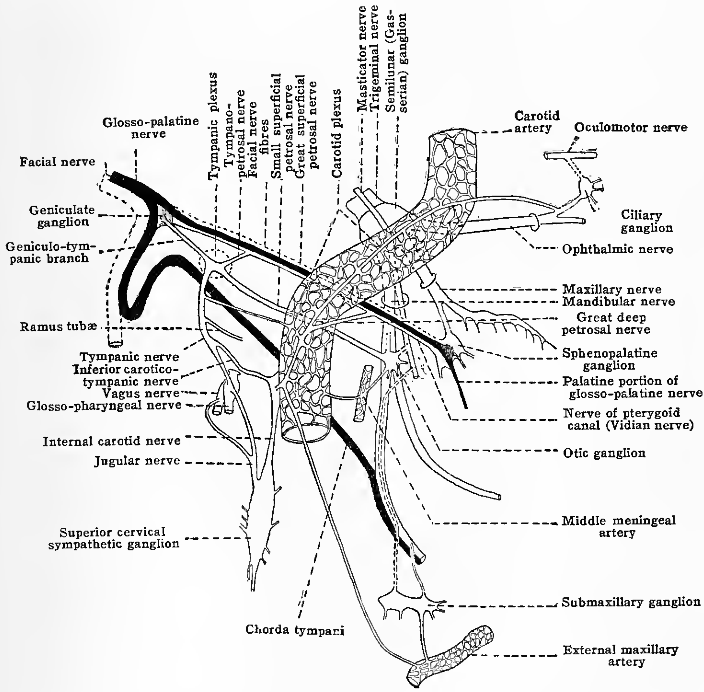
has but three **ganglia**, one at each end, the superior and inferior, and one between these two, called the middle ganglion. The latter varies somewhat in position and is sometimes absent.

1. Superior Cervical Ganglion

The **superior cervical ganglion** is usually fusiform in shape and is sometimes marked by one or more constrictions. There is ground for the belief that it is formed by the coalescence of four ganglia corresponding to the first four cervical nerves. It varies from an inch to one and one-half inches (2.5 to 3.7 cm.) in length, lying dorsal to the upper part of the sheath of the great vessels of the neck and in front of the transverse processes of the second and third cervical vertebræ.

Fig. 788.—Diagram of the Glosso-palatine Nerve and the Relations of the Gangliated Cephalic Plexus to other Cranial Nerves. (After Bean.)

Broken lines, motor; continuous lines, sympathetic; glosso-palatine in solid black. Medial view. Left side.



It occasionally extends upward as high as the transverse process of the first vertebra (fig. 787). It is connected with the middle cervical ganglion by the intervening trunk, and it gives off a large number of communicating branches.

Rarely, the ganglion may be double or split with a ventral portion lying superficial to the carotid sheath and a dorsal portion dorsal to the sheath, connected by sympathetic filaments near the superior and inferior extremities of the ganglion.

Communications:—(1) **Four grey rami communicantes** associate the ganglion with the anterior primary divisions of the first four cervical nerves.

(2) **Communicating branches to the cranial nerves.**—An irregular number of small twigs pass between the superior cervical ganglion and the hypoglossal nerve and to the ganglion nodosum of the vagus. A named branch, the *jugular nerve*, runs upward to the base of the skull and divides into two branches, one of which enters the jugular foramen and terminates in the jugular ganglion of the vagus, and the other ends in the petrous ganglion of the glossopharyngeus. (See fig. 788).

(3) **Four or five laryngo-pharyngeal branches** come from the superior ganglion and the plexus extending downward from it, and pass forward and medialward, lateral to the carotid vessels, to the wall of the pharynx, where they unite on the middle constrictor with the pharyngeal branches of the glosso-pharyngeus and vagus, forming with them the *pharyngeal plexus*, from which branches are distributed to the walls of the pharynx and to the superior and external laryngeal nerves (fig. 787).

(4) The **superior cervical cardiac nerve** springs from the lower part of the ganglion or from the trunk immediately below it. It passes downward behind the carotid sheath, either in front of or dorsal to the inferior thyreoid artery, and in front of the longus colli, and establishes communications with the upper cervical cardiac branch of the vagus, the middle cervical cardiac branch of the sympathetic, and with the inferior and external laryngeal nerves. At the root of the neck the nerve of the *right side* passes in front of or behind the first part of the right subclavian artery, and is continued along the innominate artery to the front of the bifurcation of the trachea, where it ends in the deep part of the cardiac plexus. The *left nerve* passes into the thorax along the front of the left common carotid artery, crosses the front of the arch of the aorta immediately anterior to the vagus, and terminates in the superficial part of the cardiac plexus (fig. 789). Filaments from both the right and left nerves pass to the inferior thyreoid plexus.

(5) The **external carotid nerves** (fig. 787) pass forward from the superior cervical ganglion to the external carotid artery, where they divide into branches which anastomose freely to form around the artery the **external carotid plexus.** This plexus extends to the beginning of the artery, and is continued upon the common carotid artery as the **common carotid plexus.** From the external carotid plexus, filaments pass to form secondary plexuses around each of the branches of the external carotid artery. These plexuses take the names of the arteries which they follow, namely, the **superior thyreoid plexus, lingual plexus,** etc. Filaments pass from the external carotid plexus to the *glomus caroticum* (the carotid gland), and from the superior thyreoid plexus to the thyreoid gland.

From the **external maxillary** (facial) **plexus** passes the *sympathetic root of the submaxillary ganglion.*

A part of the **internal maxillary plexus** is continued upon the middle meningeal artery as the **meningeal plexus.** From this plexus filaments pass to the otic ganglion, and sometimes a branch, called by English anatomists the **external superficial petrossal nerve,** passes to the geniculate ganglion.

(6) Small **branches to the ligaments and bones** of the upper part of the vertebral column.

(7) The **internal carotid nerve (ascending branch)** and plexus have been described with the cephalic portion of the sympathetic system.

2. The Middle Cervical Ganglion

The **middle cervical ganglion** is small and somewhat triangular in outline. It is sometimes absent. Its position is variable, but it commonly lies about the level of the cricoid cartilage, in front of the bend of the inferior thyreoid artery (fig. 787), and it is associated with the superior cervical ganglion and with the inferior cervical ganglion by the trunk of the gangliated cord. From the lower part of the middle ganglion some filaments pass dorsal to the subclavian artery, while others pass in front of and beneath that artery and anastomose with the first-mentioned filaments to form a loop, the **ansa subclavia** (*ansa Vieussenii*) (figs. 751, 787). Filaments from this loop to the inferior cervical ganglion thus form another communication between the middle and inferior cervical ganglia.

Connections.—The middle cervical ganglion gives off four or more rami.

Two (*a* and *b*) are grey rami communicantes which connect the middle ganglion with the anterior primary branches of the fifth and sixth cervical nerves.

(*c*) One or more peripheral branches pass along the inferior thyreoid artery and anastomose with branches from the superior and middle cardiac nerves and from the inferior cervical ganglion, thus taking part in the formation of the **inferior thyreoid plexus,** from which branches pass to the thyreoid gland.

(*d*) The **middle cardiac nerve** arises by one or more branches from the ganglion, or from the trunk of the cord, and passes downward dorsal to the common carotid artery and, on the right side, either in front of or dorsal to the subclavian artery, and then along the innominate artery to the deep part of the cardiac plexus (figs. 787 and 789). It is frequently larger than the superior cardiac nerve. On the left side the nerve runs between the subclavian and common carotid arteries. On both sides the nerve communicates with the inferior laryngeal nerve and external laryngeal nerve.

The middle cervical ganglion also gives branches to the common carotid plexus.

3. The Inferior Cervical Ganglion

The **inferior cervical ganglion** is irregular in form. It is larger than the middle cervical ganglion, and it lies deeply in the root of the neck dorsal to the vertebral artery or the first part of the subclavian artery, and ventral to the interval between the transverse processes of the last cervical and the first thoracic vertebræ (figs. 759, 761). It is connected with the middle cervical ganglion by the sympathetic trunk, and by filaments passing to the ansa subclavia (Vieussenii), and it is either blended directly with the first thoracic ganglion or connected with it by a short stout portion of the trunk. It gives rami to the last two cervical nerves and peripheral branches to the vertebral and internal mammary arteries, to the heart, and to the inferior thyreoid plexus.

Connections.—(1) The rami to the seventh and eighth cervical nerves are **grey rami communicantes.**

(2) The **branches to the vertebral artery** are large and they unite with similar branches from the first thoracic ganglion to form a plexus, the **vertebral plexus** (fig. 787), which accompanies the artery into the posterior fossa of the cranium, where it is continued on the basilar artery. The plexus communicates in the neck by delicate threads with the cervical spinal nerves. These are probably meningeal rami.

(3) The branches to the internal mammary artery form the **internal mammary plexus.**

(4) The **inferior cardiac nerve** may arise from the inferior cervical ganglion, from the first thoracic ganglion, or by filaments from both these ganglia (figs. 787 and 789). It communicates with the recurrent laryngeal nerve and with the middle cardiac nerve, and passes to the deep part of the cardiac plexus. On the left side it frequently joins the middle cardiac nerve to form a common trunk.

Construction of the cervical portion of the sympathetic trunk.—This portion of the trunk contains both medullated and non-medullated fibres, and a large part of the former are of cranio-spinal origin. In the absence of white rami communicantes to this portion of the sympathetic trunk, it is evident that few if any of the cranio-spinal or **efferent visceral fibres** are contributed to it below the superior ganglion by the cervical region of the spinal cord. Instead, such fibres are known to enter by way of the white rami from the upper thoracic nerves, and to ascend to this portion of the sympathetic trunk. Most of these fibres terminate about the cells of the superior, middle, and inferior cervical ganglia, and these cells in their turn give off sympathetic fibres which pass by way of the branches mentioned above for the cephalic and cervical portions, to their distribution in the structures of the head, neck, and thorax. The efferent visceral fibres which terminate in the superior ganglion especially are among those which mediate—(1) vaso-motor impulses for the head; (2) secretory impulses for the submaxillary gland; (3) pilo-motor impulses for the hairs of the face and neck; (4) motor impulses for the smooth muscle of the eyelids and orbit, and (5) dilator impulses for the pupil. The sympathetic or grey fibres in the cervical portion of the sympathetic trunk arise from the cells of the upper thoracic and the cervical ganglia, and are passing either to connect the ganglia with each other or to enter the peripheral branches and proceed to their terminal distribution.

THE THORACIC PORTION OF THE SYMPATHETIC TRUNK

The thoracic part of the gangliated trunk runs downward on the heads of the ribs from the first to the tenth, and then passes a little ventralward on the sides of the bodies of the lower two thoracic vertebræ. Above it is continuous with the cervical portion at the root of the neck, dorsal to the vertebral artery. Below it leaves the thorax dorsal to the medial lumbo-costal arch (arcuate ligament), or sometimes dorsal to the lateral lumbo-costal arch, and continues into the lumbar portion of the trunk. It lies behind the costal pleura and crosses over the aortic intercostal arteries.

The number of ganglia in this part of the trunk is variable. There are usually ten or eleven, but the first is sometimes fused with the inferior cervical ganglion and occasionally other ganglia fuse. The ganglia are irregularly angular or fusiform in shape, and lie on the head of the ribs, on the costo-vertebral articulations, or on the bodies of the vertebræ. The portions of the trunk connecting the ganglia usually are single, but sometimes they are composed of two or three small cords in juxtaposition. Each ganglion, with the possible exception of the first, receives a *white ramus communicans* from a thoracic nerve and all give off *grey rami communicantes* to these nerves.

The **white rami communicantes,** as they approach the sympathetic trunk, quite often appear double, due to the separation of a large portion of their fibres into two main streams, one passing upward in the sympathetic trunk, and one passing downward. Of the white rami from the upper five thoracic nerves, the upward stream of fibres is much larger than the downward, due to the fact that a greater part of the efferent visceral fibers from these nerves are distributed through the cervical portion of the sympathetic trunk, as noted above in the construction of that portion. Usually the white rami from the spinal nerves pass directly to the corresponding ganglia of the trunk, and thus lie in company with the corresponding grey rami. Sometimes, however, they may join the intermediate portions of the trunk, and in the lower thoracic region especially, a ramus may pass from a nerve to the ganglion corresponding to the nerve above or below. The fibres of the white rami from the lower thoracic nerves are in greater part directed downward in the sympathetic trunk, and also downward in its peripheral branches, to be distributed to the abdominal viscera. In all cases, however, some of the fibres of the thoracic white rami terminate in the ganglia nearest their junction with the trunk, while others pass into the nearest peripheral branches. In this way the white rami from all the thoracic spinal nerves, especially those of the mid-region, are directly concerned in the innervation of the thoracic viscera, lungs, œsophagus, aorta, etc.

The **first thoracic ganglion** is larger than the other ganglia of this region and is irregular in form. It may be narrowly ovoid or semilunar. It lies in front of the neck of the first rib, behind the pleura, and on the medial side of the costo-cervical trunk (superior intercostal artery), which vessel separates it from the prolongation of the portion of the first thoracic nerve which passes to the brachial plexus. It sometimes fuses with the inferior cervical ganglion, and, on the other hand, sometimes extends to the upper part of the second rib to fuse with the second thoracic ganglion. The result of the latter fusion resembles the stellate ganglion of the carnivora, and when it occurs, is sometimes referred to as the *ganglion stellatum*. When well developed, the first ganglion sends a branch to the cardiac plexus, forming the fourth cardiac nerve of Valentin.

The **second thoracic ganglion,** triangular in shape and almost as large as the preceding, is sometimes placed on the costo-vertebral articulation, and is sometimes partly concealed by the first rib.

The **third to the ninth thoracic ganglia** are usually placed opposite the heads of the corresponding ribs, but the **tenth** and **eleventh** may lie on the bodies of the vertebræ.

The fibres passing from the ganglia form two groups of branches, the *central* and the *peripheral.*

The **central** branches are the **grey rami communicantes,** which pass from the ganglia to the corresponding spinal nerves. After they have joined with the anterior primary divisions of the nerves, the fibres of these rami divide into four groups:—(1) Fibres which pass medialward along the roots of the nerves to supply vessels of the membranes of the spinal cord, or enter a meningeal or recurrent branch for the same purpose; (2) fibres which enter the spinal ganglion and terminate there (sensory sympathetic fibres); (3) fibres which pass dorsalward into the posterior primary divisions of the nerves; (4) fibres which pass lateralward in the anterior primary divisions of the nerves. The last two groups of fibres are distributed to the muscle of the blood-vessels of the body-walls, to the skin-glands, and to the muscles of the hairs of the body.

The **peripheral branches** of the ganglia form two series, an upper and a lower.

Those of the *upper series* pass from the upper four or five ganglia ventralward to be distributed as follows:—

(1) **Pulmonary branches** which accompany the intercostal arteries toward their aortic origin without forming plexuses around them, and pass to the posterior pulmonary plexus (fig. 789).

(2) **Aortic branches,** some of which arise directly from the ganglia and some from the pulmonary branches, and unite with branches from the cardiac plexus and from the splanchnic nerves to surround the aorta as the **thoracic aortic plexus** (fig. 789). This plexus accompanies the aorta into the abdomen and there joins with the cœliac (solar) plexus.

(3) **Œsophageal branches** join with the œsophageal plexus of the vagus.

(4) **Vertebral branches,** some of which pass with the nutrient arteries into the bodies of the vertebræ and some of which pass to the median line and there anastomose with similar branches from the opposite side (commissural branches).

The peripheral ganglionic branches forming the *lower series* consist largely of efferent and afferent fibres from the spinal nerves, which pass through the ganglia and reinforce the sympathetic filaments proper. Thus composed, these branches run ventralward and medialward on the sides of the bodies of the vertebræ and unite to form the splanchnic nerves which supply the abdominal organs, the afferent fibres serving to collect sensory impulses in this domain of the sympathetic.

(1) The **great splanchnic nerve** may be formed by branches from **all** the thoracic ganglia from the fifth to the tenth inclusive, or it may receive fibres from only two or three of these

ganglia (fig. 787). It is usually formed by branches from the fifth to the tenth. The superior branch, usually the largest, receives smaller inferior branches from the lower ganglia as it passes downward on the sides of the bodies of the vertebræ in the posterior mediastinum. The nerve enters the abdominal cavity by passing through the crus of the diaphragm, and joins the upper end of the cœliac (semilunar) ganglion of the cœliac (solar) plexus. Near the disk between the eleventh and the twelfth thoracic vertebra there is formed on the nerve the **splanchnic ganglion.** Filaments from the nerve and from this ganglion pass along the intercostal arteries to the aorta, œsophagus, and the thoracic duct, and some fibres from the right side pass to the vena azygos (major). Sometimes this nerve divides into two cords, giving off numerous branches which anastomose with each other and with the lesser splanchnic nerve to form a plexus, in the meshes of which are found some small ganglia.

(2) The **lesser splanchnic nerve** receives fibres from the ninth and tenth ganglia. Its course is similar to that of the great splanchnic nerve (fig. 787), but on a more dorsal plane, and it terminates in the cœliac (solar) and renal plexuses.

(3) The **least splanchnic nerve,** not always present, arises from the last thoracic ganglion or sometimes from the small splanchnic nerve. It passes through the crus of the diaphragm and ends in the renal plexus.

Construction of the thoracic portion of the cord.—The majority of the visceral efferent fibres which pass from the central nervous system enter the thoracic portion of the sympathetic trunk; some end there in ramifications around the cells of its ganglia, while others merely pass through on their way to more distant terminations. With regard to those which terminate in the ganglia, it has been shown that in the dog and cat many end in the ganglion stellatum which corresponds with the last cervical and the upper three or four thoracic ganglia in man. Among these are the fibres conveying secretory impulses to the sweat-glands of the upper limb, which emerge from the spinal cord in the thoracic nerves from the sixth to the ninth, and, in the dog, those which convey and transfer vaso-constrictor impulses to the sympathetic neurones supplying the pulmonary blood-vessels. These visceral efferent fibres leave the spinal cord in the second to the seventh thoracic nerves. Other fibres which terminate around the thoracic sympathetic ganglion-cells in the dog and cat are the vaso-constrictor fibres for the upper limbs and some of the vaso-constrictor fibres for the lower limbs.

Of the fibres which traverse the thoracic portion of the sympathetic trunk to gain more distant terminations, some ascend to the cervical region (p. 1033), others descend to the lumbar region, and many pass by the immediate peripheral branches to the splanchnic nerves.

Among those which descend to the lumbar region are pilo-motor fibres, vaso-motor fibres, and secretory fibres to the lower limb, some vaso-constrictor fibres to the abdominal blood-vessels, motor fibres to the circular, and inhibitory fibres to the longitudinal muscle of the rectum. The latter enter the sympathetic trunk by the lower thoracic nerves and pass in the lumbar peripheral branches to the aortic plexus, and terminate around the cells of the inferior mesenteric ganglion.

The visceral efferent fibres which pass through the thoracic ganglia to the splanchnic nerves are mainly vaso-motor fibres to the abdominal blood-vessels; the majority of them probably terminate around the cells of the ganglia in the cœlic (solar) plexus, but those for the renal blood-vessels no doubt end in the renal ganglia. In addition to all the above-mentioned fibres there are in the thoracic part of the sympathetic trunk afferent fibres of both sympathetic and cerebro-spinal type, passing toward the spinal ganglia and the latter, greatly predominating, pass into the dorsal roots of the thoracic spinal nerves.

THE LUMBAR PORTION OF THE SYMPATHETIC TRUNK

The lumbar portion of each trunk lies on the fronts of the bodies of the vertebræ along the anterior border of the psoas muscle, and nearer to the median line than the thoracic portion. It is connected with the thoracic portion of the sympathetic trunk by a slender intermediate portion of the trunk that may pass through the diaphragm or dorsal to it (fig. 787). The continuation of the lumbar into the sacral portion is also slender, and descends dorsal to the common iliac artery. The right trunk is partly covered by the vena cava inferior and the left by the aorta.

The **ganglia,** which are small and oval, vary in number from three to eight, but are usually four. Rarely they are so fused as to form one continuous ganglion.

White rami communicantes pass to the ganglia from the first two or three lumbar nerves only. This portion of the sympathetic trunk also receives visceral efferent and afferent fibres which are derived from the white rami communicantes of the lower thoracic nerves and continue downward in the trunk.

Branches.—As in the thoracic region, the branches from the ganglia are central and peripheral. The central are **grey rami communicantes.** There may be two branches to a nerve or one ramus may divide so as to join two adjacent spinal nerves. Sometimes a spinal nerve may receive as many as five grey rami from the sympathetic trunk.

The **peripheral branches** include:—(*a*) Branches passing to the aorta and taking part in the formation of the aortic plexus; (*b*) branches which descend in front of the common iliac artery to the hypogastric plexus; and (*c*) branches to the vertebræ and ligaments.

THE SACRAL PORTION OF THE SYMPATHETIC TRUNK

The sacral part of each trunk passes downward in front of the sacrum, immediately lateral to the medial borders of the anterior sacral foramina. It is continuous above with the lumbar portion of the trunk, and below it anastomoses freely in front of the coccyx with the trunk of the other side to form a plexus in the terminus of which is the **coccygeal ganglion** (*ganglion coccygeum impar*) (fig. 787). Like the cervical and lower lumbar portions of the sympathetic trunk, the sacral part receives no white rami communicantes from the spinal nerves.

The sacral **ganglia** are small in size, and usually four in number. The variation both in size and number is more marked in this portion of the trunk than in the two parts above.

Branches.—The branches of the sacral ganglia include:—

(1) Grey rami communicantes to the sacral nerves.

(2) Branches to the front of the sacrum which anastomose with their fellows of the opposite side (commissural branches).

(3) Branches which enter into the formation of the plexus on the middle sacral artery.

(4) Branches which join the pelvic plexuses.

(5) Branches given off by the ganglion coccygeum impar to the coccyx and its ligaments and to the *glomus coccygeum* (coccygeal gland).

Construction of the lumbar and sacral portions of the gangliated trunk.—The ganglia of both these portions of the trunk are very variable in shape, size, position, and number. There are usually four ganglia belonging to each portion, but sometimes as many as eight may be distinguished in the lumbar and at other times there may be as many as six in the sacral portion. In the majority of cases, especially in the sacral region, these masses of cells are so fused that their number is less than the number of the spinal nerves with which they are associated. As noted above, only the first two or three lumbar spinal nerves send white rami which enter these ganglia directly as such. However, visceral efferent fibres descend this entire stretch of the trunk, through both the lumbar and sacral portions, from the white rami of the lower thoracic and the upper lumbar nerves above. These fibres either terminate in the various ganglia or pass uninterrupted to the more distant sympathetic cell-bodies which are concerned in impulses that are vaso-motor to the genital organs, motor for the uterus, the vas deferens, and the muscular coats (circular coat especially) of the bladder. Also, some of them convey secretory, pilomotor, and vaso-motor impulses for the glands, skin, and vessels of the lower extremity in addition to the similar impulses conveyed in the peripheral branches from the lower part of the thoracic portion of the sympathetic trunk. The motor impulses for the uterus or vas deferens and for the bladder pass, in most part probably, by way of the peripheral branches from the lumbar portion of the cord, through the aortic plexus to the inferior mesenteric ganglion; others, the vaso-motor impulses to the genital organs especially, pass by way of the sacral ganglia and the peripheral branches from them to the hypogastric or pelvic plexus and the appropriate subplexuses of this region. Of the vaso-motor fibres for the penis, some of the constrictor fibres pass down the sacral portion of the sympathetic trunk and terminate about the cells of the sacral ganglia, and these cells send out sympathetic fibres which join and course in the pudic nerve (n. pudendus).

All of both the lumbar and sacral spinal nerves receive grey rami from the gangliated trunk. These, just as those from the other portions of the trunk, consist of—(1) vaso-motor fibres to vessels of the meninges and the vertebral canal; (2) sympathetic fibres which join the divisions of the spinal nerves and course in them to their distribution, and (3) afferent sympathetic fibres terminating in the spinal ganglia.

In addition to the visceral efferent fibres, the branches of the lumbo-sacral portion of the sympathetic trunk carry cerebro-spinal fibres of general sensibility—sensory fibres arising in the spinal ganglia of this and the lower thoracic region.

There are no white rami proper passing from the sacral spinal nerves to course or terminate in the sympathetic trunk. Visceral efferent fibres are given off by these nerves in abundance, but, instead of entering the trunk and its ganglia, they form bundles which pass over the trunk and directly into its peripheral branches and to the more distant ganglia. The bundles passing from the second, third, and fourth sacral nerves are large and especially definite. While homologous to white rami, such bundles are better known as the *visceral branches* of the sacral nerves or the **plevic splanchnics.** They contain some spinal sensory fibres, but consist for the most part of visceral efferent, conveying impulses, vaso-motor (vaso-dilator, chiefly) to the genital organs, both motor and inhibitory for the rectum, uterus, and bladder (longitudinal coat especially), and secretory for the prostate gland. These fibres contribute to the hypogastric plexus and are interrupted in the small ganglia of its sub-plexuses, named according to the various urino-genital organs concerned.

THE GREAT PREVERTEBRAL PLEXUSES

The great prevertebral plexuses, in the body cavities, are three in number—the cardiac, the cœliac (solar or epigastric), and the hypogastric or pelvic. The cardiac plexus lies behind and below the arch of the aorta, and the cœliac and hypogastric plexuses are situated in front of the lumbar vertebræ. Each plexus receives not only sympathetic fibres which have passed from or through the ganglia of the sympathetic trunks of either side, but also both afferent and efferent cranio-spinal nerve-fibres derived directly from the cranio-spinal nerves. In addition the cardiac and cœliac plexuses receive both efferent visceral and cranio-spinal sensory or afferent visceral fibres from both vagus nerves. It should be clearly understood that the branches which run from the sympathetic gangliated trunks to the prevertebral plexuses contain medullated fibres which are passing, like the fibres from the sacral nerves, directly from the spinal cord to terminate about the cells of the plexuses.

1. The Cardiac Plexus

The cardiac plexus is formed by the cardiac branches from both vagus nerves and from both sympathetic trunks. It lies beneath and dorsal to the arch of the aorta, in front of the bifurcation of the trachea, and extends a short distance upward on the sides of the trachea. It is composed of a superficial and a deep part (fig. 789).

The **superficial part of the cardiac plexus** is much smaller than the deep part, and lies beneath the arch of the aorta in front of the right pulmonary artery. It is formed chiefly by the cardiac branches of the left vagus and by the left superior cardiac nerve, but sometimes receives filaments from the deep cardiac plexus. The **cardiac ganglion (ganglion of Wrisberg,)** usually found connected with this plexus, lies on the right side of the ligamentum arteriosum.

Branches.—From this plexus some branches pass to the left half of the deep cardiac plexus, and others accompany the left pulmonary artery to the *left anterior pulmonary plexus.* It also sends branches to the *right anterior coronary plexus.*

The **deep portion of the cardiac plexus** lies dorsal to the arch of the aorta at the sides of the lower part of the trachea and in front of its bifurcation. It consists of two lateral parts, more or less distinct, connected by numerous branches, which pass around the lower part of the trachea. It is formed by the superior, middle, and inferior cervical cardiac branches from the right sympathetic trunk, the middle and inferior cervical cardiac branches from the left trunk, and all the cervical and thoracic cardiac branches of the vagus except the superior cervical cardiac branch of the left vagus. It also receives branches from the superficial cardiac plexus.

The *left part of the deep cardiac plexus* gives branches to the left atrium (auricle) of the heart, to the left anterior pulmonary plexus, to the left coronary plexus, and sometimes to the superficial part of the cardiac plexus.

The *right part of the deep cardiac plexus* gives branches to the right atrium, to the right anterior pulmonary plexus, and to the right and the left coronary plexuses (fig. 789). The branches to the left coronary plexus pass behind the pulmonary artery. Some of those to the right coronary plexus pass anterior and some posterior to the right pulmonary artery.

The **coronary plexuses** are formed by branches given off by the cardiac plexus. They accompany the coronary arteries and are right and left.

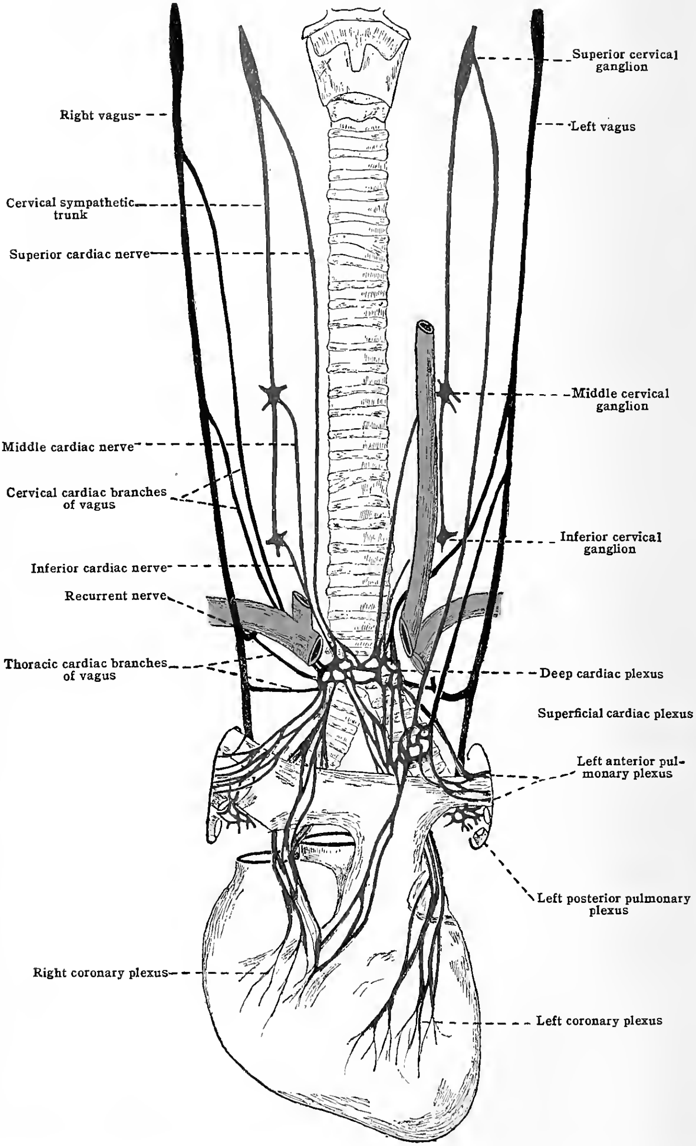
The *right* (*anterior*) *coronary plexus* receives filaments from the superficial part of the cardiac plexus, but is formed chiefly by filaments from the right portion of the deep cardiac plexus (fig. 789). Its distribution to the heart follows that of the right coronary artery.

The *left* (*posterior*) *coronary plexus* is larger than the right plexus, and is formed for the most part by filaments from the left portion of the deep cardiac plexus, but it receives some filaments from the right portion of the deep cardiac plexus (fig. 789). Its distribution to the heart follows that of the left coronary artery.

The cardiac plexus and the network of nervous structures in the walls of the atria are the remains of the primitive plexuses found in the embryo, which are called the *bulbar*, the *intermediate,* and the *atrial* plexuses, terms which sufficiently indicate their relative positions. The bulbar plexus gives off the coronary nerves and is transformed into the superficial part of the deep cardiac plexus; the remainder of the deep cardiac plexus is formed by the intermediate plexus, and the atrial plexus becomes the network of the atrium.

The fibres which pass to the cardiac plexus are medullated and non-medullated; the former

FIG. 789. CARDIAC, PULMONARY, AND CORONARY PLEXUSES. (Schematic.) (Modified from Cunningham.)



are the so-called inhibitory, the latter motor. The inhibitory impulses leave the central nervous system by the spinal accessory and vagus nerves. The motor fibres leave the spinal cord by the ventral roots and white rami communicantes of the thoracic nerves and terminate about the cells of the intervening sympathetic ganglia. From the cells of these ganglia arise the non-medullated (grey) fibres of the plexus. These fibres terminate directly upon the fibres of cardiac muscle or about the cells of the minute intrinsic cardiac ganglia which in their turn give axones to the muscle.

2. The Pulmonary Plexuses

The pulmonary plexuses are a continuation of the cardiac plexuses. The two are so intimately joined that it is difficult to distinguish them as separate plexuses. The pulmonary are formed by fibres from both the vagus and sympathetic nerves. The anterior and posterior pulmonary branches of the vagus unite, dorsal to the bifurcation of the trachea, with fibres from the second, third and fourth ganglia of the thoracic portion of the sympathetic trunk to form the anterior and posterior pulmonary plexuses that lie ventral and dorsal to the bifurcation of the trachea. Here the pulmonary plexuses of both sides connect with each other freely. Leaving the trachea, the plexuses pass into the lungs along the pulmonary arteries (figs. 744, 789). The parts of the plexus of each side are named according to their position anterior or posterior to the right and left pulmonary arteries; thus, there is a **right anterior** and a **right posterior, a left anterior** and a **left posterior pulmonary plexus.**

3. The Cœliac Plexus

The cœliac (solar or epigastric) plexus is the largest of the prevertebral plexuses. It is unpaired, and is continuous above with the aortic plexus of the thorax and below with the abdominal aortic and superior mesenteric plexuses. It lies in the epigastric region of the abdomen behind the bursa omentalis (lesser sac of the peritoneum) and the pancreas, upon the crura of the diaphragm and over the abdominal aorta, and around the origin of the cœliac and the superior mesenteric arteries. It occupies the interval between the suprarenal bodies and extends downward as far as the renal arteries. It is formed by the great and the lesser splanchnic nerves of both sides, by cœliac branches of the right vagus, and by filaments from the upper lumbar ganglia of the sympathetic trunk. It sometimes receives cœliac branches from the left vagus. It contains two large ganglia, the right and left cœliac (semilunar) ganglia (fig. 790).

The **cœliac (semilunar) ganglia** are two large, flat, irregularly shaped masses, separable into a varying number of ganglia. These two masses, or rather the smaller ganglia which compose them, are associated by a varying number of communicating branches. Each mass, right and left, lies upon the corresponding crus of the diaphragm, at the medial border of the corresponding suprarenal body, being sometimes overlapped by this body. The right mass lies behind the inferior vena cava. Each cœliac ganglion receives at its upper border the greater splanchnic nerve, and, near its lower border, lying over the origin of the renal artery, is a more or less detached part, known as the **aortico-renal ganglion.** This ganglion receives the lesser splanchnic nerve and may seemingly give origin to the greater part of the renal plexus. Another part of the cœliac ganglion, often found dorsal to the origin of the superior mesenteric artery, is known as the **superior mesenteric ganglion** (fig. 790).

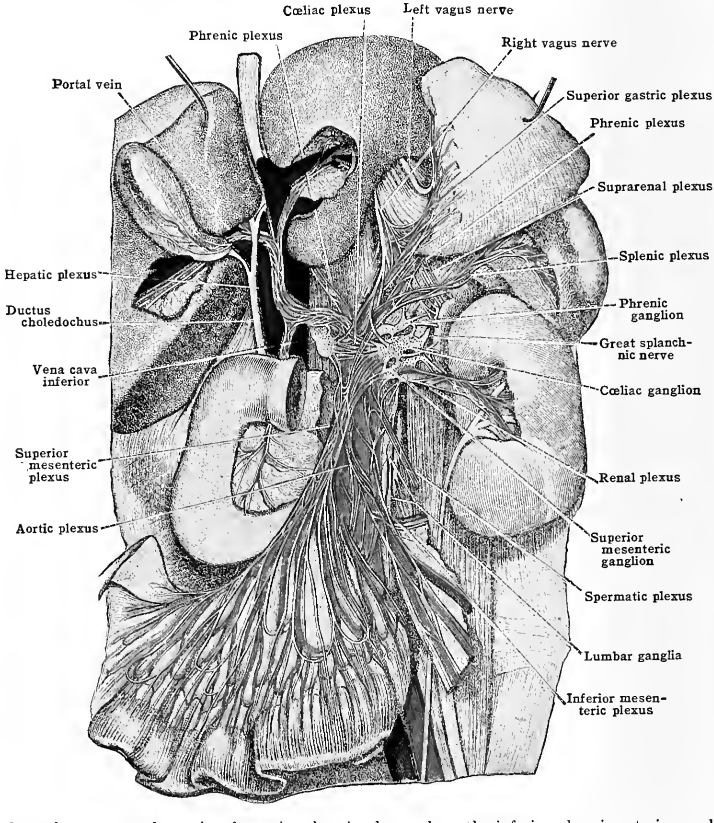
From the cœliac plexus and its ganglia subordinate plexuses are continued upon the aorta and its branches. These comprise both paired and unpaired plexuses. The paired plexuses are the phrenic, suprarenal and renal, the spermatic in the male, and, in the female, the ovarian plexuses. The unpaired plexuses are the aortic, hepatic, splenic, superior gastric, inferior gastric, superior mesenteric, and inferior mesenteric.

That part of the cœliac plexus surrounding the cœliac artery was formerly described as the *cœliac plexus*. It is better considered as an unnamed part of the larger cœliac (solar) plexus. This part of the plexus receives fibres from both vagus nerves, and gives filaments that form plexuses around the branches of the cœliac artery and their ramifications.

The paired subordinate plexuses of the cœliac.—(1) The **phrenic (diaphragmatic) plexuses** consist of fibres from the upper part of the cœliac ganglia, which follow the inferior phrenic arteries and their branches on the under surface of the diaphragm (fig. 790). Filaments are given off by the roots of the plexuses to the suprarenal bodies, and others unite with the terminal branches of the phrenic nerves. The point of junction with the right phrenic nerve is marked by the **phrenic ganglion,** from which branches are distributed to the inferior vena cava, to the right suprarenal body, and to the hepatic plexus.

(2) The **suprarenal plexuses** are comparatively large plexuses, formed mainly by branches from the cœliac (semilunar) ganglia. However, fibres come to them from the cœliac plexus

Fig. 790.—Abdominal Plexuses of the Sympathetic. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



along the suprarenal arteries, from the phrenic plexus along the inferior phrenic arteries, and from the renal plexus along the inferior suprarenal arteries. They are distributed to the substance of the suprarenal bodies. Cell-bodies of sympathetic neurones are enclosed within the suprarenal bodies forming intrinsic ganglia. The medulla of the suprarenal is of ectodermal origin and considered as derived from undeveloped components of the sympathetic nervous system.

(3) The **renal plexuses** receive fibres from the lower part of the cœliac ganglia and from the cœliac and aortic plexuses. They also receive filaments from the least splanchnic nerves, when these nerves are present, and sometimes filaments from the small splanchnic nerves and from the first lumbar ganglion of the sympathetic trunk. These plexuses pass along the renal arteries into the substance of the kidneys. Most of the fibres of each renal plexus are grey fibres, and as they pass to the kidneys small *renal ganglia* are present upon them. Both renal plexuses give branches to the corresponding spermatic plexuses and to the ureter, and the right renal plexus gives filaments also to the inferior vena cava.

(4a) The **spermatic plexuses** (fig. 790) are formed by fibres from the renal and aortic plexuses. They accompany the spermatic arteries and are joined at the abdominal inguinal (internal abdominal) ring by fibres that have passed along the vas deferens from the pelvic plexuses. Their terminal filaments are distributed to the testis and the epididymis.

(4b) The **ovarian plexuses** are formed in the female like the spermatic plexuses in the male. They accompany the ovarian arteries and, in the broad ligament, receive fibres from the utero-vaginal plexus. They supply the ovaries, the broad ligaments, and the Fallopian tubes, and send some fibres to the fundus of the uterus, where they become continuous with the utero-vaginal plexus.

The unpaired subordinate plexuses:—(1) The **abdominal aortic plexus** is formed by two strands of fibres which descend along the sides of the aorta and communicate with each other across its ventral aspect. It is connected above with the renal plexuses, and it receives peripheral branches from some of the lumbar ganglia of the sympathetic trunk on each side. It often contains a number of ganglia, which are situated at the points where the peripheral branches join the plexus, and it terminates below, chiefly by anastomoses with the hypogastric plexus (figs. 790 and 791). Besides giving filaments to the inferior vena cava, it also gives fibres that form plexuses along each of the branches of the aorta. The fibres that pass from the lower end of the aortic plexus upon the common iliac artery form the **iliac plexus,** which is continued along the femoral artery as the **femoral plexus,** and still further along the popliteal artery as the **popliteal plexus.**

(2) The **superior gastric (coronary) plexus,** receiving filaments from the cœliac plexus, accompanies the left gastric (coronary) artery along the lesser curvature of the stomach. Its filaments anastomose with filaments of the vagus nerves and with the plexus that accompanies the right gastric (pyloric) artery (fig. 790), and it gives fibres to the walls of the stomach which terminate within the walls, about the cell bodies of the delicate gangliated plexus myentericus and plexus submucosus (plexuses of Auerbach and Meissner). The axones of these supply the smooth muscle of the stomach walls and its vessels.

(3) The **inferior gastric plexus** receives from the splenic plexus filaments that accompany the left gastro-epiploic artery. It gives filaments to the walls of the stomach, which terminate as in the superior gastric plexus, and it receives filaments from the vagus nerves and from the plexus that accompanies the right gastro-epiploic artery.

(4) The **hepatic plexus** receives filaments from the cœliac plexus and from the left vagus. It accompanies the hepatic artery and gives fibres that form plexuses on the branches of the artery and on their ramifications within the liver and gives secretory fibres to the liver cells. It also gives filaments to the portal vein (fig. 790).

The **splenic** or **lienal plexus** is formed by filaments from the cœliac plexus, the left cœliac (semilunar) ganglion, and from the right vagus. It accompanies the splenic artery and gives filaments which form plexuses on the branches of this artery, and which pass with the branches to supply fibres to the stomach and the pancreas (fig. 790).

(5) The **superior mesenteric plexus** is formed chiefly by filaments from the lower part of the cœliac plexus, but it also receives fibres from the right vagus and fibres direct from the cœliac (semilunar) ganglia. At the origin of this plexus, dorsal to the superior mesenteric artery, lies the *superior mesenteric ganglion* (fig. 790). The filaments of the plexus, which are white and firm, accompany the superior mesenteric artery and, following its branches and their ramifications, are distributed to the walls of the small intestine, the cæcum, and the ascending and transverse colon. From the *secondary plexuses* that accompany the branches of the artery fibres pass to form still other plexuses that lie near the wall of the intestine, between the branches of the artery and between the layers of the mesentery. Filaments pass with the branches of the arteries and from plexuses between them into the intestinal wall, and there form between the longitudinal and circular muscle layers of the intestine the fine gangliated **plexus myentericus** (plexus of Auerbach), and filaments from this plexus form in the submucosa the delicate **plexus submucosus** or plexus of Meissner. From these latter plexuses fibres arise which terminate upon the gland cells and smooth muscle fibres of the intestinal wall and its vessels. The white appearance of the filaments of the superior mesenteric plexus is due to the large number of cranio-spinal sensory and visceral motor fibres (vagus especially) in it.

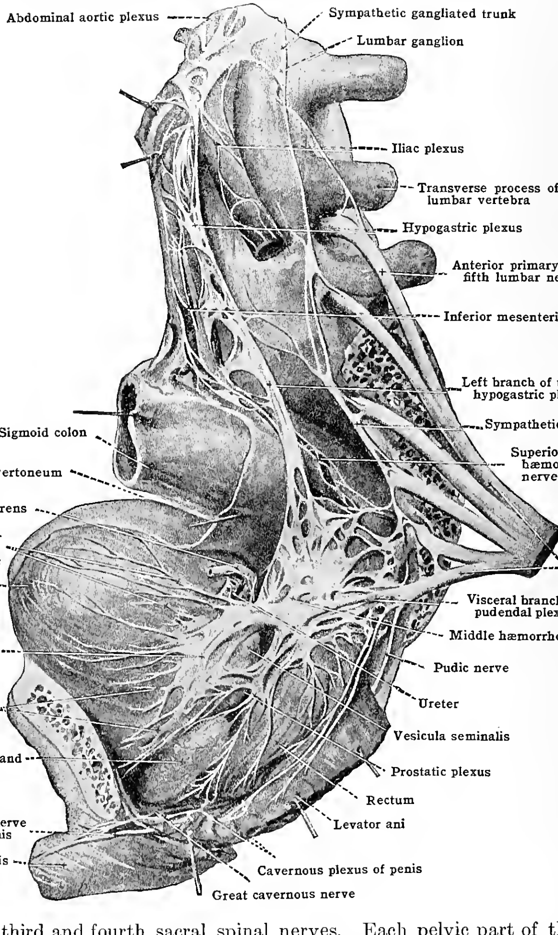
(6) The **inferior mesenteric plexus** is derived chiefly from the left side of the aortic plexus. It descends upon the inferior mesenteric artery and gives off filaments which accompany the branches of the artery and are distributed to the descending colon and to the ilio-pelvic colon (figs. 790 and 791). The filaments which accompany the left colic branch of the inferior mesenteric artery anastomose with the filaments of the superior mesenteric plexus which accompany the middle colic artery. The filaments which accompany the superior hæmorrhoidal artery form the **superior hæmorrhoidal plexus.** This plexus gives off the *superior hæmorrhoidal nerves* (fig. 791) which supply the upper part of the rectum and anastomose with the *middle hæmorrhoidal plexus.*

4. The Hypogastric Plexus

The hypogastric plexus lies partly in the abdominal cavity and partly in the pelvic cavity. It is formed chiefly by filaments continued downward from the aortic plexus, and by the pelvic splanchnics and peripheral branches from the lumbo-sacral nerves and sympathetic trunk (fig. 784). The *abdominal part* of this plexus consists of plexiform bundles of fibres descending between the common iliac arteries and interlacing in front of the fifth lumbar vertebra to form a broad, flattened, plexiform mass. In its extent it receives branches from the lumbar ganglia of the sympathetic trunk. This plexiform mass then divides into two parts, right and left, which descend into the pelvic cavity and which, by English authors, are frequently designated as the *pelvic plexuses*.

The *pelvic parts* of the hypogastric plexus (pelvic plexuses) lie at the sides of the rectum in the male, and at the sides of the rectum and the vagina in the female. They receive peripheral branches from the sacral ganglia of the sympathetic trunk and visceral efferent fibres by way of the *pelvic splanchnics* from the second and

Fig. 791.—The Hypogastric and Sub-plexuses of the Pelvic Cavity. (After Spalteholz.)



third or third and fourth sacral spinal nerves. Each pelvic part of the plexus accompanies the corresponding hypogastric (internal iliac) artery, and gives off secondary plexuses that continue on the branches of the artery to the pelvic viscera. Of these secondary plexuses, the middle hæmorrhoidal and the vesical plexus are common to both sexes and are paired.

The **middle hæmorrhoidal plexus** passes on each side along the middle hæmorrhoidal artery to the rectum, where it receives the superior hæmorrhoidal nerves and sends filaments into the wall of the rectum (fig. 791).

The **vesical plexus** receives some branches from the pelvic parts of the hypogastric plexus, but is largely reinforced by way of the pelvic splanchnics, from the third and fourth sacral nerves. Each part passes along the corresponding vesical arteries to the bladder, and gives off two sets of branches, namely, the *superior vesical nerves* (fig. 791), which supply the upper part of the bladder-wall and send some branches to the ureter, and the *inferior vesical nerves*, which supply the lower part of the bladder and, in the male, give secondary **deferential plexuses** to the vas deferens. These plexuses surround the vasa deferentia and the vesiculæ seminales and anastomose with the spermatic plexuses.

The **prostatic plexus**, found only in the male, is formed in two parts by nerves of considerable size, and lies chiefly on the sides of the prostate gland between it and the levator ani (fig. 791). Each of these parts supplies the gland and the prostatic part of the urethra, and sends offsets to the neck of the bladder and the vesiculæ seminales. This plexus is continued forward on either side to form the **cavernous plexus of the penis** (fig. 791), which anastomoses with branches of the dorsal nerve of the penis, gives off branches to the membranous part of the urethra, and also gives origin to two sets of nerves, namely, the large and the small cavernous nerves of the penis.

The **large cavernous nerve**, one on each side, runs forward to the middle of the dorsum of the penis, where it anastomoses with the dorsal nerve of the penis on the corresponding side, and ends in twigs which are distributed chiefly to the walls of the sinuses of the corpus cavernosum penis, but some of the terminal filaments supply the corpus cavernosum urethræ (corpus spongiosum) (fig. 791).

The **small cavernous** nerves are small filaments which pierce the uro-genital trigone (triangular ligament) and the compressor urethræ, and enter the posterior part of the corpus cavernosum.

The **utero-vaginal plexus**, found in the female, is formed in its *upper part* on each side largely by fibres derived from the pelvic part of the hypogastric plexus, but it receives some fibres from the pelvic splanchnics of the third and fourth sacral nerves. The nerves from this part of the plexus accompany the uterine arteries as they pass between the layers of the broad ligament. Some accompany each uterine artery and its branches to their termination, but a considerable number of fibres leave the artery and pass into the body of the uterus to supply its lower part and cervix. Between the layers of the broad ligament this plexus anastomoses with the ovarian plexus and sends some filaments to the uterine tube (Fallopian tube). The *lower part* of the plexus utero-vaginalis receives some fibres on each side from the pelvic part of the hypogastric plexus, but it is formed chiefly by efferent visceral fibres from the second, third, and fourth sacral nerves. These fibres terminate in contact with intrinsic cell-bodies whose axones supply the wall and mucous membrane of the vagina and urethra. From the plexus on the anterior surface of the vagina fibres pass to form the **cavernous plexus of the clitoris**, which gives off the great and lesser **cavernous nerves of the clitoris** for the supply of the clitoris. The utero-vaginal plexus of the female corresponds to the prostatic plexus of the male.

SECTION VIII

SPECIAL SENSE ORGANS

REVISED FOR THE FIFTH EDITION

BY DAVID WATERSTON, M.A.,M.D., F.R.C.S.E., KING'S COLLEGE, LONDON

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF LONDON

GENERAL CONSIDERATIONS

THE term "special sense organs" indicates those structures situated on or near the surface of the body which receive the impressions of sound, light taste and smell, and transmit them to the brain in the form of nerve impulses.

The essential difference between what is termed general sensibility and the special senses lies in the fact that the organs of special sense are each sensitive to a specific stimulus which does not affect the general sensory apparatus of the body surface to an appreciable degree.

Thus, the waves of light or of sound, flavoured substances which have a taste, and the minute particles which stimulate the sensory organ for smell—all these varied stimuli create no impression when they come into contact with the sensitive general surface of the body.

The vibration of sound waves present in an organ pipe may indeed be felt by the hand, but the sensation is that of vibration and not of sound.

This difference in function between the ordinary and the special senses as well as the difference between the individual organs of special sense, is associated with a difference in structure; for each special sense organ has a characteristic receptive mechanism of cells highly specialised in form and structure, which receive the stimuli coming from without, and transmit them to the brain in the form of a nerve-current. These cells may be derived by the specialisation of certain cells coming directly from the surface of the body, or they may be cells derived from the central nervous system—as in the case of the eye. In this case, the cells are placed in close relation to the terminals of a special cranial nerve.

Many of the sense organs, and especially the eye and ear, are highly complex in structure. The complexity is due largely to the elaborate mechanical arrangement for receiving the external stimulus, and for conveying it to, or focussing it upon, the sensory cells proper.

It must always be borne in mind that sensation itself is a function of the brain—it is the response in consciousness to the afferent impressions transmitted to the brain by the sensory nerves. Further, the *quality* of the sensation does not arise in the sense organ, but in the brain itself. Thus, stimulation of the trunk of the optic nerve by mechanical means produces sensations of light, apart from stimulation of the retina.

In the following account, the organs of smell, taste, vision and hearing will be successively considered.

I. THE OLFACTORY ORGAN

The olfactory apparatus [organon olfactus] in man does not reach the high development which is found in many of the lower animals. In them, not only is the sensory apparatus found distributed over a large area of the nasal mucous membrane, but the central connections of the olfactory nerves make up a considerable portion of the brain, including all those structures known under the name of rhinencephalon. In man, sensibility to smell is localised to a comparatively limited area in the upper part of the nasal cavity, known as the *olfactory area.*

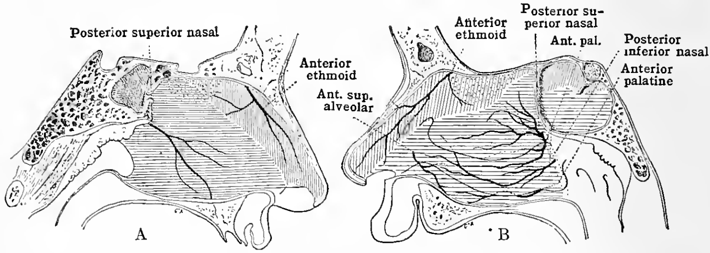
The structure of the nose in all its parts has been fully dealt with in the section on the RESPIRATORY SYSTEM—and hence it is not necessary to describe the whole nasal cavity.

The *olfactory area* of the nose includes the uppermost part of the nasal fossæ on the lateral wall above the superior concha, and a slightly larger area of the septum.

Fig. 792 shows the size of this area, and it will be noticed that the area on the lateral wall of the nose does not coincide with the area of the superior concha, but is rather smaller. It should be added that the olfactory nerves can be traced to a somewhat larger area of the mucous membrane, to the middle concha; it is, therefore, possible that the area indicated is too small.

The *mucous membrane* in the olfactory area has special characters, both naked eye and microscopic, which distinguish it from the rest of the nasal mucous

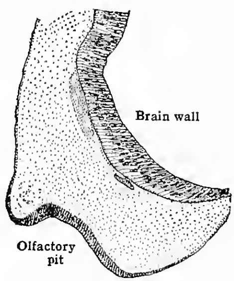
FIG. 792.—DIAGRAM OF THE DISTRIBUTION OF THE NERVES IN THE NASAL CAVITY. (Poirier and Charpy.) The olfactory area is represented by dots. A, septum. B, lateral wall.



membrane. It is usually of a yellowish colour, and is soft and pulpy in consistence It is covered by a columnar ciliated epithelium and contains numerous glands (glands of Bowman).

The olfactory apparatus within it consists of the **olfactory cells**. These cells are elongated spindle-shaped structures, lying between the deeper parts of the investing columnar cells. From each a slender process passes to the surface of the mucosa, and terminates in a group of short hair-like processes, the *olfactory hairs* (v. Bumm), while from the deep portion of the cell a long slender process passes deeply into the mucosa. These processes resemble nerve filaments, with no medullary sheath, and they pass in the olfactory nerves to the *olfactory bulb*, in which they terminate in arborisation around the dendritic enlargements of the mitral cells of the olfactory bulb (see fig. 795; also Olfactory Nerve, p. 929).

FIG. 793.—SECTION SHOWING THE DEVELOPMENT OF THE OLFACTORY PIT.



The connections of the olfactory bundle and tract with the brain are fully dealt with in the section on the NERVOUS SYSTEM.

The **development of the olfactory organ** is connected with the development of the nose, which represents at first only the olfactory portion. About the third week, a localised thickening of the surface epithelium occurs on the antero-ventral aspect of the head in the region of the fore-brain, forming on each side an *olfactory plate*. These plates become depressed from the surface by the growth of the margins, giving rise to the *olfactory pits*. The further changes are associated with the formation of the face and nose (see MORPHOGENESIS). The cells of the surface epithelium on the olfactory pits in part form olfactory cells, and send processes inward which pass to the olfactory lobe of the brain, and form the olfactory nerve.

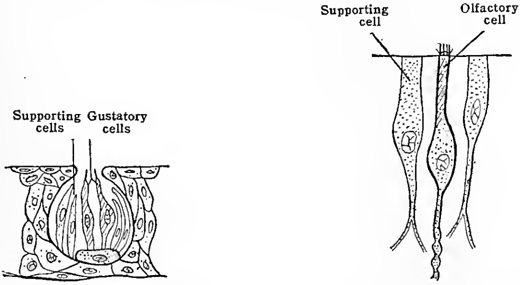
The organ of Jacobson is a small rudimentary structure in man. It is represented by a minute canal, 2 to 9 mm. long, placed on each side in the lower portion of the nasal septum, opening on the surface slightly above the orifice of the naso-palatine canal. Below it lies a small piece of cartilage, lying below the cartilage of the septum, and known as Jacobson's cartilage. The canal is lined by epithelium, but contains no olfactory cells. It is developed from a small portion of the olfactory plate which becomes separated from the area which gives rise to epithelium of the olfactory region.

II. ORGAN OF TASTE

The **taste organs** [organon gustus] consist of minute epithelial structures, the **taste buds** [calyculi gustatorii], situated mainly in the epithelial covering of the tongue and also in the epiglottis.

In the tongue, the taste buds are found mainly on the walls of the vallate papillæ (see p. 1106), but they are found to a slight extent scattered over the whole area of distribution of the glosso-pharyngeal nerve, on the surface of the foliate and fungiform papillæ, and on the plicæ fimbriatæ on the lower surface of the tongue.

FIGS. 794 AND 795.—DIAGRAMS ILLUSTRATING THE STRUCTURE OF THE TASTE BUDS AND THE OLFACTORY MUCOSA.



In the fœtus, the distribution is even wider, and they have been described as occurring on the soft palate, palatine arches, uvula, and in the mucous membrane covering the medial surfaces of the arytenoid cartilages. It is possible that such structures, though found in these regions in the fœtus, usually disappear in the adult.

Each **taste bud** is a hollow conical or oval structure, measuring .07–.08 mm. in length. At one end it opens by a small channel, termed the **pore canal,** which passes to the surface between adjacent epithelial cells. The surface opening is termed the *outer pore* and the opening at the taste bud the *inner taste pore.*

The taste bud consists of epithelial supporting, of gustatory and of basal cells, arranged as seen in figure 794. The **gustatory cells** are long slender fusiform cells. The free end of each passes to the inner taste pore, and terminates in stiff hair-like processes, which project toward the pore canal. The deep end of each is connected with a basal cell. Terminal branches of the glosso-pharyngeal nerve ramify around the gustatory cells, and convey to the brain the impulses generated by contact of the ends of these cells with sapid particles. The epithelial supporting cells line the taste buds, and also project into the interior between the olfactory cells.

Development.—The taste buds appear comparatively late in embryonic life—about the third month. They arise mainly from the entodermal portion of the tongue, by differentiation of the deeper cells of the epithelial covering over localised areas. Around these cells terminations of the glosso-pharyngeal nerve are found. These cells assume the characteristic shape and arrangement of the adult to form a taste bud. At first the opening of the bud lies upon the surface, but as the surrounding epithelial cells increase in size and thickness, the pore-canal is formed as a space between adjacent epithelial cells on the summit of the bud.

III. THE EYE

The sensory portion of the eye is the **retina,** a cup-shaped membrane, which lines the posterior half of the eyeball. It is formed of layers of nerve cells, from which processes pass to the brain in the **optic nerve.** The **eyeball** is a hollow spherical structure, whose wall is formed externally by a fibrous tunic including the **sclera** (the white of the eye), and the **cornea** (the transparent area in the anterior aspect of the eyeball). Internal to the tunic formed by these membranes is a pigmented vascular membrane, the **chorioidal membrane,** of which the anterior part forms the **iris,** or the coloured part of the eye.

Within these tunics is formed a cavity, in which lies the **crystalline lens** of the eye. In front and behind the lens are two chambers; that in front of the lens contains the *aqueous humour* and that behind it the *vitreous.*

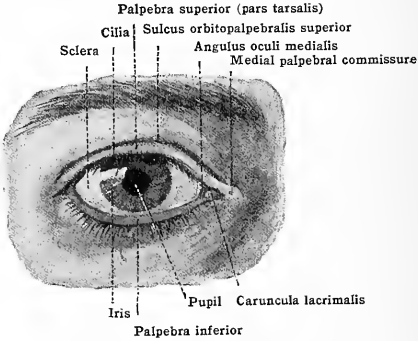
The study of the eye is best undertaken by examining the eye in the living, and subsequently by the dissection of specimens, and that order is followed in this account.

General Surface View

The two eyes are situated nearly in the line where the upper and middle thirds of the face meet; they lie right and left of the root of the nose, the most prominent part of the front of each globe being about 3 cm. ($1\frac{1}{4}$ in.) from the mid-line of the face. Each eye is overshadowed by the corresponding eyebrow, and is capable of being concealed by its eyelids, upper and lower.

The orbital margin may be traced all round with the finger. At the junction of the medial and intermediate thirds of the upper margin the supraorbital notch (incisura supraorbitalis) can usually be felt, and the supraorbital nerve passing through it can sometimes be made to roll from side to side under the finger. The medial margin is the most difficult to trace in this way, partly because it is more rounded off than the others, partly because it is bridged over by a firm band (**medial palpebral ligament**), passing medially from the medial angle of the eyelids; below this band, however, a sharp bony crest is felt, which lies anterior to the lacrimal sac. Note how the eye is protected by the rim of the orbit, above and below; if we lay a hard flat

Fig. 796.—View of the Eye with Eyelids Open.

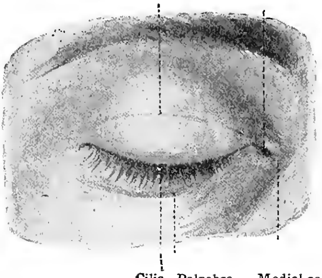


body over the orbital opening, it will rest upon the upper and lower bony prominences, and will not touch the surface of the globe. Medially, the eye is protected from injury mainly by the bridge of the nose; laterally it is most readily vulnerable, as here the orbital rim is comparatively low. With one finger placed over the closed upper lid, press the eyeball gently backward into the orbit, and observe the elastic resistance met with, due to the fact that the globe rests posteriorly on a pad of fat.

The space between the free edges of the upper and lower lids is known as the **palpebral aperture** [rima palpebrarum]: it is a mere slit when the lids are closed; but when they are open its shape is, roughly, that of an almond lying with its long axis horizontal, and about thirty millimetres in length.

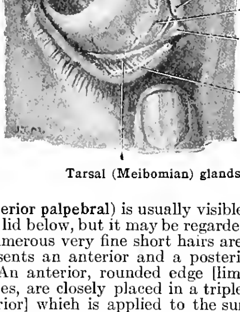
When the eyes are directed to an object straight in front of them, this aperture is about twelve millimetres wide, but its width varies with upward and downward movements of the eyeball, being greatest on looking strongly upward, diminishing gradually as the eye looks progressively lower. The angles formed by the meeting of the lids at each end of the palpebral aperture are named respectively the lateral and medial angles (or canthi) [angulus oculi lateralis, medialis], of which the lateral is sharp, while the medial is rounded off. On a closer inspection, it will be found that, for the last five millimetres or so before reaching the medial angle the edges of the lids run an almost parallel course, and are here devoid of lashes. Through the open palpebral aperture the front of the eyeball comes into view, extending quite to the lateral, but not reaching as far as the medial, angle; just within the latter we find a small reddish prominence, the **lacrimal caruncle** [caruncula lacrimalis]; and between this and the eyeball a fold of conjunctiva known as the **plica semilunaris.** While the eye is open, press one finger on the skin, a little beyond the lateral angle, and draw it firmly away from the middle line; observe that the upper **lid** then falls over the eyeball, and that the outline of a firm band already referred to (the medial palpebral ligament) becomes evident, passing between the medial angle and the nose. The falling of the lid is caused by our dragging upon a ligament (the lateral palpebral raphé) to which the lateral end of its tarsus is attached, and so putting the lid itself upon the stretch. If, while the eyeball is directed downward, we place one finger on the lateral end of the upper eyelid and draw it forcibly upward and laterally, we can usually cause the lower division of the lacrimal gland to present just above the lateral angle.

FIG. 797.—VIEW OF THE EYE WITH EYELIDS CLOSED.



The **upper eyelid** [palpebra superior] is much broader than the lower, extending upward as far as the eyebrow. The skin covering it is loosely attached to the subjacent tissues above, but more firmly below, nearer the free margin, where it overlies a firm fibrous tissue called the **tarsus superior.** When the eye is open, a fold is present at the upper border of this lower more tightly applied portion of skin, called the **superior palpebral fold,** and by it the lid is marked off into an upper or orbital, and a lower or tarsal, division. The presence of the tarsus can be readily appreciated on our pinching horizontally the entire thickness of the eyelid below the palpebral fold. The **lower eyelid** [palpebra inferior] is similarly divided anatomically into a tarsal and an orbital part, but the demarcation is sometimes unrecognisable on the surface,

FIG. 798.—VIEW OF MEDIAL REGION OF THE EYE, WITH THE EYELIDS WIDELY SEPARATED AND THE EYEBALL TURNED LATERALLY.



though a fold or groove (the **inferior palpebral**) is usually visible when the eye is widely opened. There is no precise limit of this lid below, but it may be regarded as extending to the level of the lower margin of the orbit. Numerous very fine short hairs are seen on the anterior surface of both eyelids. Each eyelid presents an anterior and a posterior surface, separated by a free margin with two edges:—(*a*) An anterior, rounded edge [limbus palpebralis anterior] along which the stiff cilia, or eyelashes, are closely placed in a triple row; and (*b*) a sharp posterior edge [limbus palpebralis posterior] which is applied to the surface of the globe (see fig. 813). The cilia of both eyelids have their points turned away from the palpebral aperture, so that the upper ones curve upward, and the lower downward; the cilia of the upper lid are the stronger, and those in the middle of each row are longer than those at each end. Between the two edges just described, the lid-margin has a smooth surface, on which is a single row of minute apertures, the openings of large modified sebaceous glands, the tarsal or **Meibomian glands.** It is by these glistening, well-lubricated surfaces that the opposite lids come into apposition when they are closed. The secretion of these glands is known as the *sebum palpebrale.* The sharp posterior edge of the lid-margin marks the situation of the transition of skin into mucous membrane. Near the medial end of the margin of the lids we find a prominence, the **lacrimal papilla,** on the summit of which is a small hole [**punctum lacrimale**], the opening of the lacrimal duct (ductus lacrimalis) for the passage of tears into the lacrimal sac. The lower punctum is rather larger than the upper, and is placed further from the medial angle of the eye.

If we now examine the posterior surface of the eyelids—e. g., of the lower—we observe that it is lined by a soft mucous membrane, the **palpebral conjunctiva** [tunica conjunctiva palpebrarum]. Over the tarsal part of the lid the conjunctiva is closely adherent, but beyond this it is freely movable along with the loose submucous tissue here present. On tracing it backward, we find that it covers the whole posterior surface of the lids, and is then continued *forward* over the front of the eyeball, forming the conjunctival tunic of the globe [tunica conjunctiva bulbi]. The bend it makes as it changes its direction here is called the **conjunctival fornix** [fornix conjunctivæ superior or inferior]. Numerous underlying blood-vessels are visible through the palpebral conjunctiva, and under cover of its tarsal part we can see a series of nearly straight, parallel, light yellow lines, arranged perpendicularly to the free margin of the lid—the tarsal glands. The conjunctiva over the medial and lateral fourths of each lid is not quite so smooth as elsewhere, and is normally of a deeper red colour; we shall find later that there are glands well developed in these positions.

When the eyelids are opened naturally, we see through the palpebral aperture the following: the greater part of the transparent cornea, and behind it the coloured iris with the pupil in its centre; white sclera to the medial and lateral sides of the cornea; the semilunar fold and lacrimal caruncle at the medial angle. The extent of the eyeball visible in this way varies according to its position. Thus, with the eyes looking straight forward, the lower margin of the upper lid is nearly opposite to the top of the cornea, or, more strictly, to a line midway between the top of the cornea and the upper border of the pupil, while the lower lid corresponds with the lower margin of the cornea. When the eyes are directed strongly upward, the upper lid is relatively on a slightly higher level, as it is simultaneously raised, but the lower lid now leaves a strip of sclera exposed below the cornea. On looking downward the upper lid covers the upper part of the cornea as low down as the level of the top of the pupil, while the lower lid is about midway between the pupil and the lower margin of the cornea.

If we draw the eyelids forcibly apart, we expose the whole cornea, and a zone of sclera about eight and a half millimetres in breadth above and below, and ten millimetres in breadth to the lateral and medial sides—altogether about one-third of the globe; all the eyeball thus exposed is covered by the **ocular conjunctiva** [tunica conjunctiva bulbi]. Over the sclera the conjunctiva is freely movable, and through it we see superficial blood-vessels that can be made to slip from side to side along with it (episcleral vessels). Occasionally other deeper vessels may also be seen which do not move with the conjunctiva, but are attached to the sclera (anterior ciliary arteries and veins). Near the corneal border the conjunctiva ceases to be freely movable, and it is closely adherent to the whole anterior surface of the cornea, giving the latter its characteristic bright, reflecting appearance; no blood-vessels are visible through it here in health. When the lids are shut, the space enclosed between their posterior surfaces and the front of the eyeball is thus everywhere lined by conjunctiva, and is known as the **conjunctival sac.**

Not unfrequently the tendinous insertions of some or all of the recti muscles into the sclera may be seen through the conjunctiva, each insertion appearing as a series of whitish parallel lines running toward, but terminating about seven millimetres from, the corresponding corneal border.

The **cornea** appears as a transparent dome, having a curvature greater than that of the sclera; the junction of the two unequally curved surfaces is marked by a shallow depression running around the cornea, known as the **scleral sulcus** [sulcus scleræ]. In outline the cornea is nearly circular, but its horizontal diameter is slightly greater than its vertical. Between it and the iris a space exists, whose depth we can estimate roughly by looking at the eye from one side; this space, or anterior chamber [camera oculi anterior] is occupied by a clear fluid, the aqueous humour. Almost the whole anterior surface of the iris is visible, its extreme periphery only being concealed by sclera.

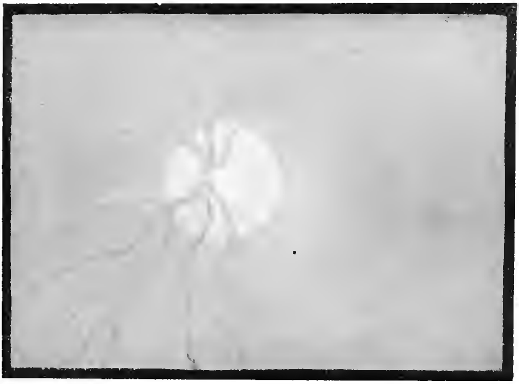
In colour the **iris** varies greatly in different individuals. Near its centre (really a little up and in) a round hole exists in the iris, the black *pupil* [pupilla], whose size varies considerably in different eyes, and in the same eye according to temporary conditions, such as exposure to light, etc.

On the surface of the iris we see a number of ridges [plicæ iridis] running more or less radially; adjoining ones occasionally unite and interlace to some extent, so as to leave large depressed meshes at intervals. These are the *crypts* of the iris. The radial ridges coming from the edge of the pupil, and those coming from the more peripheral part of the iris, meet in a zigzag elevated ridge concentric with the pupil, called the *corona iridis,* and by this ridge the iris is roughly marked off into two unequal zones—an outer, the **greater** [annulus iridis major] and an inner, the lesser [annulus iridis minor]. The border next the pupil [margo pupillaris] is edged with small, roundish, bead-like prominences of a dark brown colour, separated from one another by depressions, so that it presents a finely notched contour. Not infrequently, in a light-coloured iris, we may see the sphincter muscle through the anterior layers, in the form of a ring about one millimetre in breadth around the pupil. The annulus iridis major may be described as consisting of three parts:—(*a*) A comparatively smooth zone next the zigzag ridge; (*b*) a middle area, showing concentric but incompletely circular furrows; (*c*) a small peripheral darker part, presenting a sieve-like appearance. On the floor of the large depressed meshes, or *crypts*, parallel radial vessels can be traced, belonging to the iris-stroma. The zigzag line mentioned above corresponds to the position of the circulus arteriosus minor. Occasionally, especially in a light iris, superficial pigment spots of a rusty brown colour occur.

(In examining the living eye, the ophthalmoscope may now be used, so as to gain a view of the fundus, and to study the termination of the optic nerve, the distribution of the larger retinal vessels, etc.)

The general red reflex obtained from the fundus is due to the blood in a capillary network (**chorio-capillaris**) situated in the inner part of the chorioid. To the nasal side of the centre of the fundus is a paler area of a disc shape corresponding to the intraocular end of the optic nerve, and known as the **papilla of the optic nerve** [papilla n. optici]. This papilla (or 'optic disc') is nearly circular, but usually slightly oval vertically; it is of a light orange-pink colour, with a characteristic superficial translucency; its lateral third segment is paler than the rest as nerve-fibres and capillaries here are fewer in number. About its centre we often observe a well-marked whitish depression [excavatio papillæ n. optici], formed by the dispersion of the nerve-fibres as they spread out over the fundus; at the bottom of this depression a sieve-like appearance may be seen, due to the presence of the **lamina cribrosa scleræ**, which consists of a white fibrous tissue framework, with small, roundish, light-grey meshes in it, through which the nerve-fibre bundles pass. Also near the centre of the papilla, the retinal blood-vessels first come into view, the arteries narrower in size and lighter in colour than the veins; they divide dichotomously as they are distributed over the fundus. The retina proper is so transparent as to be ophthalmoscopically invisible, but its pigment-epithelium gives a very finely granular or darkly stippled appearance to the general red reflex. In the centre of the fundus, and therefore to the lateral side of the papilla, the ophthalmoscope often shows a shifting halo of light playing round a

FIG. 799.—THE NORMAL FUNDUS OF THE EYEBALL. (Parsons.)



horizontally oval, comparatively dark enclosed area; this latter corresponds to the **yellow spot** [macula lutea] region, and about its centre a small pale spot usually marks the position of the **fovea centralis.**

Two structures visible at the nasal end of the palpebral aperture have been previously mentioned, and should now be examined more narrowly. The **lacrimal caruncle** is an island of modified skin, and fine hairs can commonly be detected on its surface, and it contains sebaceous and sweat glands. Lateral to it and separated from it by a narrow groove, is the **semilunar fold of conjunctiva**; it rests on the eyeball, and is a rudiment of the third eyelid or nictitating membrane, present in birds and well represented in many other vertebrates.

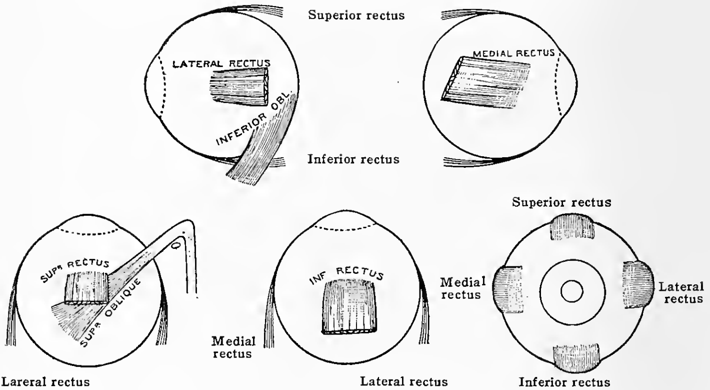
EXAMINATION OF THE EYEBALL

(In the following account, the structure of the eyeball is described as it would appear upon dissection.)

The **eyeball** [bulbus oculi] is almost spherical, but not perfectly so, mainly because its anterior, clear, or *corneal* segment has a greater curvature than the rest of the eye. Considering it as a globe, it has an **anterior pole** [polus anterior] and a **posterior pole** [polus posterior]; the former corresponding to the centre of the front of the cornea, the latter to the center of the posterior curvature. An imaginary straight line joining the two poles is called the **axis** of the eyeball. The **equator** of the eye is that part of its surface which lies midway between the two poles. The various **meridians** are circles which intersect the poles. The sagittal axis of the globe is the greatest (about 24.5 mm.), the vertical equatorial the least (about 23.5 mm.), and the transverse equatorial axis is intermediate in length (about 23.9), so that the eyeball is in reality an ellipsoid, flattened slightly from above downward. These figures refer to the adult male; in the female the eyeball is .5 mm. smaller in all axes. Again, if the globe is divided in its mid-sagittal plane, the nasal division will be found to be slightly smaller than the temporal. The optic nerve joins the globe three or four millimetres to the nasal side of the posterior pole.

The shape of the eye depends on, and is preserved by, the outermost tunic, formed conjointly by the **cornea** and **sclera,** the entire outer surfaces of which are now in view. The anterior or corneal part has already been examined. All around the cornea there remains a little adherent conjunctiva; elsewhere, the sclera is directly exposed, except for some loose connective tissue which adheres to it, especially around the optic nerve entrance. In front of the equator we see the tendinous insertions of the four recti muscles. Behind the equator are the insertions of the two oblique muscles—that of the superior oblique tendinous, and further forward; that of the inferior more fleshy, and placed between the optic nerve and the *lateral* rectus.

Fig. 800.—Diagrammatic View of the Insertions of the Ocular Muscles.



It is difficult to recognise the different recti muscles by their insertions if we do not know whether the eye examined is a right or a left one. To determine this we should hold the globe with the optic nerve toward us, and in the natural position with the superior oblique tendon uppermost. The inferior oblique tendon will now point to the side to which the eye belongs, and we can consequently determine the different recti muscles.

The medial [m. rectus medialis] rectus is inserted nearest (5.5 to 7 mm. from) the corneal border; the superior [m. rectus superior] rectus commonly, sometimes the lateral [m. rectus lateralis], is inserted furthest from it (7.7 to 8 mm.). All the recti tendons are broad and thin, but that of the medial is the broadest (8 to 10.3 mm.); those of the lateral and inferior the narrowest (6 to 9.2, or 9.8 mm., respectively). The greatest interval between two neighbouring tendons is that between the superior and medial recti (about 12 mm.); the least is between the superior and lateral (7 mm.). The form of the lines of insertion of the different tendons varies considerably, the inferior being almost straight, the superior and lateral convex forward, the medial further removed from the corneal border below than above.

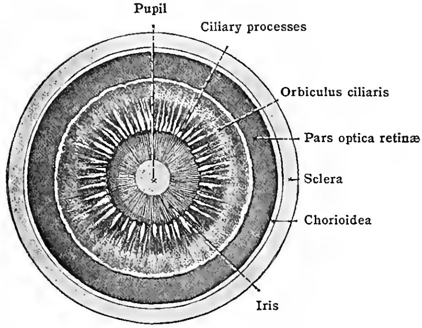
The insertions of the oblique muscles [mm. obliqui] are at more than double the average distance of the insertions of the recti from the corneal border. That of the superior oblique is found on the superior surface of the sclera, about sixteen millimetres from the corneal edge, in the form of a line 10.7 mm. long sloping from before backward and medially. The inferior oblique has a long fleshy insertion lying between the lateral rectus and the optic nerve entrance; the posterior end of the insertion, which is also the higher, is only about five to six millimetres from the optic nerve, and from this point it slopes forward, laterally, and slightly downward.

Several small nerves and two arteries may be seen running forward and ultimately perforating the sclera not far from the entrance of the optic nerve. The two arteries are the long posterior ciliary [aa. ciliares posteriores longi]; they both perforate the globe in the horizontal meridian, 3.5 mm. from the optic nerve, one on the lateral, the other on the medial, side. The short ciliary arteries [aa. ciliares posteriores breves] are too small to be seen in an ordinary examination. The nerves are the long and short ciliary [nn. ciliares longi, breves]. Nearer the equator large venous trunks emerge; they can be traced for some distance in front of their exit as dark lines, running antero-posteriorly internal to the sclera. The optic nerve is seen in section, surrounded loosely by a thick outer sheath; in the centre of the nerve-section a small red spot indicates the position of the central retinal blood-vessels [a. et v. centralis retinæ].

(The following structures appear in an eyeball divided into fore and hind halves by cutting through it in the equatorial plane.)

1. **Posterior hemisphere** seen from in front.—This is much the same view that the ophthalmoscope affords us. Unless the eye be very fresh, however, the **retina** will have lost its transparency, and will now present the appearance of a thin whitish membrane, detached in folds from the external coats, but still adherent at the optic papilla. The vitreous jelly lying within the retinal cup may be torn away. In the human eye the retina next the posterior pole is stained yellow **[macula lutea]**. On turning the retina over, a little pigment may be seen adhering to its outer surface here and there. Cut through the retina close to the optic disc all around and remove it: note how easily it is torn. We now see a dark brown surface, consisting of the **retinal pigment layer** [stratum pigmenti retinæ] adherent to the inner surface of the chorioid. Brush off the retinal pigment under water. The **chorioid** thus exposed can for the most part be fairly easily torn away from the thick sclera, as a lymph-space exists between them, but the attachment is firm around the optic nerve entrance, and also where the arteries and nerves join the chorioid after penetrating the sclera. The chorioid is darkly pigmented, of a brown colour, with markings on its surfaces corresponding to the distribution of its large veins. The inner

Fig. 801.—Anterior Hemisphere of Eyeball, Viewed from Behind.



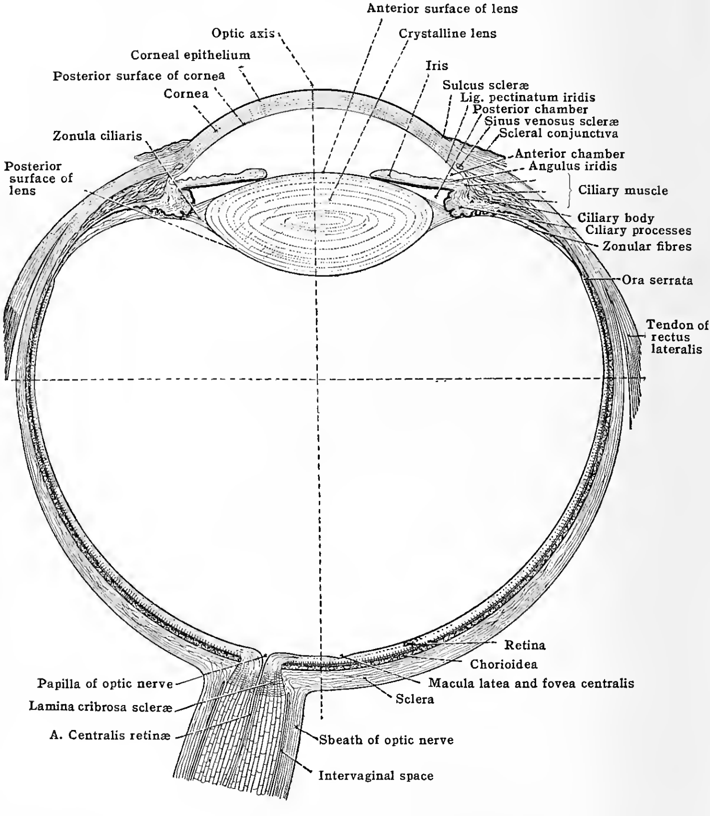
surface of the sclera is of a light brownish colour, mainly from the presence of a delicate pigmented layer, the **lamina suprachorioidea**, which adheres partly to it, partly to the chorioid, giving to their adjacent surfaces a flocculent appearance when examined under water.

2. **Anterior hemisphere** viewed from behind.—The round opening of the pupil is visible in the middle, in front of the large clear **crystalline lens**. The retina proper extends forward a little way from the line of section, and then ends abruptly in a wavy line called the **ora serrata**, beyond which it is only represented by a very thin membrane **[pars ciliaris retinæ]**. Outside the periphery of the lens are a number of **ciliary processes** arranged closely together in a circle concentric with the pupil, and each radially elongated; posteriorly they are continuous with n umerous fine folds, also radial, which soon get very indistinct as they pass backward, but reach almost to the ora serrata **[plicæ ciliares]**. Between the front of the ciliary processes and the edge of the pupil lies the **iris**. On removal of the retina the inner surface of all this region is seen to be darkly pigmented, but especially dark in front of the position of the ora serrata. Vitreous probably still adheres to the back of the lens, and by pulling upon it the lens can be removed along with its capsule and suspensory ligament; some pigment will now be found adhering to the front of the vitreous, torn from the ciliary processes, which are consequently now lighter in colour than before. The **lens-capsule** is transparent, and has a smooth glistening outer surface; through it a greyish, star-shaped figure may be observed on the anterior and posterior surfaces of the lens. The **suspensory ligament** is a transparent membrane attached to the capsule of the lens about its equator, and is best seen by floating the lens in water in a glass vessel placed on a dark ground. On opening the capsule we expose the lens itself, which is superficially soft and glutinous to the touch, but becomes firmer as we rub off its outer layers and approach its centre. Carefully tear the chorioid and iris from the sclerotic as far as possible; a firm adhesion exists just behind the corneal periphery. The outer surface of the chorioid thus exposed is found to be also rather darkly pigmented, but it shows a white ring corresponding to the adhesion just mentioned, and a pale area behind this ring indicates the position of the **ciliary muscle** [m. ciliaris]. On this surface numerous white nerve-cords are visible running

forward. Observe that the iris, the ciliary processes, etc., and the chorioid are all different parts of the same ocular tunic—mere local modifications of it. Similarly the sclera and cornea are seen to blend together to form one outer coat.

An eyeball should now be placed for half an hour in a freezing mixture of crushed ice and salt. It will thus become quite hard, and should at once be divided into two parts by cutting it antero-posteriorly through the centre of the cornea and the optic nerve. We thus gain another view of the relations of parts, the position of the lens between the aqueous and vitreous chambers, etc. On removing the lens, vitreous, and retina, and brushing off its pigment, the light markings corresponding to the chorioidal veins (**venæ vorticosæ**) should be noted, and their distribution studied. Usually four vortices or fountain-like markings are found in the whole chorioid,

Fig. 802.—Horizontal Section of the Eyeball. × 4.



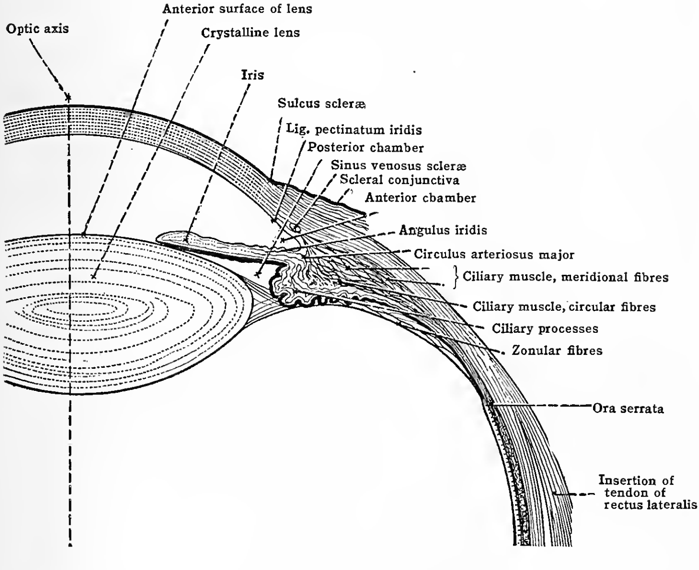
their points of junction situated at approximately equal distances from one another at about the line where the posterior and middle thirds of the globe meet. These sections should be kept for reference while following the further description of the ocular tunics.

The coats of the eyeball.—1. The **outer, fibrous coat of the eye** [tunica fibrosa oculi] is formed by the **sclera** and **cornea**, which pass into one another at the scleral sulcus. It consists throughout mainly of fine connective-tissue fibres, arranged in interlacing bundles, with small lymph-spaces at intervals between them. The naked-eye appearance of the two divisions of this fibrous coat is, however, quite different, the cornea being transparent, while the sclera is white and opaque.

The **sclera** encloses the posterior five-sixths or so of the eyeball. It is perforated by the entrance of the optic nerve, and the opening in the sclera, only partially bridged across by fibres from the inner layers, forms the **lamina cribrosa.**

The fibre-bundles composing the sclera are arranged more irregularly than in the cornea, and run mainly in two directions, viz., antero-posteriorly and circularly; the circular fibres are particularly well developed just behind the sulcus. It is thickest (about 1 mm.) posteriorly, where it is strengthened chiefly by the outer sheath of the optic nerve, and partly also by the tissue surrounding the ciliary vessels and nerves. It becomes gradually thinner as it passes forward, up to the line of insertion of the recti muscles, where it is .3 mm. thick. In front of that line it is again reinforced by their tendinous fibres becoming incorporated with it and its thickness increases to .6 mm. In children the sclera is often so thin as to allow the underlying chorioidal pigment to show through, its colour then appearing bluish white. In the aged, again, it is sometimes yellowish. It always contains a few pigment cells, but these are in the deep layer termed the *lamina fusca,* and only become visible externally where the sclera is pierced by vessels and nerves going to the chorioid. It is almost non-vascular, but quite at its anterior end a large **venous sinus** [sinus venosus scleræ; canalis Schlemmi (Lauthi)], (**canal of Schlemm**) runs in its deeper layers circularly around the cornea. Just in front of this sinus, at the corneal **limbus,** the sclera merges into the cornea, its inner layers changing first, and finally the outer ones.

FIG. 803.—PORTION OF FIG. 802, ENLARGED.



The **cornea** forms the anterior sixth of the eyeball. It is thickest at its periphery (1.1 mm.) and becomes gradually thinner toward its centre (0.8 mm.); the curvature of its posterior is consequently greater than that of its anterior surface, but even the latter is more curved than the surface of the sclera.

In the cornea proper, fibre-bundles are arranged so as to form a series of superposed lamellæ, each of which is connected here and there to the adjacent ones by fibres passing from one to the other, so that they can only be torn apart with difficulty. The corneal lymph-spaces communicate with one another by very fine canals, and thus not only is a thorough lymph-circulation provided for, but the protoplasm with which these spaces are partially occupied may be also regarded as continuous throughout. It contains no blood-vessels, with the exception of a rich plexus at its extreme periphery, on which its nutrition is ultimately dependent. The *sinus venosus of Schlemm* is an important channel for the return of blood and also of fluid which transudes into it from the anterior chamber. It consists of a network of venous spaces, formed of a principal vessel accompanied by several smaller ones, which unite with it and with one another in a plexiform manner. They commence indirectly with the spaces of the angle of the iris and they are in direct communication with the anterior ciliary veins.

The outer surface of the cornea is covered by an extension of the ocular conjunctiva, in the form of an epithelium several layers deep. The most external part of the true cornea appears homogeneous, even when highly magnified and constitutes the **anterior elastic lamina, Bowman's membrane,** though there is reason to believe that its structure only differs from that already described in the closeness of its fibrous texture; the two parts are certainly connected by fine fibres. Posteriorly, the cornea is lined by a firm, thin, glass-like layer (**posterior elastic lamina, membrane of Descemet**), distinct from the corneal tissue both anatomically and chemically. At the periphery this membrane breaks up into a number of fibres, which mainly arch over to join the base of the iris and form part of the **ligamentum pectinatum iridis.** The pectinate ligament is an open network of interlacing fibres, directly continuous with the circular and longitudinal bundles of sclera surrounding the venous sinus of Schlemm (Henderson). The interstices between these fibres constitute spaces (**spaces of Fontana**) [spatia anguli iridis (Fontanæ)] freely communicating with the aqueous chamber on the one hand, and indirectly with the venous sinus of the sclera on the other. The posterior elastic lamina is in turn lined by a single layer of flat cells, which are continuous peripherally with cells lining the spaces of the angle and the anterior surface of the iris which form the endothelium of the anterior chamber. The cornea is richly supplied with nerves, particularly in its most superficial layers.

2. The dark, **middle,** or **vascular coat of the eye** [tunica vasculosa oculi] is formed by the **iris, ciliary body,** and **chorioid.** It is closely applied to the sclera, but actually joins it only at the anterior and posterior limits of their course together, viz., at the scleral sulcus, and around the optic nerve entrance. It is separated from the sclera between these two points by a narrow slit-like lymp-space [spatium perichorioideale]. In front of the sulcus, the middle coat is separated from the outer (i. e., the iris from the cornea) by a considerable space filled with fluid, called the *anterior aqueous chamber*. The vascular coat has two openings in it; a larger one in front, the pupil, and a smaller one behind, for the passage of the optic nerve. Its structure is that of a pigmented connective tissue, supporting numerous blood-vessels and containing many nerves and three deposits of smooth muscle-fibres.

The **chorioid** [chorioidea] forms the posterior part of the vascular coat, and extends, with slowly diminishing thickness, forward as far as the ora serrata. Its outer and inner surfaces are both formed by non-vascular layers; that covering the outer, the **lamina suprachorioidea,** is pigmented, arranged in several fine loose lamellæ; that covering the inner surface is a thin, transparent, homogeneous membrane, called the **basal lamina** of the chorioid. The intervening chorioidal stroma is very rich in blood-vessels, which are of largest size next its outer surface constituting the **lamina vasculosa.** These become progressively smaller toward the basal lamina, next to which is a layer of closely placed wide capillaries, called the **lamina choriocapillaris.** The pigment becomes less in amount as we pass inward, and finally ceases, being absent entirely from the choriocapillary and basal laminæ.

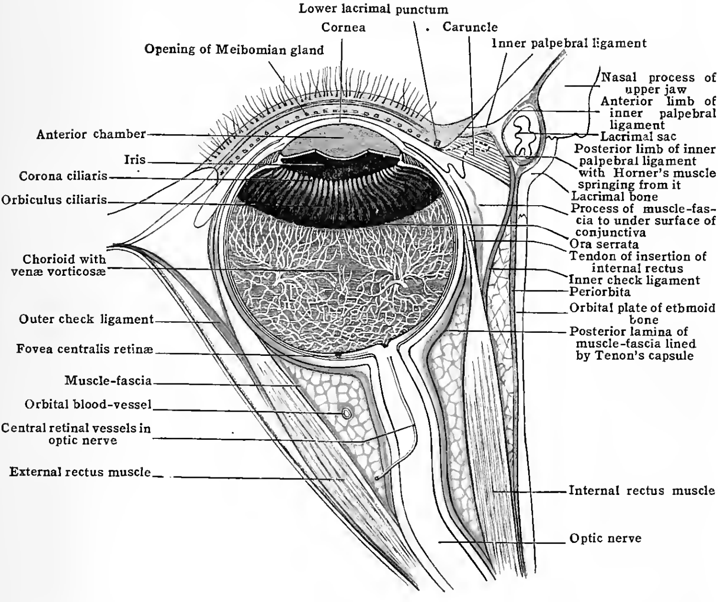
In front of the ora serrata the vascular coat becomes considerably modified' and the part reaching from the ora serrata of the retina to the iris is termed the ciliary region of the tract, or **ciliary body** [corpus ciliare]. Its superficial aspects have been already briefly described. In front, the ciliary processes, about seventy in number, project toward the interior of the eye, forming the **corona ciliaris.** Behind this part lies the **orbiculus ciliaris,** whose inner surface is almost smooth, faint radial folds [plicæ ciliares] only being present, three or four of which join each ciliary process.

The more minute structure of this ciliary region resembles closely that of the chorioid, except that the chorio-capillaris is no longer present, that the stroma is thicker and richer in blood-vessels, and that a muscular element (ciliary muscle) exists between the vascular layer and the lamina suprachorioidea. On antero-posterior section the ciliary body is triangular; the shortest side looks forward, and from about its middle the iris arises; the two long sides look respectively inward and outward, the inner having the ciliary processes upon it, while the outer is formed by the **ciliary muscle.** This muscle possesses smooth fibres and consists of an outer [fibræ meridionales (Brueckei)] and an inner division [fibræ circulares (Muelleri)]. The meridional fibres take origin from the outer fibrous coat of the eye at the sclero-corneal junction in front, and passing backward to join the outer layers of the orbiculus ciliaris and chorioid; the circular fibres are situated next to the ciliary processes. The entire muscle is destitute of pigment, and therefore is recognisable in the section by its light colour. The whole thickening of the vascular tunic in this region, muscle and folds and processes together, is named the **ciliary body.** It includes the corona ciliaris, formed of the ciliary processes and folds, and the orbicularis ciliaris containing the ciliary muscle.

The **iris** projects into the interior of the front half of the eye in the form of a circular disc perforated in the middle. The appearance of its anterior surface has already been described. The anterior surface is covered with a layer of endothelium except at the crypts near the ciliary border. Thus the lymph spaces between the stroma cells communicate directly with the anterior chamber. Its posterior surface exhibits numerous radial folds running from the ciliary processes to near the pupillary margin; a thick layer of black pigment covers it and curls around this edge, so as to come into view all around the pupil as seen from in front. The *ciliary border* of the iris is continuous with the front of the ciliary body, and there it also receives fibres from the ligamentum pectinatum iridis; in other respects the iris is quite free, merely resting on the front of the lens-capsule near the pupil.

Its stroma [stroma iridis] is spongy in character, being made up of vessels covered by a thick adventitia, running from the periphery to the pupillary border, with interspaces filled by branching pigment cells, which are particularly abundant near the front surface. Deep in the stroma, running around near the pupillary border, we find a broad flat band of smooth muscle-fibres, constituting the m. **sphincter pupillæ.** Immediately behind the vascular tissue lies a thin membrane, consisting of fine, straight fibres running radially from the ciliary border to the stroma behind the sphincter. The nature of these fibres was long in dispute, but they are now accepted as being undoubtedly smooth muscular—and comprise the **m. dilatator pupillæ.**

Fig. 804.—Diagrammatic Horizontal Section of Eyeball and Orbit. (After Fuchs, much modified.)
Periorbita *green;* muscle-fascia *red;* Tenon's capsule *yellow.*



The *m. sphincter pupillæ* and the *ciliary muscle* are supplied indirectly by the oculomotor nerve through the ciliary ganglion. The dilatator pupillæ is supplied by *sympathetic fibres*, which have their origin from the cells of the superior cervical ganglion. Thence they ascend in the carotid and cavernous plexuses, and join the ophthalmic division of the trigeminal nerve, passing to the eyeball by way of the long ciliary nerves. The pre-ganglionic sympathetic fibres leave the spinal cord by the motor roots of the first two or three thoracic nerves, and ascend the sympathetic trunk to the superior cervical ganglion without interruption.

The posterior surface of the iris is lined by pigment already mentioned, consisting of two layers of pigmented cells, each layer representing the extension forward of one subdivision of the retina. The anterior surface of the iris is covered by a delicate epithelial layer, continuous with the cells of the posterior elastic lamina of the cornea. The colour of the iris in different individuals depends upon the amount of *stromal* pigment.

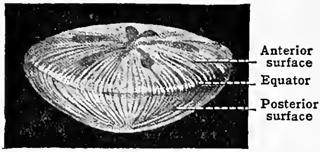
3. **The retina.**—The inner surface of the vascular coat is everywhere lined by a layer of pigment of corresponding extent, which usually adheres to it closely on dissection.

Developmentally this general pigment lining is quite distinct from the vascular coat, and represents the *outer wall* of the secondary optic vesicle or embryonic retina; it consists of a single layer of pigmented epithelial cells. It is known as the *stratum pigmenti*. The amount of pigment is greatest anteriorly, over the ciliary region and iris, and there is again a small local increase posteriorly, corresponding to the macula lutea and to the edge of the optic nerve entrance. In the ciliary region these cells have recently been described as lining numerous narrow tubular depressions in the inner part of the vascular tract, and they are said to have here a special function, viz., that of secreting the intraocular fluid.

From the manner in which the secondary optic vesicle, or *optic cup*, is formed, its two walls are necessarily continuous in front, at what may be termed the *lip* of the cup; we have just observed that the outer wall lines the vascular coat everywhere and corresponds in extent; consequently, the lip must be looked for at the edge of the pupil, i. e., at the termination of this coat anteriorly. The inner wall of the cup, consequently, reaches from the lip, or pupillary edge, in front to the optic stalk or nerve behind, and is in close apposition to the pigment-epithelium; unlike the outer, however, this wall is represented in the developed eye by tissues very dissimilar in structure in different parts of its extent. Tracing it backward from the pupillary edge, we find that over the whole posterior surface of the iris it exists as a single layer of pigmented epithelium, the two layers of the cup having here produced a double layer of pigment cells. At the root of the iris the single inner layer of cells still exists; but now they become destitute of pigment, and this condition obtains over the entire ciliary region, constituting what is known as the **pars ciliaris retinæ.** At the line of the ora serrata the tissue derived from the inner wall abruptly increases in thickness, and rapidly acquires that complexity of structure characteristic of the **retina proper,** which extends from here to the optic nerve and is termed the *pars optica retinæ.* It consists of several layers—nerve-fibres, nerve-cells, and nerve-epithelium—held together by a supporting framework of delicate connective tissue.

The nerve-epithelium is on the outer surface, immediately applied to the pigment-epithelium; at the posterior pole of the eye a small spot [fovea centralis] exists, where this is the only retinal layer represented, and where consequently the retina is extremely thin. The nerve-fibres run on the inner surface of the retina and are continuous with those of the optic nerve; they constitute the only retinal layer that is continued into the intraocular end of the nerve. The nerve-cells are found between these surface layers. The larger blood-vessels of the retina run in the inner layers, and none encroach on the layer of nerve-epithelium.

Fig. 805.—The Lens. (Side view; enlarged.)



Within the coats mentioned, the interior of the eyeball is fully occupied by contents, which are divided into three parts, which are named according to their consistence and anatomical form. They are all transparent, as through them the light has to pass so as to gain the retina. Of these, the only one that is sharply and independently outlined is the lens, which is situated in the anterior half of the globe at the level of the ciliary processes, where it is suspended between the other contents, which fill respectively the space in front of it and the space behind it. The space in front of the lens called the aqueous chamber; that behind the lens is the vitreous chamber.

The **lens** [lens crystallina] is a biconvex disc, with its surfaces directed anteriorly and posteriorly; these surfaces meet at its rounded-off edge or **equator** [æquator lentis] which is near (but does not touch) the adjacent ciliary processes. The posterior is considerably more convex than the anterior surface; the central part of each surface is called its **pole** [polus anterior; polus posterior]. The lens is closely encased in a hyaline elastic capsule [capsula lentis] thicker over the anterior than over the posterior surface. Thus enclosed, it is held in position in the globe by a suspensory ligament, attached to the lens capsule near the equator of the eye, and swung from the ciliary region. Posteriorly, the lens rests in a cup formed by the front part of the vitreous, while its anterior capsule is in contact with the aqueous fluid and lies close against the back of the pupillary margin of the iris. When in position the lens measures nine millimetres across, and about four millimetres between its poles.

On each surface a series of fine, sinuous, grey lines can be seen radiating from the pole toward the equator, called respectively the anterior and posterior **stellate figures**. The lines observable on the posterior are always so placed as to be intermediate with those on the anterior surface, so that on viewing them *through the lens* they occupy a position corresponding to the

Fig. 806.—Diagrammatic Representation of the Blood-vessels of the Eyeball. (Parsons, after Leber.)

Arteries *red*; veins *blue*.

s.p., Short posterior ciliary arteries. *l.p.c.*, Long posterior ciliary artery. *a.c.*, Anterior ciliary vessels. *C of S.*, Canal of Schlemm. *c.a.i.ma.*, Circulus arteriosus iridis major. *v.v*,. intervals between the lines on the anterior surface. The lens-capsule is comparatively brittle, and can be readily cut through when scraped with a sharp-pointed instrument; on doing so the divided edges curl outward, away from the lenticular substance. When removed from its capsule, the outer portion of the lens is found to be soft and glutinous, but its substance gets progressively firmer as we approach the centre. This harder central part is known as the **nucleus** [nucleus lentis], and the surrounding softer matter as **cortex** [substantia corticalis]. The cortical part shows a tendency to peel off in successive layers. It consists of long fibres, the ends of which meet in front and behind at the anterior and posterior stellate figures.

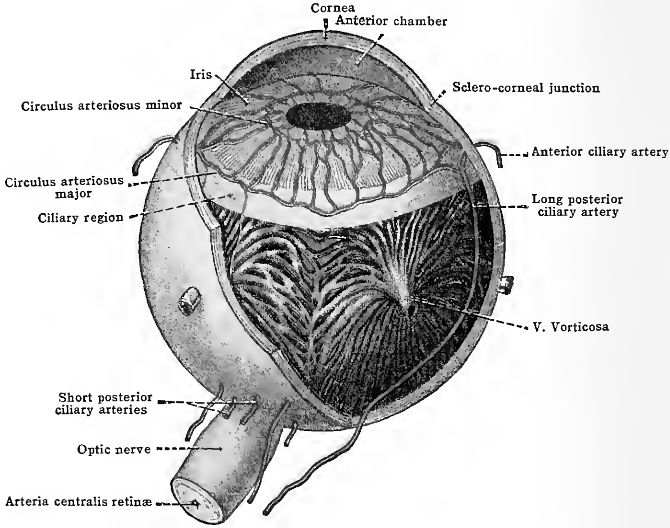
Histologically the capsule is not in immediate contact with the cortex over the front surface of the lens, a single layer of cells intervening, called the **epithelium lentis.**

The **zonula ciliaris** or **suspensory ligament of the lens** is formed by a number of fine zonular fibres [fibræ zonulares] passing from the ciliary body. They are attached to the lens-capsule a little in front of and behind the equator, and the spaces included between the fibres of the ligament are termed the *zonular spaces* [spatia zonularia]. A continuous space, which can be injected after death, round the margin of the lens is known as the canal of Petit. It is probably an artefact. This space is bridged across by fine intermediate suspensory fibres, and is occupied by fluid.

The **vitreous body** [corpus vitreum] is a transparent, colourless, jelly-like mass, the **vitreous humour,** enclosed in a delicate, clear, structureless membrane, called the *hyaloid membrane.* This latter is closely applied to the back of the posterior lens-capsule and of the suspensory ligament, and to the inner surface of the pars ciliaris retinæ, retina proper, and optic papilla. Although possessing some degree of firmness, the vitreous humour contains quite 98 per cent. of water, and has no definite structure.

Fig. 807.—Blood-vessels of the Eyeball, Lateral View.



Membranes have been described in it, but these are really artificial products. In certain situations spaces exist in the vitreous mass, the most determinate of which runs in the form of a canal from the optic papilla to the posterior pole of the lens, corresponding to the position of the fœtal hyaloid artery (**hyaloid canal** or **canalis hyaloidea**). Other very fine spaces are described running circularly in the peripheral part of the vitreous concentric with its outer surface. Microscopically, wandering cells are found in the vitreous, which often here assume peculiar forms which the observer can, not infrequently, study subjectively.

The **aqueous humour** is a clear, watery fluid, occupying the space between the cornea on the one hand, and the ciliary body, zonula ciliaris, and lens on the other. The iris, projecting into this space, has both its surfaces bathed in the aqueous; but, as its inner part rests on the lens, it is regarded as dividing the space into two parts, an **anterior** larger, and a **posterior** smaller, **aqueous chamber** [camera oculi anterior; posterior], which communicate freely through the pupil.

Ciliary nerves of the eyeball.—The long and short ciliary nerves, after perforating the sclera run forward between it and the chorioid to the ciliary region, where they form a plexus, from which proceed branches for the ciliary muscle, the iris, and the cornea.

The nerves of the iris enter it at its ciliary border, and run toward its pupillary edge, losing their medullary sheath sooner or later, and supplying especially the sphincter muscle. The corneal nerves form an annular plexus near the limbus, from which a few twigs proceed to the sclera and conjunctiva, while most of the offsets enter and run radially in the corneal stroma, branching and anastomosing so as to form a plexus. The nerves entering the cornea are about sixty in number, each containing from two to twelve non-medullated nerve-fibres.

Blood-vessels of the eyeball.—The eyeball receives blood from two sets of vessels, viz., the **retinal** and the **ciliary arteries,** as described in the section on the BLOOD-VASCULAR SYSTEM.

1. The **arteria centralis retinæ** either comes direct from the ophthalmic artery, or from one of its branches near the apex of the orbit. Entering the optic nerve twenty millimetres or less behind the globe, it runs forward in its axis to the end of the nerve-trunk, and then divides into branches which run in the inner layers of the retina, and divide dichotomously as they radiate toward the equator. The smaller branches lie more deeply in the retina, but none penetrate into the nerve-epithelium, so that the fovea centralis is non-vascular. In the retina, the branches of the central artery do not communicate with any other arteries, but while still in the optic nerve fine communications take place between this artery and neighbouring vessels. Thus (*a*) minute twigs from it, which help to nourish the axial part of the nerve, communicate with those running in the septa derived from the pial sheath. Again, as the nerve passes through the sclera, it is surrounded by a vascular ring [circulus vasculosus n. optici (Halleri)], formed of fine branches derived from the short posterior ciliary arteries; fine twigs passing inward from this ring to the optic nerve join the vessels of the pial sheath, and (*b*) an indirect communication is thus brought about between the retinal and ciliary vessels. Finally, as the nerve passes through the chorioid, there is (*c*) a direct connection between these two sets of vessels, the capillary network of the optic nerve being here continuous with the chorio-capillaris. Not infrequently, a branch from a short posterior ciliary artery pierces the optic papilla, and then courses over the adjoining retina (a cilio-retinal artery), supplying the latter in part in place of the central artery.

The **branches** of the a. centralis retinæ in the retina are: arteriola temporalis retinæ superior, arteriola temporalis retinæ inferior, arteriola nasalis retinæ superior, arteriola nasalis retinæ inferior, arteriola macularis superior, arteriola macularis inferior, arteriola retinæ medialis.

The **vena centralis retinæ** returns the blood of the corresponding artery and has branches corresponding to those of the artery.

2. **The ciliary system of blood-vessels** (see Blood-Vascular System).—There are three sets of arteries belonging to this system, all derived directly or indirectly from the ophthalmic artery.

(1) **Short posterior ciliary arteries** twelve to twenty in number, pierce the sclera round the optic nerve entrance, and are distributed in the chorioid. Before entering the eyeball, small twigs are given off to the adjoining sclera and to the dural sheath of the optic nerve.

(2) Two **long posterior ciliary arteries,** medial and lateral, piercing the sclera further from the nerve than the short ciliaries, run horizontally forward between the sclera and chorioid, one on each side of the globe. On arriving at the ciliary body, they join with the anterior ciliary arteries, forming the **circulus arteriosus major,** which sends off branches to the ciliary processes and the iris. The long ciliaries also give twigs to the ciliary muscle, and small recurrent branches run backward to anastomose with the short ciliary arteries. The arteries of the iris run radially toward the pupillary border, anastomosing with one another opposite the outer border of the sphincter and forming there the **circulus arteriosus minor.**

(3) The **anterior ciliary arteries** come from the arteries of the four recti muscles, one or two from each; they run forward, branching as they go, and finally pierce the sclera near the corneal border. Externally to the globe they send twigs to the adjoining sclera, to the conjunctiva, and to the border of the cornea. After passing through the sclera the arteries enter the ciliary muscle, where they end in twigs to the muscle and to the circulus arteriosus major, and in recurrent branches to the chorioid.

Veins.—The venous blood from almost the whole middle coat (chorioid, ciliary processes and iris, and part of the ciliary muscle) ultimately leaves the eyeball by—(1) the **venæ vorticosæ,** which have been already noticed in describing an antero-posterior section through the globe. One large vein passes backward from each vortex, piercing the sclera obliquely; it is joined by small episcleral veins when outside the globe.

(2) The **anterior ciliary veins** commence by the junction of a few small veins of the ciliary muscle; they pass outward through the sclera near the corneal border, receiving blood from the veins in connection with the sinus venosus of the sclera, and afterward from episcleral and conjunctival veins, and from the marginal corneal plexus. Finally they join the veins running in the recti muscles.

Lymphatic system of the eyeball.—Apart from those in the conjunctiva there are no lymphatic *vessels* in the eyeball, but the fluid is contained in *spaces* of various sizes. These are usually divided into an anterior and a posterior set.

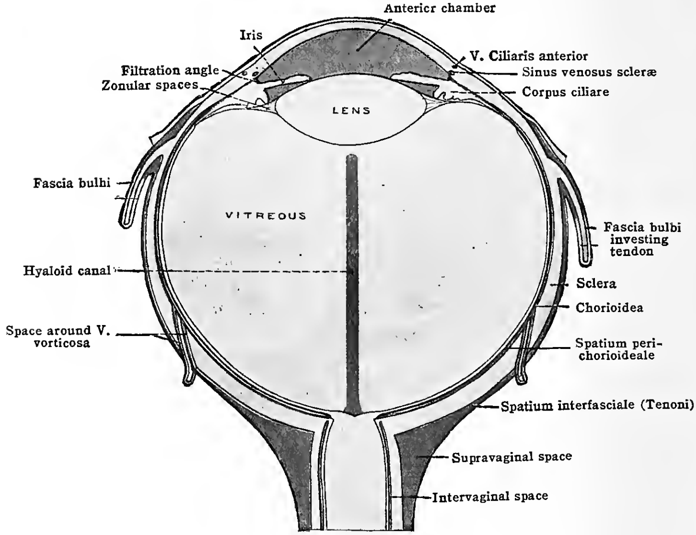
1. **Anteriorly,** we have the anterior and posterior aqueous chambers (together composing the aqueous chamber of the eye), which communicate freely through the pupil. The aqueous humour is formed in the posterior of these chambers by

transudation from the vessels of the ciliary body and posterior surface of the iris (see also page 1076). The stream passes mainly forward through the pupil into the anterior aqueous chamber, whence it escapes slowly by passing through the spaces of the angle of the iris into the venous sinus of the sclera, and thence into the anterior ciliary veins. Part of the lymph-stream passes from the posterior aqueous chamber backward into the zonular spaces, out of which fluid can pass into the lens substance, or diffuse itself into the front of the vitreous body.

In the **cornea** the lymph travels in the spaces already mentioned as existing between the fibre-bundles, and in the nerve-channels and at the periphery of the cornea it flows off into the lymphatic vessels of the conjunctiva.

In the **iris** there is a system of lymphatic spaces opening anteriorly into the crypts of the surface, and communicating peripherally with the spaces of the angle of the iris.

Fig. 808.—Lymphatic Spaces of the Eyeball (in green).



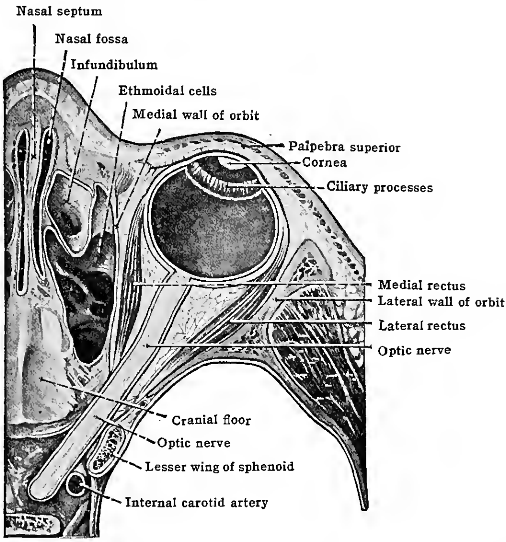
2. **Posteriorly,** we have (*a*) the hyaloid canal, between the posterior pole of the lens and the optic nerve entrance, and (*b*) the perivascular canals of the retina; the lymph from both of these situations flows into the spaces of the optic nerve, which communicate with the intervaginal spaces of the nerve, and thus with the great intracranial spaces. Further, between chorioid and sclera we have (*c*) the perichorioidal space, which gets the lymph from the chorioid, and communicates with the interfascial space (of Tenon) outside the sclera by perforations corresponding to the vasa vorticosa and posterior ciliary arteries, and with the intervaginal spaces around the optic nerve entrance. The interfascial space of Tenon, again, is continuous with the supravaginal space around the optic nerve, which communicates both with the intervaginal spaces, with the lymph-spaces of the orbit, and directly with the intracranial spaces at the apex of the orbit.

CAVITY OF THE ORBIT

General Arrangement of its Contents

The anterior wider half of the cavity is mainly occupied by the eyeball, which lies almost axially, but is rather nearer to the upper and lateral than it is to the other walls. The posterior two-thirds of the globe are in relation with soft parts, chiefly muscles and fat, and its posterior pole is situated midway between the base (or opening) and the apex of the orbital cavity. The anterior third of the eyeball is naturally free, except for a thin covering of the conjunctiva, and projects slightly beyond the opening of the orbit, the degree of prominence varying with the amount of orbital fat, and also to some extent with the length of the globe. A straight line joining the medial and lateral orbital margins usually cuts the eye behind the cornea—laterally behind the ora serrata, medially further forward, at the junction of the ciliary body and iris. The globe is held in position by numerous bands of connective tissue. The lacrimal gland lies under the lateral part of the roof of the orbit anteriorly. The orbital fat occupies the spaces between the orbital muscles, and is in greatest amount immediately behind the eyeball; it also exists between the muscles and the orbital walls in the anterior half of the cavity. Six muscles, viz., the four recti, the superior oblique, and the levator palpebræ superioris, arise at the apex of the orbit, and diverge as they pass forward. The recti muscles—superior, inferior, lateral, and medial—run each near the corresponding orbital wall, but the superior is overlapped in part by the levator palpebræ. The superior oblique lies about midway between the superior and medial recti. A seventh muscle, the inferior oblique, has a short course entirely in the anterior part of the orbit, coming from its medial wall and passing below the globe between the termination of the inferior rectus and the orbital floor. The optic nerve with its sheaths passes from the optic foramen to the back of the eyeball, surrounded by the orbital fat, and more immediately by a loose connective tissue. Among the contents of the cavity are also to be enumerated many vessels and nerves and fibrous tissue septa, while its walls are clothed by periosteum (periorbita).

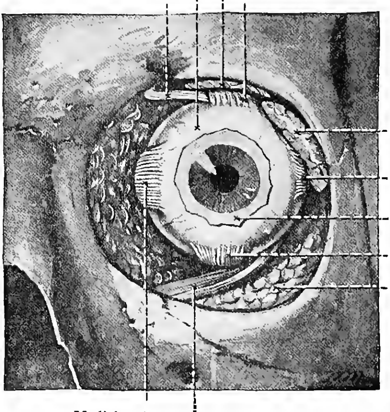
Fig. 809.—Horizontal Section of the Orbital Region, Viewed From Above.



The **muscles of the orbit** are seven in number, of which six are *ocular*, i. e., are inserted into the eyeball and rotate it in different directions. These ocular muscles are arranged in opponent pairs, viz., **superior** and **inferior recti**, **superior** and **inferior obliques**, **lateral** and **medial recti.** With the exception of the short inferior oblique, they all arise from the back of the orbit along with the seventh orbital muscle, the **levator palpebræ superioris.** All these long muscles take their **origin** from the periosteum in the vicinity of the optic foramen. The four recti muscles arise from a fibrous ring, the **annulus tendineus communis,** which arches close over the upper and medial edge of the foramen, and extends down and out so as to embrace part of the opening of the superior orbital fissure. Their origins may be said at first to form a short, common, tendinous tube, from which the individual muscles soon separate, taking the positions indicated by their respective names. The lateral rectus has two origins from bone, one on either side of the superior orbital fissure. But in the fresh state the fissure is here bridged across by fibrous tissue, from which this rectus also springs, so that its origin is in reality continuous. The part of this fibrous ring nearest the foramen (corresponding to the origins of the superior and medial recti) is closely connected with the outer sheath of the optic nerve. The remaining two long muscles arise just outside the upper and medial part of the above-mentioned ring, and are often partially united; the levator palpebræ tendon is in close relation to the origin of the superior rectus, while the superior oblique arises from the periosteum of the body of the sphenoid bone one or two millimetres in front of the origin of the medial rectus.

The **four recti muscles** lie rather close to the corresponding orbital walls for the first half of their course, the superior rectus, however, being overlapped in part by the levator palpebræ; they then turn toward the eyeball, running obliquely through the orbital fat, and are finally inserted by broad, thin tendons into the sclera in front of the equator. From their respective positions in the orbit, the axis of this cone of muscles is oblique to the antero-posterior axis of the eyeball. The thickest of these muscles is the medial rectus, next the lateral, then the infe-

FIG. 810.—DISSECTION OF THE LEFT ORBIT FROM IN FRONT.



rior, and the superior rectus is the thinnest. As regards length, the muscular belly of the superior rectus has the longest course, and the others diminish in the order—medial, lateral, and inferior rectus. The lateral rectus is supplied by the abducens nerve. The other three recti muscles are all supplied by the oculomotor nerve.

The **levator palpebræ superioris** courses along the roof of the orbit close to the periosteum for the greater part of its course, partially overlapping the superior rectus; it finally descends through the orbital fat, and widens out to be inserted into the root of the upper lid. It may be briefly described as being inserted in two distinct layers separated by a horizontal interval. The upper or anterior layer of insertion is fibrous, and passes in front of the tarsus, where it comes into relation with fibres of the orbicularis. The lower layer consists of smooth muscle (Müller's **superior tarsal muscle**), and is inserted along the upper border of the tarsus. The levator has also connections with the sheath of the superior rectus. These different insertions of the muscle will be referred to later along with the description of the orbital fasciæ and of the upper eyelid. It gets its nerve supply from the oculomotor nerve, but the smooth muscle developed in its lower layer of insertion is supplied by the sympathetic nervous system. As its name expresses, its *action* is to raise the upper lid and to support it while the eye is open.

The **superior oblique** runs forward close to the medial part of the orbital roof until it reaches the fovea trochlearis near the medial angular process, where it becomes tendinous and passes through a fibro-cartilaginous pulley attached to the fovea just named. On passing through this pulley, or **trochlea**, the tendon bends at an angle of 50°, running posteriorly and laterally under the superior rectus to its insertion into the sclera. It is supplied by the trochlear nerve.

The **inferior oblique** arises from the front of the orbit, about the junction of its medial and inferior walls, just lateral to the lower end of the lacrimal groove. It runs, in a sloping direction, laterally and posteriorly, lying at first between the inferior rectus and the orbital floor, then between the lateral rectus and the globe; finally it ascends slightly, to be inserted by a short tendon into the sclera at the back of the eye. Its nervous supply is derived from the oculomotor nerve. The precise manner of insertion of the different ocular muscles has been described above (p. 1056). For muscles of the eyelids and eyebrows, see pp. 1077 and 1078.

Action of the ocular muscles.—While rotating the globe so that the cornea is turned in different directions, the ocular muscles do not alter the position of the eyeball in the orbit either

FIG. 811.—SECTION THROUGH CONTENTS OF RIGHT ORBIT 8–11 MM. BEHIND THE EYEBALL, VIEWED FROM BEHIND. (After Lange.)

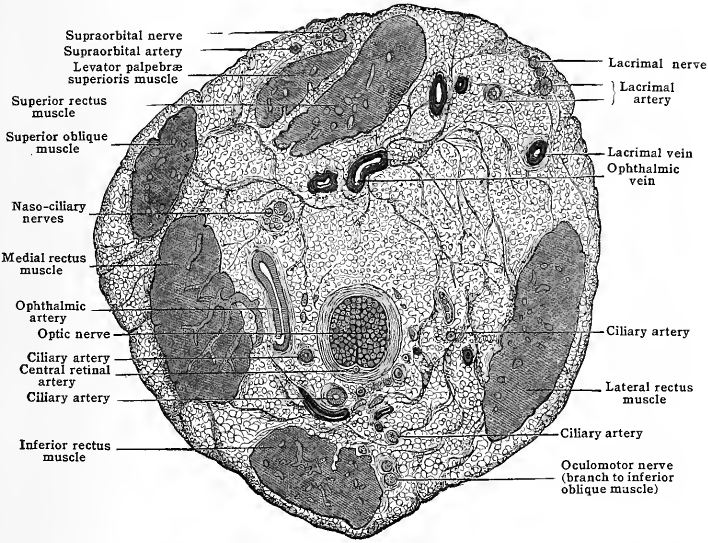


FIG. 812.—DIAGRAM REPRESENTING THE ORIGIN OF THE MUSCLES AT THE APEX OF THE RIGHT ORBIT.

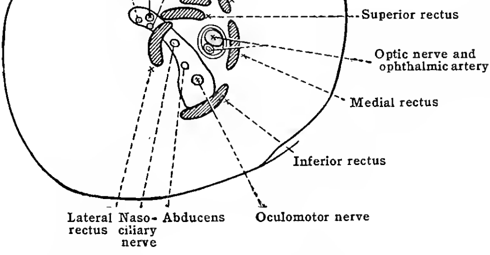

laterally, vertically, or antero-posteriorly. In speaking, therefore, of the eye being moved *upward* or *laterally*, etc., it is the altered position of the cornea or front of the eye that we mean to express; it is manifest that, if the cornea moves up, the back of the eyeball must simultaneously be depressed, and similarly with other movements. All the movements of the globe take place by rotation, on axes passing through the centre. Though the possible axes are numerous in combined muscular action, there are three **principal axes** of rotation of the **eyeball,** and in reference to these the action of individual muscles must be described. Two of these axes are horizontal and one vertical; they all pass through the centre of rotation at right angles to one another. By rotation of the eye on its vertical axis the cornea is moved laterally (toward the temple) and medially (toward the nose): movements called respectively **abduction** and **adduction.** In upward and downward movements of the cornea the eye rotates on its horizontal equatorial axis. The other principal axis of rotation is the sagittal, which we have previously described as corresponding to the line joining the anterior and posterior poles of the globe (page 1055). In rotation of the eye on its sagittal axis, therefore, the cornea may be said to move as a wheel on its axle, for its centre now corresponds to one end of the axis; in other words, this is a **rotation of the cornea.** Such movements may, consequently, be expressed with reference to their effect on an imaginary spoke of the corneal wheel—e. g., one running vertically upward from the corneal centre. Thus we may say 'rotation of the cornea laterally' when this part of the wheel moves toward the lateral angle, or 'medially' when toward the nose.

Fig. 813.—Dissection of the Muscles of the Right Orbit, Lateral View.

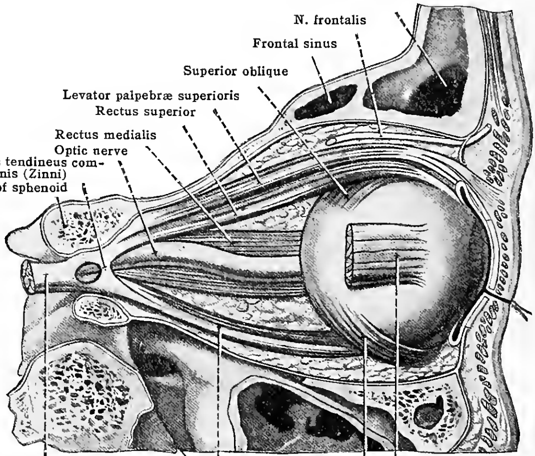

Fig. 814.—Dissection of the Muscles of the Left Orbit, From Above.

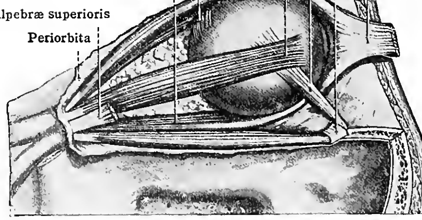


The only two muscles that rotate the eyeball merely on one axis are the **lateral rectus** and the **medial rectus**; the former abducting, and the latter adducting, the cornea. The action of the superior and inferior recti is complicated by the obliquity of the axes of muscles and globe previously mentioned.

The chief action of the **superior rectus** is to draw the cornea upward, but at the same time it adducts and rotates the cornea medially.

The **inferior rectus** mainly draws the cornea downward, also adducting it and rotating it laterally.

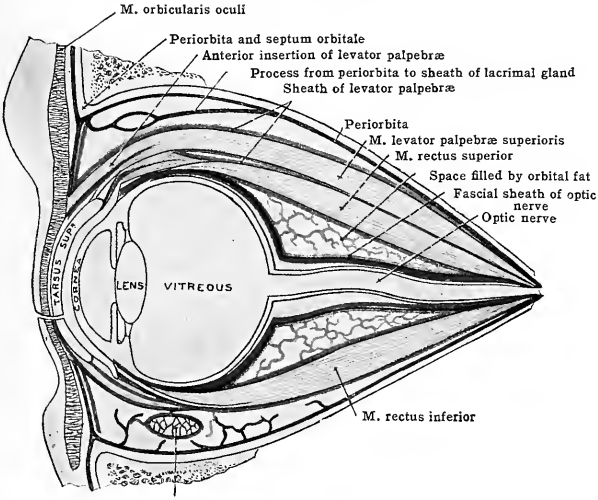
The chief action of the **superior oblique** is to rotate the cornea medially, also drawing it downward and slightly abducting it.

The **inferior oblique** mainly rotates the cornea laterally, also drawing it upward and slightly abducting it.

The fasciæ of the orbit [fasciæ orbitales].—The orbital contents are bound together and supported by fibrous tissues, which are connected with each other, but which may conveniently be regarded as belonging to three systems. These are:—(1) Those lining the bony walls; (2) those ensheathing the muscles; and (3) the tissue which partially encapsules the eyeball.

1. The **orbital periosteum** [periorbita], is closely applied to the bones forming the walls of the cavity, but may be stripped off with comparative ease. It presents openings for the passage of vessels and nerves entering and leaving the orbit.

Fig. 815.—Diagram Representing the Orbital Fasciæ in Vertical Section. Periorbita *black;* muscular sheaths *violet;* Tenon's capsule *green.*



Posteriorly this tissue is very firm, being joined by processes of the dura mater at the optic foramen and superior orbital fissure; at the optic foramen it is also connected with the dura sheath of the optic nerve. As it covers the inferior orbital (spheno-maxillary) fissure its fibres are interwoven with smooth muscle, forming the **orbital muscle of Müller.** From its inner surface processes run into the orbital cavity, separating the fat lobules. One important process comes from the periorbita about midway along the roof of the orbit, runs forward to the back of the upper division of the lacrimal gland, and there splits, helping to form the gland-capsule: this capsule is joined at its medial border by other periorbital bands coming off near the upper orbital rim, and forming the suspensory ligament of the gland. On the side of the orbit the periorbita sends fibrous processes to the trochlea of the superior oblique, which keep it in position. On arriving at the lacrimal groove the periorbita divides into two layers, a thin posterior one continuing to line the bone forming the floor of the groove, whilst the thicker anterior layer bridges over the groove and the sac which lies in it, forming the limbs of the medial palpebral ligament (p. 1052).

Quite anteriorly, at the rim of the orbit, the periorbita sends off a membranous process which aids in forming the fibrous tissue of the eyelids (**orbito-tarsal ligament,** or **palpebral fascia**), and is itself continuous with the periosteum of the bones outside the orbital margin.

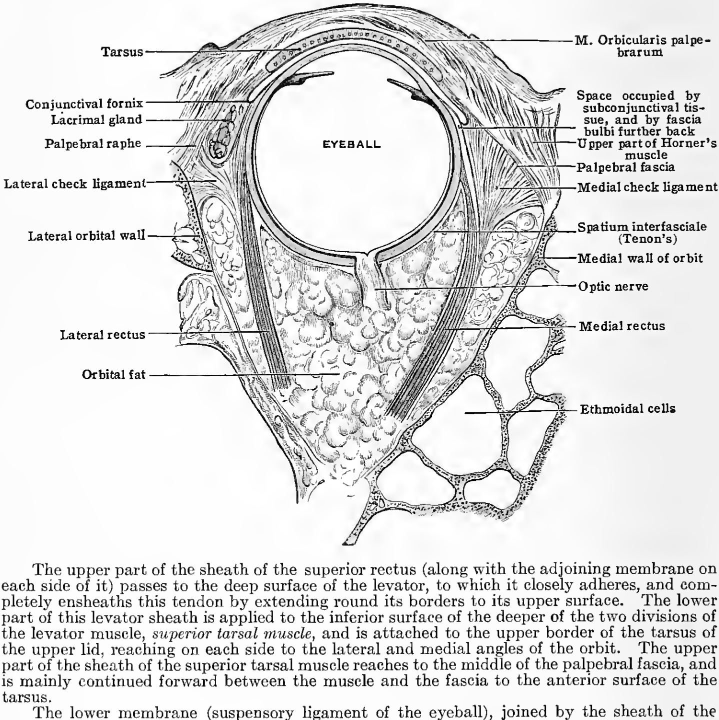
2. The orbital muscles are connected by a common fascia, which splits at their borders and furnishes a sheath to each. Processes of this fascia give membranous investments for the vessels and nerves (including the optic nerve), splitting simi-

larly to enclose them; these membranous processes also assist in separating the fat lobules.

Posteriorly, this fascia is thin and loose, and blends with the periorbita at the origin of the muscles. Anteriorly, it becomes thicker and firmer, accompanies the muscles to near the equator of the eyeball, and there divides into two laminæ, an anterior and a posterior; the former continues a forward course, forming a complete funnel-shaped investment all around, passing ultimately to the eyelids and orbital margin—whilst the latter turns backward, covering the hinder third of the globe.

The *anterior lamina* is a well-marked membrane everywhere, but in certain situations it presents special bands of thickening, corresponding to the direct continuation forward of the sheath of each rectus muscle. Above and below, this lamina spreads out in the form of two large membranes, which are finally applied to the deep surface of the palpebral fascia; the lower membrane constitutes what has been described as 'the suspensory ligament of the eyeball.' The upper membrane requires a fuller description, as its distribution is modified by the presence of the levator palpebræ muscle.

FIG. 816.—HORIZONTAL SECTION THROUGH LEFT ORBIT, VIEWED FROM ABOVE. (After von Gerlach. To show check ligaments, etc.)



The upper part of the sheath of the superior rectus (along with the adjoining membrane on each side of it) passes to the deep surface of the levator, to which it closely adheres, and completely ensheaths this tendon by extending round its borders to its upper surface. The lower part of this levator sheath is applied to the inferior surface of the deeper of the two divisions of the levator muscle, *superior tarsal muscle*, and is attached to the upper border of the tarsus of the upper lid, reaching on each side to the lateral and medial angles of the orbit. The upper part of the sheath of the superior tarsal muscle reaches to the middle of the palpebral fascia, and is mainly continued forward between the muscle and the fascia to the anterior surface of the tarsus.

The lower membrane (suspensory ligament of the eyeball), joined by the sheath of the inferior rectus, reaches forward to the attached (posterior) border of the tarsus of the lower lid, where it is mainly attached, while a part of it extends to the lower palpebral fascia.

To understand the *special bands* of the anterior lamina mentioned above, we must follow the sheath of each rectus muscle forward, when we find that, while it is rather loosely applied to the muscular belly in its posterior two-thirds, it then suddenly becomes thicker, and is firmly attached to the muscle for some distance before finally leaving it, and is thereafter often accompanied by some muscle-fibres. The best developed of these bands, the *lateral check ligament*, passes anteriorly and laterally to the lateral angle of the orbit, helping to support the lacrimal gland on its way, and is inserted near the orbital edge immediately behind the lateral palpebral raphe. The medial band, or *medial check ligament*, is larger than the lateral, but not so thick; it passes forward and medially to be inserted into the upper part of the lacrimal crest and just behind it. These two bands, lateral and medial, come from the sheaths of the corresponding recti muscles. From the sheath of the superior rectus come two thin bands, one from each border. The medial joins the sheath of the tendon of the superior oblique; the lateral goes to the lateral angle of the orbit, assisting in the support of part of the lacrimal gland. The sheath of the inferior rectus is thickened in front, and, on leaving the muscle, goes to the middle of the inferior oblique, splitting to enclose it; it then passes to be inserted into the lower medial angle of the orbit close behind its margin, about midway between the medial check ligament and the orbital attachment of the inferior oblique.

3. In addition to its partial investment by the muscle-fascia, the eyeball has a special membrane enclosing its hinder two-thirds, the **fascia bulbi** ("Tenon's capsule").

This is a thin, transparent tissue, situated immediately internal to the posterior lamina of the muscle-fascia. It follows the curve of the sclera from the insertion of the recti to about 3 mm. from the optic nerve entrance. There it leaves the eyeball and blends with the posterior lamina of the muscle-fascia; the combined membrane may be traced backward, enveloping the optic nerve-sheath loosely, approaching it as it nears the optic foramen, but never actually joining it. The interval between it and the nerve-sheath is called the *supravaginal lymph-space.* The fascia bulbi first comes into relation with the muscles at the point where they are left by their proper sheaths; it there invests their tendons, forms a small serous bursa on the anterior surface of each, and adheres to the sclera along a line running around the globe, just anterior to the insertions of the four recti muscles. Between this line and the corneal border, the conjunctiva is separated from the sclera by the subconjunctival tissue, strengthened by a fine expansion of the muscle-fascia.

The inner surface of the fascia is smooth, and is only connected with the sclera by a loose, wide-meshed areolar tissue. This interval between the sclera and fascia, known as the **interfascial (Tenon's) space,** is a lymph cavity, and permits free movements of the eyeball within the capsule.

Relation of the Fascia Bulbi to the Oblique Muscles.—The fascia surrounds the posterior third of the inferior oblique and its tendon, running along its ocular surface till it meets the fascial band coming from the inferior rectus (see above), and forming a serous bursa on the superficial surface of the oblique near its insertion. The tendon of the superior oblique for about its last five millimetres is invested solely by the fascia bulbi; in front of this, as far as the trochlea, the tendon lies in a membranous tube derived from the muscle fascia, the inner lining of which is smooth, and may be considered as a prolongation of the fascia bulbi.

The Optic Nerve

The part of this nerve with which we have here to do lies within the orbit, extending from the optic foramen to the eyeball (fig. 813). The length of this portion of the nerve is from 20 to 30 mm. and its diameter about 5 mm. Its course is somewhat S-shaped; thus, on entering the orbit, it describes a curve, with its convexity down and laterally, and then a second slighter curve, convex medially. Finally, it runs straight forward to the globe, which it enters 3 to 4 mm. to the medial side of its posterior pole.

In its passage through the optic foramen the nerve is surrounded by a prolongation of the meninges. The dura mater splits at the optic foramen, part of it joining the periorbita, while the remainder continues to surround the nerve loosely as its outer or **dural sheath.** The nerve is closely enveloped by a vascular covering derived from the pia mater, named accordingly the **pial sheath.** The space between these two sheaths is subdivided by a fine prolongation of the arachnoid (the **arachnoidal sheath**) into two parts, termed the intervaginal spaces [spatia intervaginalia], viz., an outer, narrow, *subdural,* and an inner, wider, *subarachnoid space,* communicating with the corresponding intracranial spaces. The arachnoidal sheath is connected with the sheath on each side of it by numerous fine processes which bridge across the intervening spaces. The pial sheath sends processes inward, which form a framework separating the bundles of nerve-fibres; between the enclosed nerve-fibres and each mesh of this framework there is a narrow interval occupied by lymph. The nerve-fibres are medullated, but have no primitive sheath. About fifteen or twenty millimetres behind the globe the central vessels enter, piercing obliquely the lower lateral quadrant of the nerve, and then run forward in its axis. They are accompanied throughout by a special process of the pial sheath, which forms a fibrous cord in the centre of the nerve.

On reaching the eyeball, the dural sheath is joined by the arachnoid, and turns away from the nerve to be continued into the outer two-thirds of the sclera. Similarly the pial sheath also here leaves the nerve, its greater part running into the inner third of the sclera, while a few of its fibres join the chorioid; the intervaginal spaces consequently end abruptly in the sclera around the nerve-entrance. In this locality the connective-tissue framework of the nerve becomes thicker and closer in its meshwork, and has been already alluded to as the **lamina cribrosa scleræ.** It is formed by processes passing out from the central fibrous cord at its termination and by processes passing inward from the pial sheath, sclera, and chorioid. It does not pass straight across the nerve, but follows the curve of the surrounding sclera, being therefore slightly convex backward. The nerve-trunk here quickly becomes reduced to one-half its former diameter, the fibres losing their medullary sheath, and being continued henceforward as mere axis-cylinders. Apart from the consequent loss of bulk, this histological change may be readily recognised macroscopically in a longitudinal section of the nerve, its aspect here changing from opaque white to semi-translucent grey. The part of the nerve within the lamina cribrosa has already been noted in the ophthalmoscopic examination of the living eye (p. 1055).

The optic nerve is mainly nourished by fine vessels derived from those of the pial sheath, which run into the substance of the nerve in the processes above mentioned. In front of the entrance of the central retinal artery this vessel aids to some extent in the blood-supply of the axial part of the nerve.

FIG. 817.—TRANSVERSE SECTION THROUGH OPTIC NERVE, SHOWING THE RELATIONS OF ITS SHEATHS AND CONNECTIVE-TISSUE FRAMEWORK.

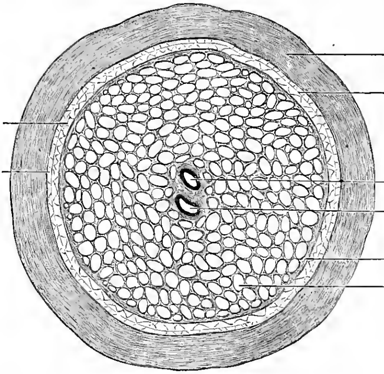


FIG. 818.—LONGITUDINAL SECTION THROUGH TERMINATION OF OPTIC NERVE.

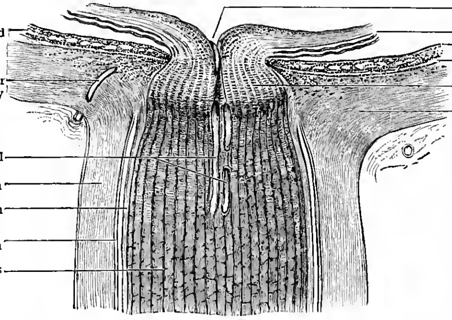


THE BLOOD-VESSELS AND NERVES OF THE ORBIT

As these structures will be more particularly described in other sections of this work, a very short general account will suffice here.

Arteries.—The main blood-supply is afforded by the **ophthalmic artery,** a branch of the internal carotid, which gains the orbit through the optic foramen, where it lies below and lateral to the nerve. On entering the orbit it ascends, and passes obliquely over the optic nerve to the medial wall of the orbit; in this early part of its course it gives off most of its branches, which vary much in their manner of origin and also in their course. The arteries of the orbit are remarkable for their tortuous course, for their delicate walls, and for their loose attachment to the surrounding tissues. The ophthalmic artery gives off special branches in the orbit to the lacrimal gland, the muscles, the retina (through the optic nerve), and the eyeball, as well as to the meninges, the ethmoidal cells, and the nasal mucous membrane. Twigs from all the different branches go to supply the fat, fasciæ, and ordinary nerves of the orbit. Branches which leave the orbit anteriorly ramify on the forehead and nose, and also go to the supply of the eyelids and the tear-passages. The ophthalmic artery has many anastomoses with branches of the external carotid. The contents of the orbit are also supplied in part by the **infraorbital artery, a** branch of the internal maxillary; in particular this artery supplies part of the inferior rectus and inferior oblique muscles in the cavity, and also gives a branch to the lower eyelid.

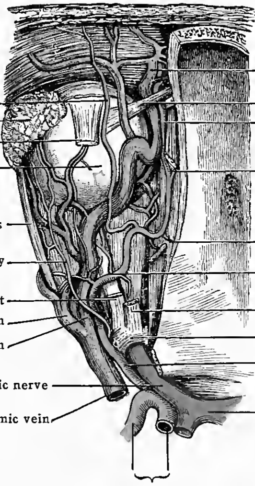
Veins.—Branches, corresponding generally to those of the artery, unite to form the **superior** and **inferior ophthalmic veins,** which ultimately, either separately or united into one trunk, pass through the superior orbital fissure and empty into the cavernous sinus. The inferior vein is connected with the pterygoid plexus by a branch which leaves the orbit by the inferior orbital fissure.

Nerves of the orbit.—These are (A) **motor,** (B) **sensory,** and (C) **sympathetic,** and all enter the orbit by the superior orbital fissure, with the exception of one small sensory branch passing through the inferior orbital fissure. (The optic nerve has been already described, and is not included in this account.)

A. The **motor nerves** are the oculomotor, trochlear, and abducens.

1. The **oculomotor nerve** enters the orbit in two parts, an upper smaller, and a lower larger, division. The *upper division* [ramus superior] gives off two branches: one supplies the superior rectus, entering its lower surface far back; the other branch goes to the levator palpebræ, entering its lower surface in its posterior third. The *lower division* [ramus inferior] divides into three branches, of which one supplies the inferior rectus, entering its upper surface

FIG. 819.—THE BLOOD-VESSELS OF THE LEFT ORBIT, VIEWED FROM ABOVE.



far back, and another supplies the medial rectus, entering its medial surface a little behind its middle. The third branch of the lower division gives (1) the short root to the ciliary ganglion, and (2) one or more twigs to the inferior rectus, and the remainder of this branch then enters the lower surface of the inferior oblique muscle about its middle.

2. The **trochlear nerve** supplies the superior oblique muscle, entering its upper surface about midway in its course.

3. The **abducens nerve** supplies the lateral rectus, entering its medial surface about the junction of the posterior and middle thirds of the muscle.

As regards the manner of termination of these motor nerves, it is found that in all the ocular muscles the nerve on its entrance breaks up into numerous bundles of fibres, which form first coarse and then fine plexuses, the latter ultimately sending off fine twigs supplying the muscle throughout with nerve-endings. The *posterior third* of these muscles is, however, comparatively poorly supplied with both kinds of plexuses and with nerve-endings.

B. The **sensory nerves** are supplied by the ophthalmic and maxillary divisions of the trigeminal cranial nerve. The ophthalmic division is chiefly orbital; while the maxillary sends only a small branch to the orbit.

1. The **ophthalmic division** of the trigeminal nerve enters the orbit in three divisions, namely:—

(1) **Frontal,** splitting subsequently into *supratrochlear* and *supraorbital,* both passing out of the orbit. It is distributed to the corresponding upper eyelid, and the skin over the root of the nose, the forehead, and the hairy scalp as far back as the coronal suture on the same side. It also gives branches to the periosteum in this region, and to the frontal sinus.

(2) **Lacrimal,** supplying the lacrimal gland, anastomosing with a branch of the maxillary

in the orbit, and finally piercing the upper eyelid. Outside the orbit it is distributed to the lateral part of the upper lid, the conjunctiva at the lateral angle, and the skin between this and the temporal region.

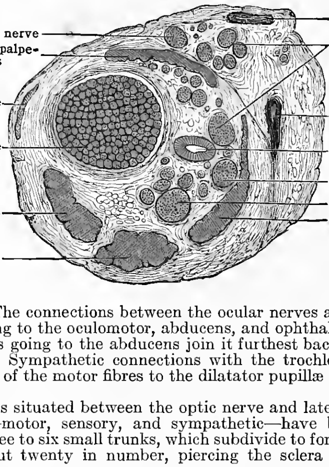
(3) **Naso-ciliary** [n. naso-ciliaris] giving off—(*a*) a branch to the ciliary ganglion, constituting its long root; (*b*) two or three *long ciliary nerves;* and (*c*) the *infratrochlear*, passing out of the orbit. The nerve then leaves the orbit as the anterior ethmoidal nerve [n. ethmoidalis anterior], re-entering the cranial cavity before being finally distributed to the nose. The infratrochlear branch [n. infratrochlearis], supplies the eyelids and skin of the side of the nose near the medial angle of the eye, the lacrimal sac, caruncle, and plica semilunaris. The anterior ethmoidal nerve, after its course in the cranial cavity, passes through an aperture in the front of the lamina cribrosa of the ethmoid bone, and is ultimately distributed to the nasal mucous membrane, and to the skin of the side and ridge of the nose near its tip.

2. The **maxillary division of the fifth** nerve gives a branch, called the **zygomatic nerve,** which passes into the orbit through the inferior orbital fissure, anastomoses with the lacrimal, and leaves the orbit in two divisions. These are distributed to the skin of the temple and of the prominent part of the cheek.

A few minute twigs from the spheno-palatine ganglion, and sometimes from the maxillary division of the fifth nerve, also pass through the inferior orbital fissure to supply the periorbita in this neighbourhood.

C. The **sympathetic nerves of the orbit** are mainly derived from the plexus on the internal carotid artery. With the exception of branches accompanying the ophthalmic artery, and of the distinct sympathetic root of the ciliary ganglion, they enter the orbit in the substance of

Fig. 820.—Section through Contents of Right Orbit, 1–2 mm. in front of the Optic Foramen, viewed from behind. (After Lange.)



the other nerve-cords. The connections between the ocular nerves and the carotid plexus are recognisable as fibres going to the oculomotor, abducens, and ophthalmic nerves; as a rule, the comparatively large twigs going to the abducens join it furthest back, and those to the oculomotor furthest forward. Sympathetic connections with the trochlear nerve are very doubtful. The special courses of the motor fibres to the dilatator pupillæ muscle have already been described.

The **ciliary ganglion** is situated between the optic nerve and lateral rectus far back in the orbit. Its three roots—motor, sensory, and sympathetic—have been already mentioned. Anteriorly, it gives off three to six small trunks, which subdivide to form the **short ciliary nerves** [nn. ciliares breves] about twenty in number, piercing the sclera around the optic nerve entrance.

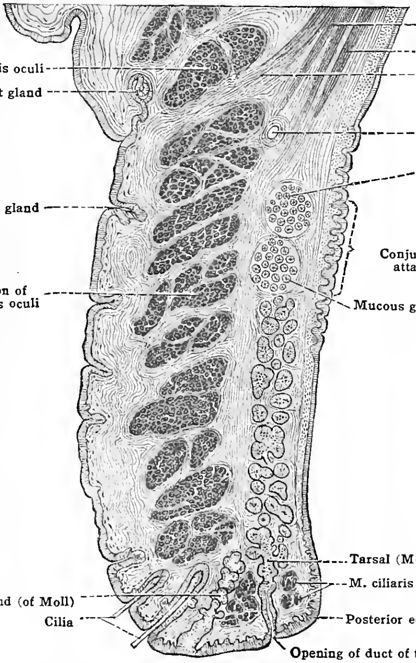
The lymphatic system of the orbit.—Although there are no lymphatic *vessels* or *glands* in the orbit, the passage of lymph is nevertheless well provided for. We have already observed the lymph channels within, between, and outside the sheaths of the optic nerve, and have seen how these communicate anteriorly with the lymph channels of the eyeball, and posteriorly with the intracranial meningeal spaces. In addition, there are lymph-spaces around the blood-vessels, situated between the outer coat and the loose investment furnished by the muscle fascia. The nerves of the orbit (apart from the optic) are probably similarly surrounded by lymph-spaces. In the absence of lymphatic vessels it is difficult to trace the circulation thoroughly; much of the lymph from the orbital cavity is said to pass into the parotid nodes.

The Eyelids

The cutaneous and conjunctival surfaces of the eyelids [palpebræ] have already been examined (p. 1053), and the position of the tarsus has been indicated. We have now to ascertain the nature and relations of the tarsus, and describe the other tissues entering into the formation of the eyelids (fig. 821).

The skin here is thin, bearing fine hairs, and having small sebaceous and numerous small sweat-glands. Immediately beneath it is a loose subcutaneous tissue, destitute of fat, separating the skin from the palpebral part of the **orbicularis muscle.** The lid-fibres of this muscle arise from the medial palpebral ligament, and course over the whole upper and lower eyelids in a succession of arches, so as to meet again beyond the lateral angle; there they in part join one another, in part are inserted into the lateral palpebral raphe. The muscular fibres are arranged in loose bundles, with spaces between them occupied by connective tissue; in the upper lid these connective-tissue fibres may be traced upward and backward into the fibrous expansion of the tendon of the levator palpebræ supe-

Fig. 821.—Sagittal Section of the Upper Eyelid. (After Waldeyer and Fuchs.)



rioris. One strong bundle of orbicularis fibres, called the **musculus ciliaris Riolani,** is found near the edge of the lid, in front of and behind the efferent ducts of the tarsal glands (fig. 821).

A **central connective tissue** separates the orbicularis muscle from the tarsus in the tarsal division of the lids. In the upper lid this is to be regarded as mainly the anterior or fibrous expansion of the tendon of the levator palpebræ, which sends connective-tissue septa between the bundles of the overlying orbicularis (as just mentioned) going to the skin. In the orbital part of this lid the central connective tissue includes also the palpebral fascia, lying here immediately beneath the orbicularis muscle; but this soon thins off and fades into the more deeply placed levator expansion. This latter is strengthened by an extension of the sheath of the superior rectus, by which this muscle is enabled to influence the elevation of the lid indirectly. In the lower lid the central connective tissue similarly consists of palpebral fascia, blended with a thin fibrous extension of the sheath of the inferior rectus. Immediately in front of each tarsus is a little loose connective tissue, which contains the large blood-vessels and nerves of the lids.

The **tarsus** of each lid is a stiff plate of close connective tissue, with its surfaces directed anteriorly and posteriorly; in its substance the tarsal glands are embedded. One tarsal border is free, viz., toward the edge of the lid, the other is attached; the former is straight, while the latter is convex, especially in the upper lid.

The length of each tarsus is about twenty millimetres. Its breadth is greatest in the middle of the lid, and becomes gradually smaller toward each angle, where the tarsi are joined to the lateral raphe and medial palpebral ligament. The breadth of the upper tarsus (10 mm.) is about twice that of the lower. The thickness of each is greatest, and its texture closest, at the middle of its length, thinning off toward the angles of the eye and toward both borders. Into the superior anterior border of the upper tarsus the lower layer of the levator expansion is attached, consisting of smooth muscle-fibres constituting the **superior tarsal muscle** of Müller. In like manner, at the inferior border of the lower tarsus, bundles of smooth muscle-fibre are inserted (the **inferior tarsal muscle** of Müller), developed in what has been regarded as part of the extension of the sheath of the inferior rectus.

The **palpebral conjunctiva** is firmly adherent to the posterior aspect of the tarsus; but in the orbital part of the lid loose subconjunctival tissue intervenes between it and Müller's tarsal muscle. Lymphoid tissue occurs in the substance of the conjunctiva, especially in its orbital division. Near the upper fornix, the conjunctiva receives expansions of the tendon of the levator palpebræ and of the sheath of the superior rectus, and, at the lower fornix, of the sheath of the inferior rectus. The surface of the tarsal conjunctiva shows small elevations or papillæ everywhere; but these are particularly well marked over the attached border of the tarsus.

Glands of the eyelids.—From its manner of formation the eyelid may be regarded as consisting of two thicknesses of skin, the posterior having been doubled back upon the anterior at the edge of the lid; thus the epidermis and corium of the skin proper are represented respectively by the conjunctiva (epithelium) and tarsus of the inner thickness. At the free border of the lid, accordingly, we find glands corresponding to the sebaceous and sweat-glands of the skin, viz., large sebaceous glands of the cilia (Zeiss's glands) and the ciliary glands of Moll, which are modified sweat-glands. Again, in the inner skin-thickness of the lid, the tarsal (Meibomian) glands are sebaceous.

Acino-tubular mucous glands occur at the attached border of the tarsus (Krause's or Waldeyer's glands), and similar glands also occur at the fornix, and are especially abundant near the outer angle of the upper lid, close to the efferent ducts of the lacrimal gland; from their structure and the character of their secretion, these acinous or acino-tubular glands have been termed by Henle 'accessory lacrimal glands.' Other simple tubular glands (Henle), formed merely by the depressions between the papillæ, are best developed in the medial and lateral fourths of the tarsal conjunctiva of both lids.

Blood-vessels.—The arteries run in the central connective tissue of the lids, mainly in the form of arches near the borders of the tarsus, from which twigs go to the different palpebral tissues. They are supplied by the lacrimal and palpebral branches of the ophthalmic, and by small branches derived from the temporal artery. The veins are more numerous and larger than the arteries, and form a close plexus beneath each fornix. They empty themselves into the veins of the face at the medial, and into the orbital veins at the lateral angle of the eye.

The **lymphatic vessels of the lids** are numerous, and are principally situated in the conjunctiva. Lymph-spaces also surround the follicles of the tarsal glands. The palpebral lymphatic vessels from the lateral three-fourths of the lid pass through the anterior auricular and parotid nodes; those from the medial fourth of the lower lid go to the facial and submaxillary lymphatic nodes.

Nerves.—(*a*) **Sensory.** The upper lid is chiefly supplied by branches of the supraorbital and supratrochlear nerves, the lower lid by one or two branches of the infraorbital. At the medial angle the infratrochlear nerve also aids in the supply, and, at the lateral angle, the lacrimal. (*b*) **Motor.** The palpebral part of the orbicularis is supplied by branches of the facial nerve, which mainly enter it near the lateral angle. The tarsal muscles are supplied by the sympathetic nervous system.

The **medial palpebral ligament** has been referred to previously. Arising from the frontal process of the maxilla, it extends laterally over the front wall of the lacrimal sac, bends round the lateral wall of the sac, and then passes backward to the posterior crest on the lacrimal bone. It is thus U-shaped, having its limbs anterior and posterior, embracing the lacrimal sac; the anterior limb lies immediately beneath the skin, and is visible in the living. The palpebral fibres of the orbicularis are inserted into the anterior surface of both limbs, those attached to the posterior limb constituting the pars lacrimalis of the orbicularis palpebrarum (Horner's muscle). The **lateral palpebral raphe** is merely a stronger development of connective tissue in the orbicularis. Both ligaments are connected with the tarsi as already mentioned.

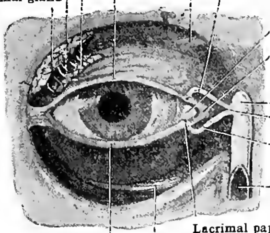
The Lacrimal Apparatus

The tears are secreted by an acinous gland, and flow through fine ducts to the upper lateral part of the conjunctival sac, whence they pass over the cornea and are drained off through the puncta, pass along the canaliculi into the lacrimal sac, and ultimately down the naso-lacrimal duct to the inferior meatus of the nose.

The **lacrimal gland** is situated near the front of the lateral part of the roof of the orbit, lying in a depression in the orbital plate of the frontal bone. It consists of two very unequal parts, one placed above and the other beneath the tendinous expansion of the levator palpebræ superioris, but small gaps in the expansion permit of connections between these two parts of the gland. The upper and larger subdivision (*superior lacrimal gland*) is a firm elongated body, about the size of a small almond; it has a greyish-red colour, and is made up of closely aggregated lobules. The upper surface (next the orbital roof) is convex, and its lower surface is slightly concave.

Anteriorly, the gland almost reaches the upper orbital margin, and it extends backward for approximately one-fourth the depth of the orbit, measuring about twelve millimetres in this direction. The lateral border of the gland descends to near the insertion of the fascial expansion of the lateral rectus, while its medial border almost reaches the lateral edge of the superior rectus; its transverse measurement is about twenty millimetres. It is enveloped in a capsule, which is slung by strong fibrous bands passing to its medial border from the orbital margin (suspensory ligament of the gland).

Fig. 822.—Dissection of the Eye to Show the Lacrimal Apparatus, Anterior View.



The lower subdivision of the gland (*inferior lacrimal gland*) is composed of loosely applied lobules, and lies immediately over the lateral third of the upper conjunctival fornix, reaching lateralward as far as the lateral angle.

Each subdivision of the gland possesses several **excretory ducts,** which all open on the lateral part of the upper fornix conjunctivæ, about four millimetres above the upper border of the tarsus. Those of the superior gland, three or four in number, pass between the lobules of the lower gland; the most lateral duct is the largest, and opens at the level of the lateral angle of the eye. The ducts of the inferior gland in part discharge themselves into those of the upper, but there are also several fine ducts from this subdivision that run an independent course.

Near the medial angle are the two **puncta lacrimalia,** upper and lower, each situated at the summit of its papilla. The top of each papilla curves backward toward the conjunctival sac, so that the puncta are well adapted for their function of draining off any fluid collecting there.

The **ductus (canaliculi) lacrimales** extend from the puncta to the lacrimal sac. The lumen at the punctum is horizontally oval, from its lips being slightly compressed antero-posteriorly; the lumen of the lower punctum is somewhat larger than that of the upper. As the lower papilla is a little further from the medial angle of the eye than the upper, the corresponding canaliculus is longer.

On tracing either ductus from its origin, we find that at first it runs nearly vertically for a short distance, then bends sharply toward the nose, and finally courses more or less horizontally, converging slightly toward its fellow, and not infrequently joining it before opening into the sac. The calibre varies considerably in this course, being narrowest a short distance from the punctum, and widest at the bend, from which point it again narrows very gradually as it nears the sac.

The wall of the ductus consists mainly of elastic and white fibrous tissue, lined internally by epithelium, and covered externally by striated muscle (part of the orbicularis). The muscle-fibres run parallel to the ductus in the horizontal part of its course; but they are placed, some in front and some behind, around the vertical part, acting here as a kind of sphincter. Just before their termination, the ducts pierce the periosteal thickening that constitutes the posterior limb of the medial palpebral ligament.

The **lacrimal sac** [saccus lacrimalis] lies in a depression in the bone at the medial angle of the orbit (the lacrimal fossa). It is vertically elongated, and narrows at its upper and lower ends; the upper extremity or *fundus* is closed, while the lower is continuous with the naso-lacrimal duct. Laterally, the sac is somewhat compressed, so that its antero-posterior is greater than its transverse diameter. The ducts, either separately or by a short common tube, open into a bulging on the lateral surface of the sac near the fundus.

As has previously been mentioned, the sac is surrounded by periosteum, but between this and the mucous membrane forming the true sac-wall there is a loose connective tissue, so that the cavity is capable of considerable distention. The relations of the medial palpebral ligament have already been described; it is to be noted that the fundus of the sac extends above this ligament.

The **naso-lacrimal duct** [ductus naso-lacrimalis] reaches from the lower end of the sac to the top of the inferior meatus of the nose, opening into the latter just beneath the adherent border of the inferior nasal concha. Traced from above, its main direction is downward, but it has also a slight inclination backward and laterally. It lies in a bony canal, whose periosteum forms its outer covering. Between this and the mucous membrane of the duct there is a little intermediate tissue, in which run veins of considerable size connected with the plexus of the inferior concha. The duct does not usually open directly into the nasal cavity at the lower end of the bony canal, but pierces the nasal mucous membrane very obliquely, so that a *flap* [plica lacrimalis (Hasneri)] of mucous membrane covers the lower border of the opening in the bone, upon which flap the tears first trickle after escaping from the duct proper.

The sac and naso-lacrimal duct together constitute the **lacrimal canal,** lined throughout by a continuous mucous membrane. This membrane presents *folds* in some situations, especially near the opening of the canaliculi, at the junction of the sac and duct, and at the lower end of the duct. That at the top of the duct is the most important, as it sometimes interferes with the proper flow of tears out of the sac. The total length of the lacrimal canal is roughly twenty-four millimetres, half of this being sac, and half naso-lacrimal duct. If, however, we reckon as duct the oblique passage through the nasal mucous membrane, this measurement may occasionally be increased by eight or ten millimetres. The lacrimal sac, when distended, measures about six millimetres from before backward, by four millimetres transversely. The naso-lacrimal duct is practically circular, and has a diameter of about three millimetres, rather less at its junction with the sac, where we find the narrowest part of the whole lacrimal canal.

Development of the Eye

The eye is developed from the three sources involving two fundamental embryonic layers—the retina from a portion of the ectodermal wall of the forebrain on each side; the lens from the ectodermal surface epithelium; and the sclera, cornea (except epithelium) and chorioidal coat from the mesoderm which surrounds the former structures.

The process of development is, briefly, as follows:—The site of the eye is marked by a slight depression on the surface of the forebrain on either side. There later an outgrowth occurs from the ventro-lateral aspect on each side of the forebrain, in the form of a hollow vesicle, whose cavity is continuous with that of the forebrain. This outgrowth is termed the *primary optic vesicle* [vesicula ophthalmica]. The lateral surface of the vesicle comes into contact with the surface epithelium of the head and this epithelium becomes thickened at the area of contact. The superficial portion of the vesicle expands, while its connection with the brain remains slender; becoming depressed on the surface, it forms a cup-shaped hollow, the *secondary optic vesicle* or *optic cup* [caliculus ophthalmicus] whose wall is formed of two layers, an outer investing layer and an inner inverted one.

The *chorioidal fissure* is present almost from the first stages, as a cleft on the ventral aspect of both the distal portion of the vesicle, or cup, and of the stalk; and it is formed by an infolding of the surface into the cavity of the vesicle along a narrow linear area.

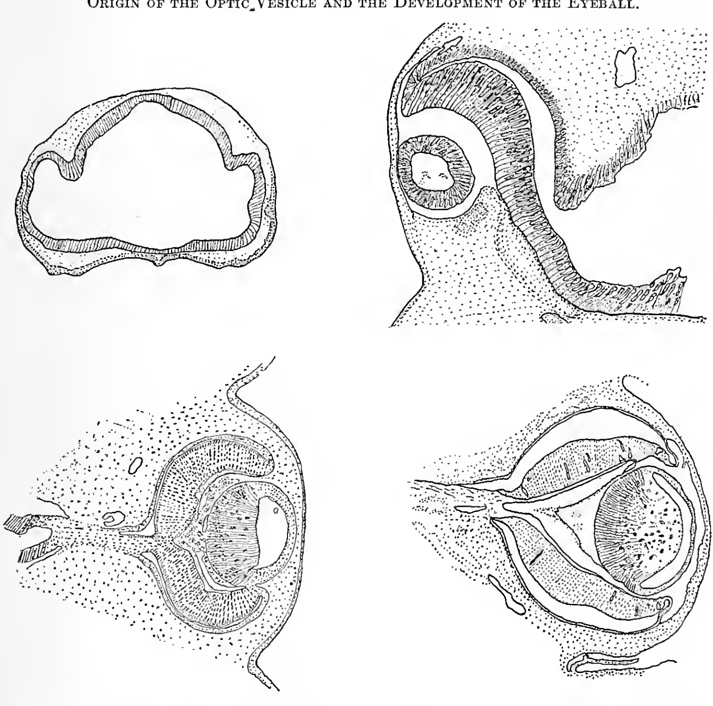
In this cleft are found vessels which pass to the hollow of the optic cup. The margins of the cleft meet and fuse, and enclose the vessels in the interior—hence the enclosure of the a. centralis retinæ within the optic nerve, and of the hyaloid artery in the interior of the vitreous. Should the margins of the cleft remain separate, the condition of coloboma results.

From the optic cup is formed the whole of the retinal or nervous tunic. It will be noticed that this tunic is composed of two layers, with a narrow slit-like interval between them, but that the layers are continuous with one another at the margin of the cup. This margin is afterward found, in the fully developed eye, at the pupillary margin of the iris. The outer investing layer forms the pigment layer, and the inner inverted layer gives rise to the other parts of the retina, viz., the pars optica, over the bottom of the cup, the pars ciliaris, in the ciliary region, and the pars iridica, near the margin of the original cup, including the dilatator and sphincter pupillæ muscles of the iris.

The *lens* is formed as a hollow invagination from the surface epithelium, which sinks into the hollow of the optic cup. The margins meet and fuse, enclosing a cavity, and the lens mass sinking more deeply in, loses its connection with the surface, and a layer of mesoderm passes in between them.

The anlages of the lens and the primitive retina are at first in contact with one another. They gradually draw apart, and the intervening space is filled by the *vitreous humour*. The origin of the vitreous humour is not yet fully understood, but it appears to be developed from the adjacent ectoderm of the optic cup, and in part from the surrounding mesoderm.

FIGS. 823, 824, 825 AND 826.—SECTIONS REPRESENTING FOUR SUCCESSIVE STAGES IN THE ORIGIN OF THE OPTIC VESICLE AND THE DEVELOPMENT OF THE EYEBALL.



The optic cup and the lens are surrounded by mesoderm and from it are formed the structures of the tunica vasculosa (middle coat) in its different parts, viz., chorioid, ciliary body and iris, and also the sclera and cornea (fibrous portion).

The anterior chamber is formed by cleavage of the mesoderm, a space appearing in it, filled with fluid. The mesoderm surrounding this space forms the endothelium lining the anterior chamber. The mesoderm also forms a vascular covering for the front of the lens, termed the *capsula vasculosa lentis*, or pupillary membrane, which disappears from the surface of the lens in the later months of development.

The eyelids and conjunctiva are formed from the integumentary covering of the eye. The former are mostly skin folds, which, at first separate, meet and fuse with one another along their margin. Subsequently they become undermined by the ingrowth of epithelium from a central horizontal slit, the rima palpebrarum; the central part of the invading epithelium breaks down, and the free folds are formed.

The lacrimal gland is developed from a series of tubular outgrowths from the conjunctival sac.

The lacrimal canals and naso-lacrimal duct are formed by the growth of an epithelial band which passes through the mesoderm to the nasal cavity along the naso-lacrimal groove. This band loses its primitive connection with the groove, and is reunited to the lid margins by secondary epithelial bands which grow from the naso-lacrimal duct to the lid margin. Similarly a secondary connection is later made with the nasal cavity at the lower end of the duct. The position of the naso-lacrimal duct corresponds to the line of union of the nasal and maxillary processes; but the duct does not represent a portion of the cleft between these processes, and is formed secondarily between them.

IV. THE EAR

Under the name of the ear [organon auditus] there is included a number of structures of which some, the ear proper, constitute the auditory mechanism—that is, an apparatus for the collection, transmission and reception of the waves of sound; while others—the semicircular ducts and associated structures—are concerned in receiving and transmitting impressions produced by movements of the head. These impressions constitute the basis of what may be termed the static or equilibratory sense, and afford data employed in estimating movements of the body in relation to surrounding objects.

The former of these, the ear proper, consists of three main parts, each possessing distinct structural and functional characters. The first portion, often known as the *external* ear, consists of a receptive organ placed upon the surface of the head, the auricle or pinna, and of a short tube, the external auditory meatus, which leads into the interior, and is closed at its deep end by the tympanic membrane.

The *second* portion, known as the *middle* ear, consists of the tympanic cavity, a small air-containing chamber in the petrous portion of the temporal bone, connected with the nasal part of the pharynx by a tube, the auditory (or Eustachian) tube. From the tympanic chamber a recess passes posteriorly and leads to a cavity in the mastoid portion of the temporal bone, the mastoid or tympanic **antrum.** A chain of three small bones transmits the sounds across the middle ear.

The third part, or *internal* ear which contains the essential sensory apparatus, lies within the complex cavities in the interior of the petrous temporal bone known as the osseous labyrinth. It consists of (1) the utricle and saccule, two small vesicular structures lying in the bony vestibule, and (2) the membranous semicircular ducts and (3) the membranous cochlea, which lie within the corresponding bony canals.

These structures are filled with fluid, the endolymph, and communicate with one another. They are largely separated from the bony walls by fluid, perilymph, and they are lined by sensory epithelium. Closely related to the epithelial sensory cells are found the terminal branches of the cochlear and vestibular nerves.

The description of the three divisions of the ear is taken up in order from the surface inward.

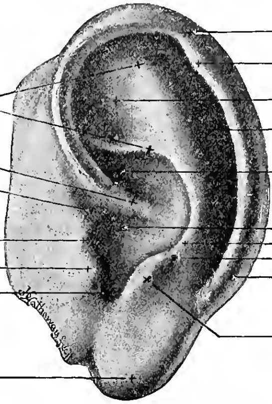
1. THE EXTERNAL EAR

The **external ear** consists of the auricle attached to the side of the head, and the external auditory meatus leading from it to the middle ear (fig. 829).

THE AURICLE

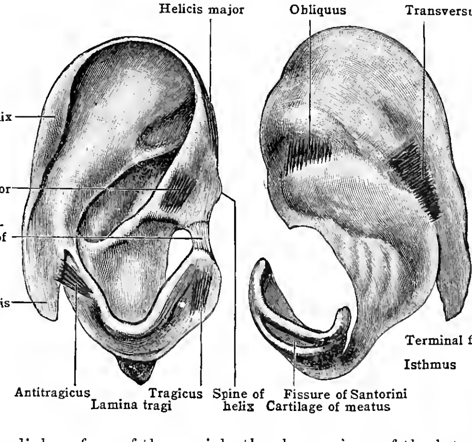
The **auricle,** or pinna, is an irregular oval plate-like structure which lies upon the lateral surface of the head. It presents a lateral and a medial surface. The lateral surface is irregularly concave (fig. 827). The deepest part of its concavity situated near the centre, is termed the **concha,** and it is partially divided by a prominent oblique ridge, the **crus of the helix,** into a superior part, the **cymba conchæ,** and a large inferior part, the **cavum conchæ.** The cavum conchæ leads into the external auditory meatus, and is bounded ventrally by a prominent process, the **tragus,** which projects posteriorly over the entrance to the meatus. The tragus, is separated from the crus of the helix by a well-marked depression, the **anterior incisure** and has a small tubercle on it superiorly, the **supratragic tubercle.** Bounding the cavum conchæ posteriorly and inferiorly is a projection, the **antitragus,** lying opposite, but inferior, to the tragus, and between the two is a deep notch, the **intertragic notch** [incisura intertragica]. A prominent semicircular ridge, the **anthelix,** bounds the concha posteriorly and superiorly. Inferiorly it is separated from the antitragus by a slight depression, the **posterior auricular sulcus.** Superiorly the anthelix divides into two ridges, the **crura of the anthelix,** and between these is a shallow depression, the **triangular fossa.** The superior and dorsal margin of the auricle is inverted and forms a prominent rim, the **helix,** which

Fig. 827—Lateral Surface of the Left Auricle.



is continued anteriorly into the crus of the helix, and inferiorly into the **lobule.** An elongated depression, partly overlapped by the helix, termed the **scapha** (scaphoid fossa) separates the helix and the anthelix. Superiorly and dorsally the free margin of the helix frequently presents a slight projection, the **auricular. tubercle** (tubercle of Darwin).

Fig. 828.—Lateral and Medial Surface of the Cartilage of the Right Auricle and its Muscles, etc.



Upon the medial surface of the auricle the depressions of the lateral surface are represented by elevations, viz., the **eminence of the concha,** the **eminence of the scapha,** and the **eminence of the triangular fossa,** respectively; and the elevations by depressed areas, viz., the **fossa of the anthelix, transverse sulcus of the anthelix,** and the **sulcus of the crus of the helix.** The attachment of approximately one-third of the medial surface covers up the two latter depressions. The **cephalo-auricular angle,** between the dorsal free part of the auricle and the side of the head, averages 20 to 30 degrees.

Structure of the Auricle

The features of the auricle just described are mainly produced by a plate of yellow elastic cartilage, the **auricular cartilage.** In addition to the elevations and depressions already noted, it presents the following additional features. Projecting anteriorly from the helix, near the crus is a small tubercle, **spine of the helix** (fig 828); while the posterior margin of the helix terminates in a pointed tail-like process, the **cauda helicis** which is separated inferiorly from the antitragus by the deep **antitrago-helicine fissure.** Another deep fissure, the **terminal notch** [incisura terminalis auris], separates the cartilage of the auricle from that of the meatus, leaving only a narrow strip, the **isthmus,** connecting the two. The cartilage of the tragus, the **lamina tragi,** is separated from that of the auricle and is attached to the lateral margin of the cartilage of the meatus.

The auricle is covered on both its medial and lateral aspects by skin which closely follows the irregularities of the cartilage. Thus it is tightly bound to the perichondrium of the lateral surface by the subcutaneous areolar tissue, but much more loosely attached to the medial surface, and in the subcutaneous tissue there is little fat except in the lobule, which is made up almost entirely of fat and tough fibrous tissue. **Hairs** are abundant but rudimentary, except in the region of the tragus and antitragus, where they may be large and long, particularly in males and in the aged. **Sebaceous glands** are found on both surfaces, and are especially well developed in the concha and triangular fossa, but **sudoriferous glands** are few and scattered.

Ligaments and muscles.—The auricle is attached to the side of the head by the skin, by the continuity of its cartilage with that of the acoustic meatus, and by certain extrinsic ligamente and muscles. Three ligaments may be distinguished in the connective tissue:—The **anterior ligament,** stretching from the zygoma to the helix and tragus; the **superior ligament,** from the superior margin of the bony external acoustic meatus to the spine of the helix; and the **posterior ligament,** from the mastoid process to the eminence of the concha. There are also three extrinsic muscles, the anterior, superior, and posterior auricular (see p. 337, fig. 341). Six intrinsic muscles are distinguished. These are poorly marked in man and vary much in development. Upon the lateral surface (fig. 828) the **helicis major** stretches from the spine of the helix to the ventral superior margin of the helix; the **helicis minor** overlies the crus helicis; the **tragicus** runs vertically upon the tragus; and the **antitragicus** stretches from the antitragus to the cauda helicis. Upon the medial surface (fig. 828) the **transversus auriculæ** stretches between the eminences of concha and scapha, and the **obliquus** between the eminences of the concha and the triangular fossa. Two small muscles occasionally present are the m. pyramidalis auriculæ (Jungi) and the m. incisuræ helicis (Santorini).

Vessels and Nerves of the Auricle

The arteries are the auricular branch of the posterior auricular and the anterior auricular branches of the superficial temporal arteries. The veins are the anterior auricular vein of the posterior facial (temporal) and the auricular branches of the posterior auricular veins. The latter vessels sometimes join the transverse (lateral) sinus through the mastoid emissary vein. The **lymphatics** empty into the anterior, posterior and inferior auricular lymph-nodes. The sensory **nerves** of the auricle are the branches of the great auricular, small occipital (p. 977, fig. 753), and auriculo-temporal (p. 941, fig. 740). The muscles are supplied by the posterior auricular branch of the facial (p. 944, fig. 740).

Variations

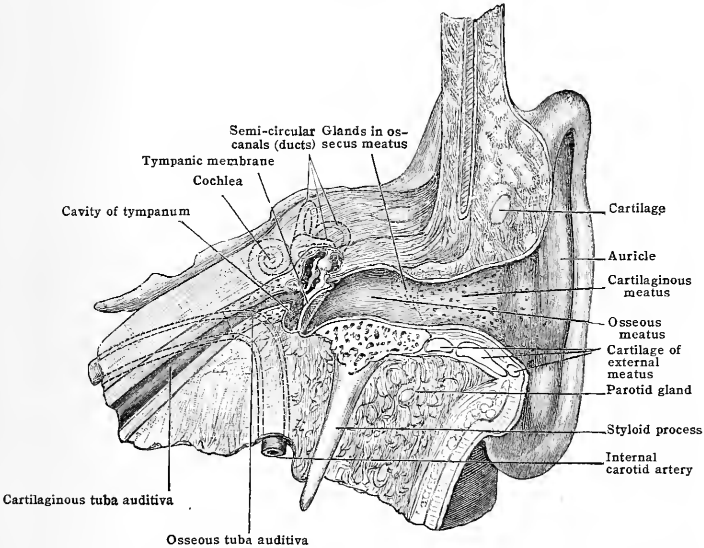
There are many variations in the size, shape, and conformation of the auricle and in the cephalo-auricular angle. These are associated not only with differences in sex, age, and race, but are also found in individuals of the same family.

THE EXTERNAL AUDITORY MEATUS

The **external auditory (acoustic) meatus** [meatus acusticus externus] extends medially and somewhat anteriorly and inferiorly from the concha to the tympanic membrane (fig. 829). It is about twenty-five mm. (1 in.) long, and, owing to the obliquity of the tympanic membrane, its anterior and inferior wall is 5–6 mm.

longer than the posterior and superior. It consists of a lateral **cartilaginous** and a medial **osseous portion.** The canal describes an S-shaped curve in both horizontal and vertical directions. Near the auricular end it is convex anteriorly and inferiorly, while at the tympanic end the curve is reversed, and is concave in the same direction. The lumen is irregularly elliptical in outline, the longer axis being vertical at the auricular, but nearly horizontal at its tympanic end. The meatus is constricted at about its centre, and also near the tympanum.

FIG. 829.—VERTICAL SECTION OF THE MIDDLE AND EXTERNAL EAR.



Relations.—The *anterior wall* is in relation with the condyle of the mandible medially, and with the parotid gland laterally; the *inferior wall* is closely bound to the parotid gland; and the *posterior wall* of the bony part is separated by only a thin plate of bone from the mastoid cells. The *superior wall* is separated at its medial end by a thin plate of bone from the epitympanic recess, and laterally a thicker layer of bone separates it from the cranial cavity.

Structure of the meatus.—The walls of the meatus are formed laterally of fibro-cartilage and medially of bone, lined internally by skin. The cartilage is folded upon itself to form a groove, deficient in its dorsal part, where the edges of the cartilage are united by dense connective tissue. The cartilaginous groove is thus converted into a canal. Medially, the cartilage forms about one-third of the circumference; laterally, two-thirds. Two fissures (*incisures of Santorini*) usually occur in its anterior wall (fig. 828). Laterally the cartilage is directly continuous with the cartilage of the auricle and medially it is firmly connected with the lateral lip of the osseous portion. The **osseous portion,** which forms slightly more than half the canal, is formed by the tympanic portion of the temporal bone; it is described in connection with that bone.

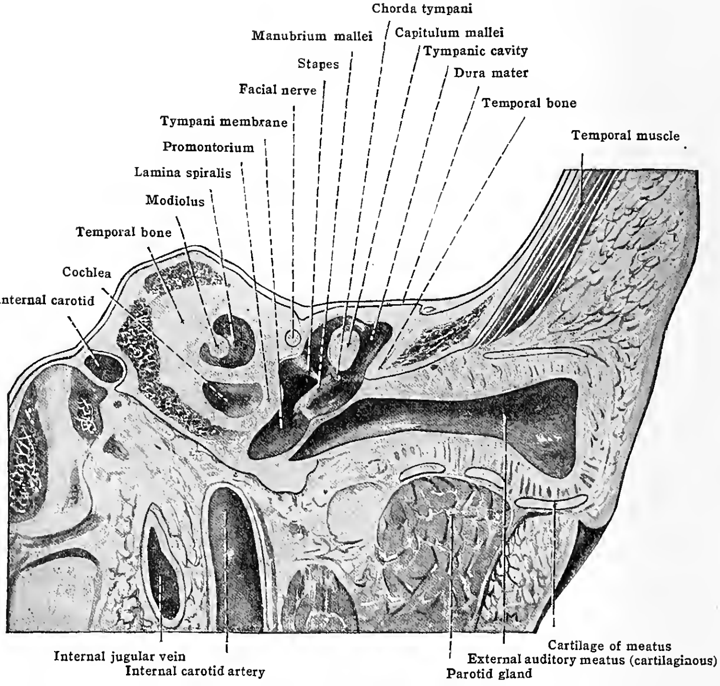
The **skin of the meatus** forms a continuous covering for the canal and tympanic membrane. It is thick in the cartilaginous, but very thin in the bony, part of the meatus, especially near the tympanic end, where it is tightly bound to the periosteum. In the cartilaginous meatus it contains numerous fine hairs and sebaceous glands, but neither hairs nor sebaceous glands are found in the bony meatus. Tubular **ceruminous glands,** which secrete the **cerumen** (ear wax), form a nearly continuous layer throughout the cartilaginous, but occur on only a small part of the posterior and superior wall of the bony, meatus. The openings of their ducts appear as dark points to the naked eye (fig. 829).

The arteries are branches from the posterior auricular, superficial temporal, and deep auricular arteries (q.v.). The veins and lymphatics connect with those of the auricle and empty similarly. The nerves are branches from the auriculo-temporal and the auricular ramus of the vagus.

2. THE MIDDLE EAR

Under the term middle ear there are included the tympanic cavity (tympanum), the tympanic antrum and the auditory (Eustachian) tube. These form a continuous irregular passage, filled with air, and located within and upon the surface of the temporal bone. The tympanum is shut off from the external ear

Fig. 830.—Frozen Coronal Section of the Right Ear. (Somewhat Enlarged.)



by the tympanic membrane; and from the chamber which forms the internal ear by the structures which fill in the cochlear and vestibular fenestræ. It communicates with the pharynx by the auditory (Eustachian) tube. The structures of the middle ear are of importance, and the study is somewhat difficult, on account of the small size of the structures, the depth at which they lie, and the hard character of the surrounding bone.

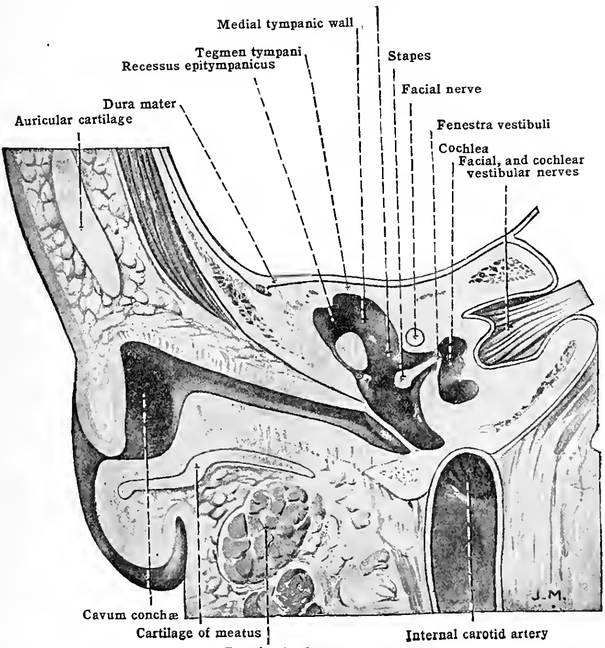
The illustrations (figs. 829, 830, 831, 833, 834) will help to explain the text and should be constantly referred to. Figs. 830 and 831 are taken from frozen sections traversing the right ear in the coronal planes; while figs. 833, 834 represent dissections.

The parts to be considered in order are the tympanic membrane, the tympanic cavity, the tympanic antrum and the auditory (Eustachian) tube.

The Tympanic Membrane

The **tympanic membrane** [membrana tympani] (fig. 835) is elliptical in shape, its long axis nearly vertical, measuring 9 to 10 mm., its short axis, 8 to 9 mm. It slopes medially from the superior and posterior to the inferior and anterior wall of the meatus, forming, as a rule, with the superior wall, an angle of 140 degrees. It varies, however, greatly in form, size, and obliquity. Viewed from the meatus, it appears as a semitransparent membrane, which sometimes has a reddish tinge. It is drawn medially and made funnel-shape by the manubrium of the malleus, but the walls of the funnel bulge toward the meatus (fig. 834). The most depressed point at its centre, the **umbo,** is slightly inferior and posterior to the centre of the membrane, and corresponds to the tip of the manubrium (fig. 832). From it a whitish streak, the **malleolar stria,** caused by the manubrium shining through, passes superiorly toward the circumference. At the superior end of the stria is a slight projection, the **malleolar prominence,** formed by the lateral process of the malleus. From it two folds, the **anterior and posterior**

FIG. 831.—FROZEN CORONAL SECTION OF THE RIGHT EAR. (Somewhat Enlarged.)



plicæ, stretch to the extremities of the tympanic sulcus (fig. 832). The small triangular area of the membrane bounded by the plicæ, is termed the **pars flaccida** (Shrapnell's membrane). It is thin and flaccid, and is attached directly to the petrous bone in the tympanic notch (notch of Rivinus). The larger part of the tympanic membrane, the **pars tensa,** is inferior to the plicæ and is tightly stretched. Its thickened margin, the **limbus,** is attached by a **fibro-cartilaginous annulus** to the tympanic sulcus, and at the spines of the tympanic ring is continuous with the plicæ.

Structure of the tympanic membrane.—The tympanic membrane is about .1 mm. thick, and consists of four layers. The lateral **cutaneous layer,** relatively thick, is a continuation of the skin lining the external auditory meatus. Next to it is a **radiate fibrous layer,** composed of connective tissue, the fibres of which are attached to the manubrium of the malleus and radiate from it. Medial to it is the **circular fibrous layer,** which has its fibres arranged concentrically and is especially thick at the circumference. It is closely bound to the radiate layer. The **mucous layer,** which is a continuation of the mucosa of the tympanic cavity, covers the medial surface of the membrane smoothly, except where the manubrium of the malleus causes a projection. The fibrous layers are attached to the fibro-cartilaginous ring and are not present in the pars flaccida.

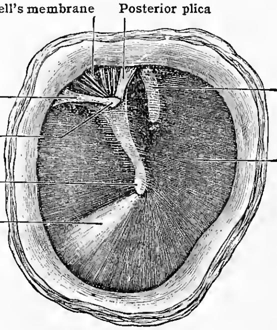
The Tympanic Cavity

The **tympanic cavity** [cavum tympani], as has been stated, is an air-space, lined with mucous membrane, situated between the external and the internal ear. It is of irregular outline, but, roughly, it is a slit-like cavity, lying in an oblique antero-posterior plane. Its transverse diameter measures only from 2–4 mm., while the vertical and antero-posterior diameters measure about 15 mm. (fig. 834).

It is narrowest at the centre, and wider superiorly than inferiorly. The bony walls have already been partly described with the temporal bone, and hence the description given here will refer to the appearance found in the fresh, or unmacerated condition.

It will be noticed (see fig. 829) that the *floor* of the space is on very much the same horizontal plane as the floor of the external meatus, and the lower margin of the tympanic membrane. The *roof*, on the other hand, lies at a much

Fig. 832.—Lateral Surface of the Left Membrana Tympani. (Enlarged from life.)



higher level than the upper margin of that membrane. Hence the cavity may be divided into two regions, a *lower* part, corresponding in extent to the tympanic membrane, and an *upper*, above the upper border of the membrane, known as the *epitympanic recess*. This division forms a definite chamber, and contains the head of the malleus and the body and short process of the incus. It is on the posterior part of this chamber that the communication with the tympanic antrum is found (fig. 835).

As the shape of the tympanum is irregular, its walls are not everywhere clearly marked off from one another, but there may be recognized (figs. 829 and 835) a **roof,** or **tegmental** wall, **a floor,** or **jugular** wall, **a medial** or **labyrinthine** wall and a **lateral** or **membranous** wall, an **anterior** or **carotid,** and a **posterior** or **mastoid** boundary or wall.

The roof, or tegmental **wall,** is formed by a portion of the tegmen tympani, a thin plate of bone which is continued backward to form the roof of the tympanic antrum. This plate is formed by the petrous part of the temporal bone, and at its lateral margin is the petro-squamous suture, where a slight deficiency in the roof may occur.

The floor, or **jugular wall** is very narrow transversely, and is in intimate relation to the internal jugular vein (fig. 831). As shown in fig. 833, the surface is frequently very irregular from stalactite-like projections between which are the tympanic cellulæ (air cells), while near the back there is occasionally a marked projection corresponding externally to the root of the styloid process.

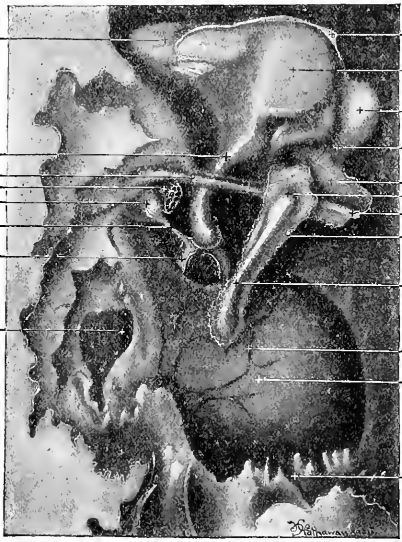
The posterior or **mastoid wall** presents at its lower part, many additional tympanic cellulæ, and higher up, an elevation, the *pyramidal eminence*, on whose apex is an aperture transmitting the tendon of the stapedius muscle. The fleshy belly of that muscle is contained in a cavity in the interior of the bony pyramid of the posterior wall. Lateral to this is an aperture, the *apertura tympanica canaliculæ chordæ*, through which the chorda tympani nerve enters the tympanum, covered by a reflexion of the mucous membrane. Between this opening and the pyramid is a slight elevation; and above it is a fossa, termed the *sinus posterior*. Above this again is a recess, where the posterior ligament of the incus is attached, known as the *fossa incudis*. This portion of the posterior wall forms the boundary of the epitympanic recess. Here the cavity of the tympanum is continued with that of the antrum tympanicum, or mastoid antrum, a large irregular space into which open the mastoid cells (see p. 1092). The boundaries of the orifice are formed above by the tegmen tympani, medially by the prominences of the lateral semicircular canal and facial nerve, and laterally by a plate of bone termed the *scutum*.

The **carotid (anterior) wall** presents superiorly the *tensor tympani muscle* in its canal, and at a lower level the opening of the *tuba auditiva* (Eustachian tube) (fig. 835). Inferiorly, a thin, bony wall, covered with tympanic cellulæ and pierced by the carotico-tympanic nerves, separates the tympanic cavity from the carotid canal.

The **membranous (lateral) wall** is formed mainly by the tympanic membrane, with the small rim of bone to which it is attached, but superiorly the lateral wall of the epitympanic recess is formed by a plate of bone termed the scutum.

The **labyrinth (medial) wall** (fig. 833) presents inferiorly the *promontory*, produced by the first turn of the cochlea with the *tympanic plexus* (Jacobson's nerve) lodged in grooves upon its surface. Inferior and posterior to the promontory is a depression or fossula at the bottom of

Fig. 833.—The Labyrinth (Medial) Wall of the Right Tympanum with the Tympanic Ossicles in Position.



which is the *cochlear fenestra* (fenestra rotunda), closed by the *secondary tympanic membrane*, and posterior to the promontory is a smooth projection, the *subiculum of the promontory*, which forms the inferior border of a rather deep depression known as the *tympanic sinus*. Anteriorly and superiorly is the *cochleariform process*, and superiorly and posteriorly are a depression or fossula leading to the *vestibular fenestra* (*fenestra ovalis*), which is closed by the base of the stapes, the prominence of the facial (Fallopian) canal, and the prominence of the lateral semicircular canal, the two latter being formed in the medial wall of the entrance to the mastoid antrum.

The **tympanic mucous membrane** forms a complete covering for the walls and contents of the tympanic cavity. It is continuous anteriorly with the mucosa of the tuba auditiva (Eustachian tube) and posteriorly with that of the tympanic (mastoid) antrum and mastoid cells. It is a thin, transparent, vascular membrane intimately united to the periosteum. As it passes from the walls to the contents of the tympanic cavity, besides covering the ligaments of the malleus and the incus and the tendons of the tensor tympani and stapedius muscles, it forms a number of special folds and pouches.

The **anterior malleolar fold** is reflected from the tympanic membrane over the anterior process and ligament of the malleus and the adjacent part of the chorda tympani, and the **posterior malleolar fold** stretching between the manubrium and the posterior tympanic wall, surrounds the lateral ligament of the malleus and the posterior part of the chorda tympani. Each of these folds presents inferiorly a concave free border, and between them and the tympanic membrane are two blind pouches, the **anterior and posterior malleolar** recesses or pouches of Tröltsch. Connected with the posterior recess is a third cul-de-sac, the **superior recess** of the tympanic membrane, or pouch of Prussak, situated between the pars flaccida of the tympanic membrane and the neck of the malleus. The floor of this recess is formed by the lateral process of the malleus, and is lower than its outlet; therefore, the recess may serve as a pocket in which pus or other fluid may accumulate. A somewhat variable fold of mucosa, the **plica incudis,** passes from the roof of the tympanic cavity to the body and short process of the incus. The body and short process of the incus, the head of the malleus, and this fold incompletely separate off a lateral **cupular portion** of the epitympanic recess, and a **stapedial fold** stretches from the posterior wall of the tympanic cavity and surrounds the stapes, including the oburator membrane, which stretches between its crura. Other inconstant folds have been described. The mucosa of the typanic cavity, except over the tympanic membrane, promontory, and ossicles, is covered by a columnar ciliated epithelium.

FIG. 834.—THE TYMPANIC CAVITY, ANTERIOR WALL REMOVED.

Bones.—The tympanic cavity contains three small movable bones, joined together and to the walls of the cavity, and having attached to them special muscles and ligaments. These auditory ossicles form a chain across the tympanic cavity connecting the tympanic membrane and the vestibular (oval) fenestra. They are the **malleus,** the **incus,** and the **stapes,** and are described in the section on OSTEOLOGY on p. 79.

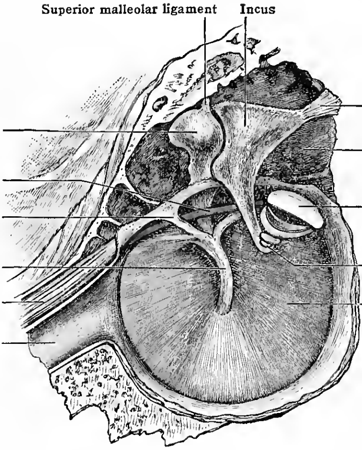
Articulations of the ossicles.—The manubrium and lateral process of the malleus are imoedded in the tympanic membrane. The margin of the irregularly elliptical articular surface bn the posterior side of the head of the malleus is bound to the body of the incus by a thin capsular ligament, forming a diarthrodial joint, the **incudo-malleolar articulation.** From the inner surface of the capsular ligament, a wedge-shaped rim projects into the joint cavity and incompletely divides it. The long crus of the incus lies parallel to the manubrium of the malleus and on its superior and medial aspect (figs. 833 and 835). It ends in the lenticular process. The convex extremity of this fits into the concavity on the head of the stapes, to form a diarthrodial joint, the **incudo-stapedial articulation.** From its articulation with the incus, the stapes passes almost horizontally across the tympanic cavity to its junction with the medial wall. The cartilage-covered edge of the base is bound to the cartilage-covered rim of the vestibular (oval) fenestra by the annular ligament of the base of the stapes, thus forming the **tympano-stapedial syndesmosis.**

Ligaments of the ossicles.—In addition to the attachment of the manubrium of the malleus and the base of the stapes to the walls of the tympanic cavity, the bones have additional ligamentous attachments. The **superior malleolar liga-**

ment runs almost vertically from the superior wall of the epitympanic recess to the head of the malleus (fig. 834). The **anterior malleolar ligament** extends from the angular spine of the sphenoid bone through the petro-tympanic (Glaserian) fissure to the anterior or long process of the malleus, which it surrounds, and is inserted with it into the neck of the malleus. The **lateral malleolar ligament** is short and thick, and runs from the margins of the tympanic notch (notch of Rivinus) to the neck of the malleus (fig. 834). The **posterior ligament of the incus** passes from the fossa on the posterior tympanic wall to the crus brevis of the incus (fig. 835). The **superior ligament** of the incus is little more than mucous membrane; it runs from the tympanic roof to the body of the incus.

Muscles of the ossicles.—Each of the muscles of the ossicles is contained in a bony canal. The **tensor tympani** is a pinniform muscle about 2 cm. long. It arises from the cartilaginous part of the tuba auditiva (Eustachian tube), from the

Fig. 835.—Medial Surface of Right Membrana Tympani. (Enlarged.)



adjacent part of the great wing of the sphenoid, and from the bony walls of the semicanal which encloses it. It ends in a round tendon which turns almost at right angles over the cochleariform process and passes laterally across the tympanic cavity to be attached to the manubrium of the malleus near the neck. It draws the manubrium medially and tightens the tympanic membrane, and is supplied by the motor division of the trigeminal cranial nerve, through the tensor tympani branch from the otic ganglion. The **stapedius** arises in the interior of the hollow pyramidal eminence. The tendon escapes through the openings at the apex and then turns inferiorly and is inserted on the posterior surface of the neck of the stapes. It draws laterally the ventral border of the base of the stapes and is supplied by the facial nerve.

Vessels and nerves.—The arteries of the tympanic cavity are the anterior tympanic from the internal maxillary artery (fig. 451), the stylo-mastoid from the posterior auricular artery, the superficial petrosal from the middle meningeal artery, the inferior-tympanic from the ascending pharyngeal (fig. 446), and the carotio-tympanic branch from the internal carotid. The veins empty into the superior petrosal sinus and into the posterior facial (temporo-maxillary vein). The nerves are the tympanic plexus formed by the tympanic branch of the glosso-pharyngeal (p. 951), and the inferior and superior carotico-tympanic nerves which join the internal carotid plexus of the sympathetic (p. 960). The small superficial petrosal nerve takes its origin from the tympanic plexus, and the chorda tympani crosses the tympanic cavity from the posterior to the anterior wall (p. 948, figs. 738 and 835).

The Antrum Tympanicum

The aperture (*aditus*) in the upper part of the posterior wall of the tympanum leads into the chamber termed the **antrum tympanicum.** This is a comparatively large cavity, of irregular form, lying mainly behind but also somewhat above and lateral to the tympanum, and extends to the medial end of the external auditory meatus. It is lined by mucous membrane, continuous with that of the tympanic cavity, and into it open the **mastoid cells** (cellulæ mastoideæ). These cells are small, irregular cavities in the interior of the mastoid process and they communicate with one another freely. They vary exceedingly in their size and asrangement.

The *antrum tympanicum* has a roof, formed by the tegmen tympani, a posterior wall, separating it from the bend of the transverse sinus, a lateral wall, lying about 10 mm. from the surface of the head, a medial wall, and an anterior wall (see also p. 78).

The Auditory (Eustachian) Tube

The **auditory tube** [tuba auditiva] (Eustachian tube) (fig. 829) extends from the carotid (anterior) wall of the tympanic cavity inferiorly, medially, and anteriorly to the pharynx. It is about 37 mm. (1.5 in.) long. In the lateral one-third of its length it has a bony wall, while in the medial two-thirds this wall is cartilaginous. The **osseous part** (see p. 74) begins at the **tympanic ostium** on the anterior wall of the tympanic cavity. It is in relation medially and inferiorly with the carotid canal, and gradually contracts to its irregular medial extremity, which is the narrowest point in the tube, and is termed the **isthmus.** The **cartilaginous part** is firmly attached to the osseous and lies in a sulcus at the base of the angular spine of the sphenoid bone. It gradually dilates in its passage to the lateral wall of the pharynx, where its opening, **pharyngeal sotium,** is just posterior to the inferior nasal concha (turbinated bone). The walls of the cartilaginous part are formed by a cartilaginous plate which is folded so as to form a trough-like structure, consisting of a medial and a lateral **lamina,** completed inferiorly by a **membranous lamina** formed of connective tissue.

A small portion of the lumen in the superior part of the cartilaginous tube remains permanently open; elsewhere the walls are in contact, except during deglutition, when they are opened by the tensor veli palatini muscles. The mucosa of the osseous part is thin, and firmly attached to the bony wall, but in the cartilaginous part it becomes thicker, looser, and folded, and contains mucous glands, especially near the pharynx, where there is also some adenoid tissue.

3. THE INTERNAL EAR

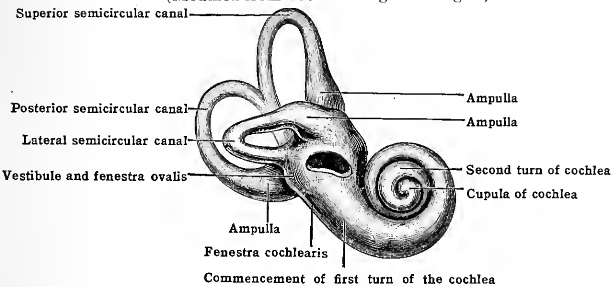
The **internal ear** [auris interna] is the essential part of the organ of hearing. It consists of a cavity, the osseous labyrinth, contained within the petrous portion of the temporal bone, and enclosing a membranous labyrinth. The **osseous labyrinth** is divided into **cochlea, vestibule,** and **semicircular canals** (see p. 80), and the accompanying figures (338–838)show their position and relations.

It will be noticed that the vestibule forms a central chamber, from which the semicircular canals and the cochlea branch off; the former from the superior and dorsal portion, and the latter from the ventral and inferior.

It will further be noticed that the bony wall of this vestibule shows depressions and ridges on its interior, which are associated with parts of the membranous labyrinth, viz., an upper recess for the utricle (fovea hemielliptica) and a lower recess for the saccule (fovea hemispherica). There are openings in the bony wall for the entrance of nerves to the different parts of the membranous labyrinth, and for the transmission of the ductus endolymphaticus, as well as the small openings of the semicircular canals (ducts) and the opening of the cochlear canal (or duct).

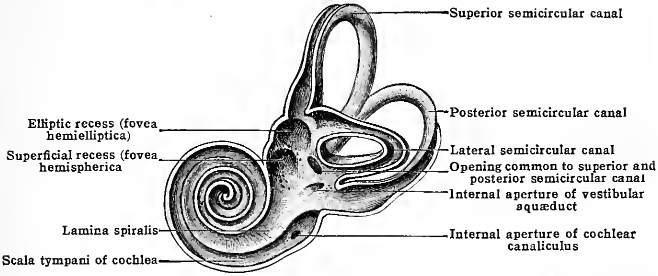
The **membranous labyrinth,** in which the auditory (acoustic) nerves (cochlear and vestibular) end, lies within the osseous labyrinth, the form of which it more or less closely resembles. Thus the membranous semicircular ducts lie within the bony semicircular canals, the membranous cochlear duct within the bony cochlea; while the vestibule contains two small membranous sacs, the utricle and saccule, with their connections. The membranous structures are much smaller in diameter than the osseous, and are partially separated from the bone by an endothelial-lined space which is filled with a fluid, the **perilymph.** The membranes are in contact, however, with the bony wall along their convex margin, and the utricle, saccule and cochlear canals are in contact with the bony walls over the areas where the nerves enter them. The fluid which fills the membranous labyrinth is termed the **endolymph.**

FIG. 836.—THE OSSEOUS LABYRINTH OF THE RIGHT SIDE. (Modified from Soemmerring. Enlarged.)



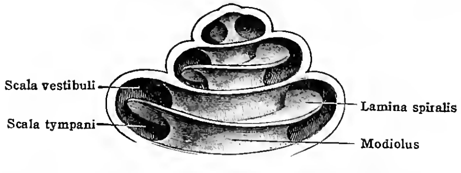
The **utricle** is an oval tubular sac, whose rounded end lies in the superior and dorsal portion of the vestibule. It is here tightly bound to the elliptic recess (fovea hemielliptica) by connective tissue and by the entrance of the filaments of the utricular division of the vestibular nerve as they pass from the superior

FIG. 837.—INTERIOR OF THE OSSEOUS LABYRINTH OF THE LEFT SIDE. (Modified from Soemmerring. Enlarged.)



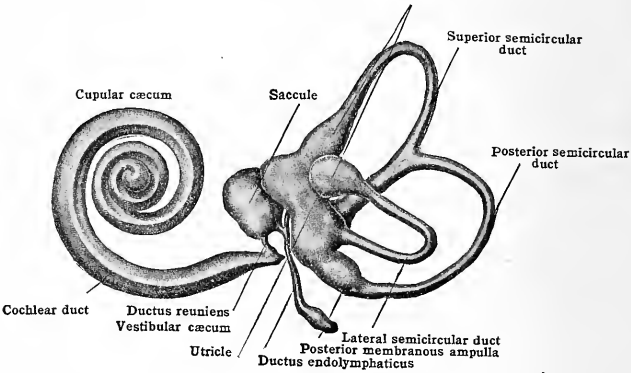
macula cribrosa to the wall of the utricle. In the anterior part of the interior of the utricle, an oval, whitish, thickened area, **macula acustica utriculi,** marks the terminal distribution of the nerve, and posteriorly the utricle is joined by the orifices of the semicircular ducts.

FIG. 838.—INTERIOR OF THE OSSEOUS COCHLEA. (Enlarged.)



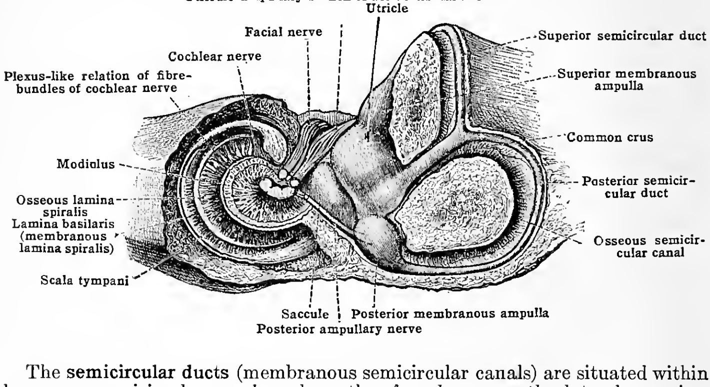
The **saccule** is a flattened, oval sac, smaller than the utricle, and situated in the anterior and inferior part of the vestibule. It is bound to the spherical recess (fovea hemisphærica) by connective tissue and by the saccular division of the vestibular nerve, filaments of which extend from the middle macula cribrosa to the anterior and medial wall of the saccule, to be distributed over a thickened area, **macula acustica sacculi.** Anteriorly and inferiorly the saccule gradually passes into a short canal, the **ductus reuniens,** which connects it with the cochlear duct, and posteriorly the very small **endolymphatic duct** is attached (fig. 839).

Fig. 839.—Diagram of the Left Membranous Labyrinth. (Deaver.)



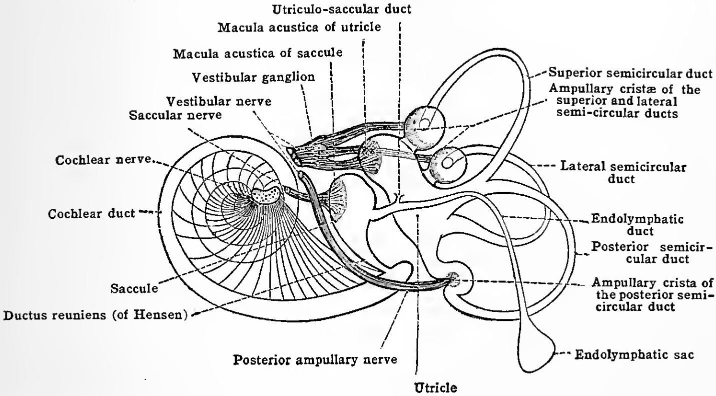
This extends through the aquæductus vestibuli to the posterior surface of the petrous portion of the temporal bone, where it ends in a dilated blind pouch, the **endolymphatic** sac, situated just beneath the dura. Just beyond the saccule, the endolymphatic duct is joined at an acute angle by a short canal of minute calibre, the **utriculo-saccular duct,** which opens into the utricle through its anterior medial wall and, with the endolymphatic duct, connects it with the saccule.

Fig. 840.—Right Membranous Labyrinth of a Newborn Child. Exposed by Partial Removal of the Bony Labyrinth. Dorsal view. (Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



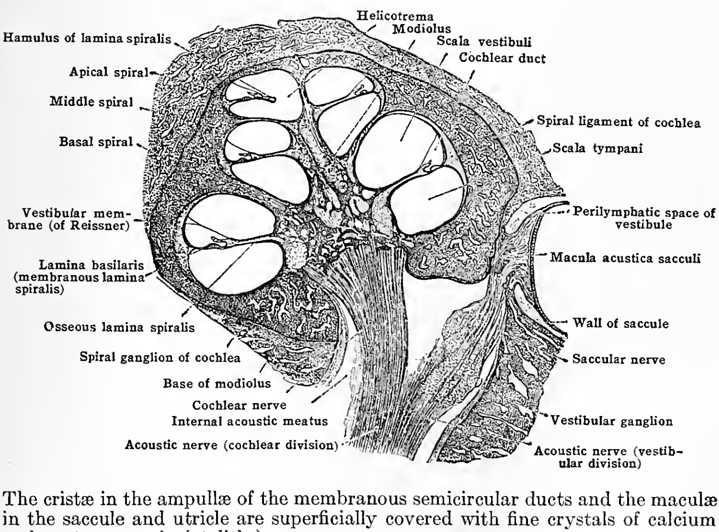
The **semicircular ducts** (membranous semicircular canals) are situated within the osseous semicircular canals and are, therefore, known as the lateral, superior, and posterior semicircular ducts. They connect with the utricle by five openings, the posterior and superior ducts uniting to form a common crus before their termination. Each duct is less than a third of the diameter of the bony canal, from which it is separated by a large **perilymphatic space**, except along the greater curvature, where it is attached. The ducts are dilated in the bony

FIG. 841.—SCHEMATIC REPRESENTATION OF THE RIGHT MEMBRANOUS LABYRINTH AND THE DIVISIONS OF THE ACOUSTIC NERVE. Dorsal view. (Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



ampullæ, producing the **lateral, superior,** and **posterior membranous ampullæ,** and on the attached surface of each of these there is a transverse groove, the **ampullary sulcus,** for the ampullary division of the vestibular nerve, and corresponding to the sulcus a ridge, the **ampullary crista,** projects into the interior.

FIG. 842.—AXIAL SECTION THROUGH THE DECALCIFIED COCHLEA OF A NEWBORN CHILD (Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)

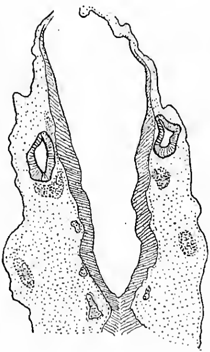


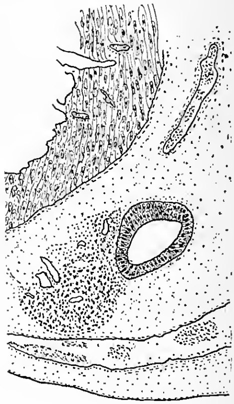
The cristæ in the ampullæ of the membranous semicircular ducts and the maculæ in the saccule and utricle are superficially covered with fine crystals of calcium carbonate, **otoconia** (otoliths).

The **cochlear duct** (membranous cochlea or scala media) begins within the cochlear recess of the vestibule in a blind pouch, the **vestibular cæcum,** and traversing the spiral canal of the cochlea, ends just beyond the hamulus of the lamina spiralis in a second blind pouch, the **cupular cæcum.** Close to the vestibular cæcum it is joined to the saccule by the **ductus reuniens.** It is lined throughout by epithelium and is somewhat triangular in cross-section. Its floor is formed by thickened periosteum over part of the osseous lamina spiralis and by a fibrous membrane, the **lamina basilaris,** which stretches from the free border of the lamina spiralis to a thickening of the periosteum, the **spiral ligament** of the cochlea, on the peripheral wall.

The epithelium of this floor is greatly modified, forming the **spiral organ (organ of Corti)** in which the fibres of the cochlear nerve terminate. The peripheral wall is formed by the thickened periosteum upon the peripheral wall of the cochlear canal, while the third wall is

Figs. 843 and 844.—Sections Showing Early Stages in the Development of the Otic Vesicle.





fomed by a thin **vestibular membrane (membrane of Reissner)** which passes from the periphera wall to the osseous lamina spiralis near its free margin, forming with the lamina spiralis an angle Ff 45 degrees. The cochlear duct and the osseous spiral lamina divide the cochlear spiral canal into two parts, one next to the basilar membrane, the **scala tympani,** and one next to the vestibular membrane, the **scala vestibuli.** The scala tympani unites with the scala vestibuli at the helicotrema, and from the scala tympani a minute canal, the **perilymphatic duct,** passes through the cochlear canaliculus and connects with the subarachnoid space. A thin fibrous layer, the **secondary tympanic membrane,** closes the cochlear fenestra (fenestra rotunda) and thus separates the scala tympani from the tympanic cavity, and the vestibular perilymphatic space (scala vestibuli) is separated from the tympanic cavity by the base of the stapes in the vestibular fenestra (fenestra ovalis).

Vessels and nerves.—The internal auditory artery , fig. 514), a branch of the basilar artery, accompanies the cochlear and vestibular nerve. It supplies the vestibule, semicircular canals, and cochlea, and their membranous contents. The blood is returned by the internal auditory vein into the inferior petrosal sinus, and by small veins which pass through the cochlear and vestibular aqueducts to the inferior and superior petrosal sinuses. **The acoustic nerve** (p. 949, figs. 841 and 842) consists of a vestibular and a cochlear division. The membranous ampullæ of the semicircular ducts and the acoustic maculæ of the utricle and saccule are supplied by the vestibular nerve. The spiral organ (organ of Corti) in the cochlear duct is supplied by the cochlear nerve.

Development of the Ear

The external and middle ears have a common origin quite distinct from that which gives rise to the internal ears, and are to be regarded as portions of the branchial arch apparatus secondarily adapted to auditory purposes.

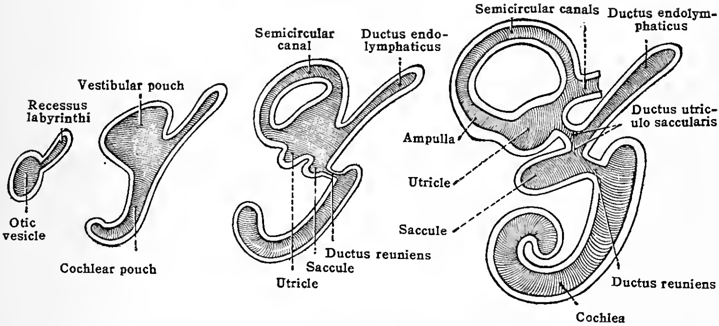
The sensory epithelium lining the internal ear is derived from the otic vesicle, a structure formed from the surface epithelium of the head, while the membrane and bones surrounding it are formed from the mesoderm which surrounds the vesicle.

Internal ear.—The process of development is as follows (fig. 843–845):—

By invagination from the surface, an epithelial-lined vesicle, termed the primitive otocyst or otic vesicle, is formed dorsal to the extremity of the second branchial cleft. It is at first merely a pit on the surface, but eventually it loses its connection with the surface epithelium and sinks into the interior. It then undergoes the alterations in shape and form shown in the accompanying fig. 845. The vesicle is at first somewhat oval, and a small hollow stalk arises from it, the *recess of the labyrinth*, which forms the ductus endolymphaticus in the adult. The ventral and dorsal portions of the cyst become enlarged. From the former two hollow plate-like projections arise, one placed vertically, the other horizontally, and along the free margins of these plates are formed the semicircular ducts, the superior and posterior from the vertical, and the lateral duct from the horizontal one. The central part of each plate becomes peforated, and the periphery is thus altered to the characteristic loop form of the adult semicircular ducts. The portion of the vesicle lying between the dorsal and ventral enlargements forms the primitive *atrium*. It becomes divided into two chambers, an upper dorsal connected with the semicircular ducts, forming the utricle, and an inferior ventral, the saccule, which is connected with that portion of the ventral expansion from which the cochlea is formed.

The recess of the labyrinth retains its connection with the cavity of the vesicle at the narrow stalk connecting utricle and saccule, (fig. 845). The cochlea is formed by an outgrowth from the saccule, at first straight, and later coiled in the fashion formed in the adult.

Fig. 845.—Diagrams Illustrating Successive Stages in the Development of the Membranous Ear.



External and middle ear.—The *external auditory meatus* is formed from the dorsal part of the first (external branchial) pouch, and the tympanic membrane from the membrane which forms the floor of that pocket and separates it from the corresponding pharyngeal (internal) pouch. Its outer surface is thus formed from ectoderm and the inner from endoderm. The internal (pharyngeal) groove gives origin to the tympanic cavity and tuba auditiva, the margins of the groove uniting.

The *auricle* is formed from nodular thickening of the tissue bounding the outer end of the first branchial cleft. Three nodules are formed on the first (mandibular) and three on the second (hyoid) arch. Behind the latter, the free margin of the auricle is formed by a folding off of the integument. Later an additional tubercle is formed dorsally between the two sets of nodules. From the mandibular nodules are formed mainly the tragus and the crus of the helix—from the hyoid tubercles the scaphoid fossa, antitragus and the crus of the anthelix.

The *auditory ossicles*, and their muscles are formed from the neighbouring arches, the malleus and incus, together with the tensor tympani, being derived from the first arch, while the stapes and stapedius probably are derived from the second arch.

The tympanic cavity is at first quite small, but later increases greatly, partly by the condensation of the loose areolar tissue which underlies its mucous membrane, the auditory ossicles and their muscles being thus apparently brought within the cavity, and partly by the absorption of the neighbouring bone. By this latter process the antrum and the tympanic and mastoid cells are formed, all these depressions or cavities being lined by mucous membrane continuous with that of the tympanic cavity.

The Ear in the Child.—The ear in the newborn child shows several marked differences from the adult ear.

Among the principal differences are the following:—

1. The external auditory meatus is very short, since the bony portion is undeveloped, and is represented only by the tympanic ring. As a result of this, the tympanic membrane is placed on a level with the surface of the head, and looks very much downward.
2. The mastoid or tympanic antrum is relatively very large, and lies above and behind the tympanum. Its lateral wall is only about 1 mm. in thickness.
3. The mastoid process is not developed, and hence the stylomastoid foramen opens on the surface behind the lower part of the tympanic ring. The exit of the facial nerve is therefore much more upon the surface, and higher up than in the adult.
4. The auditory (Eustachian) tube is nearly horizontal in direction.
5. The ossicles are of nearly the same size as in the adult.

SECTION IX

DIGESTIVE SYSTEM

Revised for the Fifth Edition

By C. M. JACKSON, M.S., M.D.,

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF MINNESOTA

IN order to furnish the living protoplasm with the materials necessary for energy, growth and repair, a constant supply of food must be provided. Most foods must be rendered soluble, and must undergo certain preliminary chemical changes, in order to render them suitable for absorption and assimilation by the cells of the body. For this preparation of the food-supply, the *digestive system* [apparatus digestorius] is provided, which includes the alimentary canal and certain accessory glands (salivary glands, liver and pancreas). The alimentary canal is divided into a number of successive segments, varying in size and structure according to their function. These segments (fig. 846) include the mouth, pharynx, œsophagus, stomach, small and large intestines.

Typical structure.—The most important layer of the tubular alimentary canal is the inner *mucous membrane* [tunica mucosa]. From its epithelial lining, the various digestive glands are derived, and through it the process of absorption takes place. The epithelium is supported by a fibrous tunic [lamina propria mucosæ] beneath which is a thin layer of smooth muscle [lamina muscularis mucosæ]. The layer next in importance is the *muscular* coat [tunica muscularis] which propels the contents along the canal. It is typically composed of two layers of smooth (involuntary) muscle, the inner circular and the outer longitudinal in arrangement. Between the mucosa and the muscularis is a loose, fibrous *submucous* layer [tela submucosa], which allows the folds in the mucosa to spread out when the canal is distended. Finally, there is an outer *fibrous* coat [tunica fibrosa], which in the abdominal cavity becomes the smooth *serous* coat [tunica serosa], or visceral layer of the peritoneum, which eliminates friction during movements. The variations in the structure of the alimentary canal in different regions are due chiefly to differences in the mucosa.

Glands.—Since the glands form an important part of the digestive system, the classification of glands in general will be discussed briefly. A gland may be somewhat loosely defined as an organ which elaborates a definite substance which is either a waste product to be eliminated (excreted), or a secretion to be further utilized by the organism. Glands may be divided into (a) *ductless glands* (e. g., spleen, thyreoid gland), which pour their secretions directly into the blood or lymph; and (b) *glands with ducts*, which open upon an epithelial surface. Some organs, however, belong in *both* classes (e. g., liver, pancreas).

The glands with ducts (the so-called 'true' glands) are always derived from an epithelial surface and may be further subdivided upon the basis of either (1) form or (2) cell-structure. According to **form**, glands are classified as either *tubular* or *saccular* (alveolar, acinous). Each of these may be either *simple* or *compound* (branched). The compound saccular form is often called *racemose*. Moreover, intermediate forms (tubulo-racemose) occur.

According to **cell-structure** and character of secretion, glands are divided into mucous and serous types. In the *mucous* type, the cells appear larger and lighter (fig. 867) when swollen with mucus which is secreted for purposes of lubrication. The goblet-cells of the intestine represent unicellular glands of this type. In the *serous* (or albuminous) type of glands, the cells usually appear somewhat smaller and more deeply stained, with numerous zymogen granules (fig. 867). The secretion is a watery, albuminous fluid, which contains the digestive enzymes. There occurs also a *mixed* type, with separate mucous and serous saccules, or both types of cells may occur in the same saccule (the serous cells as 'demilunes' or 'crescents' (fig. 867). In all cases, the epithelial gland cells are supported by a fibrous connective-tissue stroma, which provides a rich vascular and nerve-supply.

Morphology.—The alimentary canal in comparative anatomy is divided into the *head-gut* (mouth and pharynx), *fore-gut* (œsophagus and stomach), *mid-gut* (small intestine), and *hind-gut* (large intestine). Embryologically, the mid-gut corresponds roughly to the portion of the archenteron attached to the yolk-sac, the portions of the archenteron anterior and posterior to the yolk-sac being designated as fore-gut and hind-gut respectively. (See Section I, Morphogenesis.) The lining epithelium of the alimentary tract is endodermal, excepting the anal canal and the mouth cavity, which are lined by invaginations of the ectoderm.

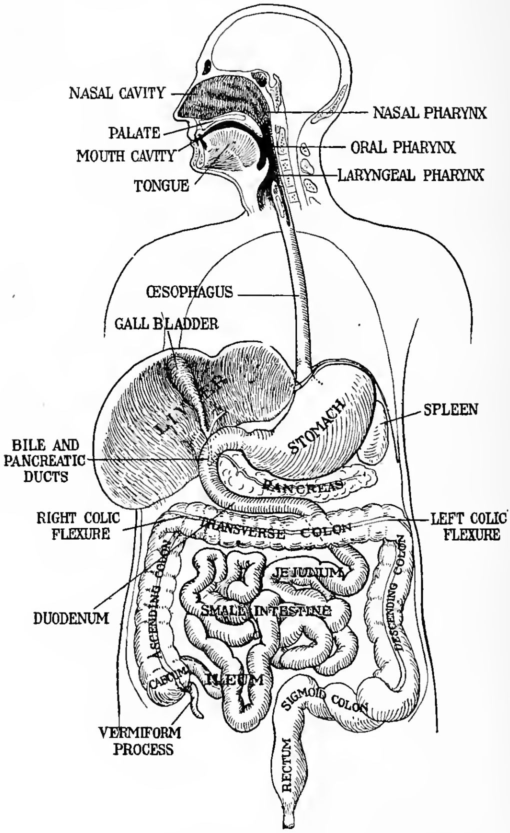
In the region of the mouth and pharynx, the digestive and respiratory systems are closely related in position, structure, function and origin. Morphologically, the head-gut represents a primitive alimentary-respiratory apparatus.

THE MOUTH

The **oral cavity** [cavum oris] represents the first segment of the alimentary canal. Its walls are exceedingly specialised in structure, corresponding to its manifold functions (mastication, insalivation, taste, speech, etc.).

Boundaries.—The oral cavity communicates anteriorly with the exterior through the transverse *oral fissure* [rima oris], and posteriorly with the pharynx through the *isthmus of the fauces* [isthmus faucium]. The *anterolateral walls* are formed by the flexible lips and cheeks. The *roof* is chiefly immovable and is

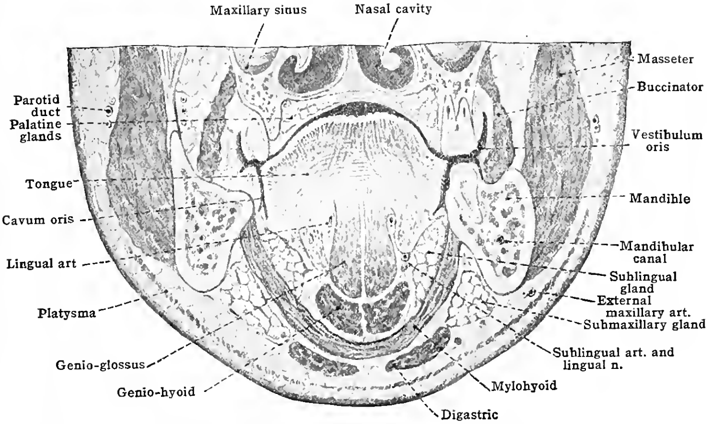
Fig. 846.—Diagram of the Alimentary Canal.



formed by the upper jaw with the hard and soft palate. The movable *floor* is formed by the lower jaw and the tongue.

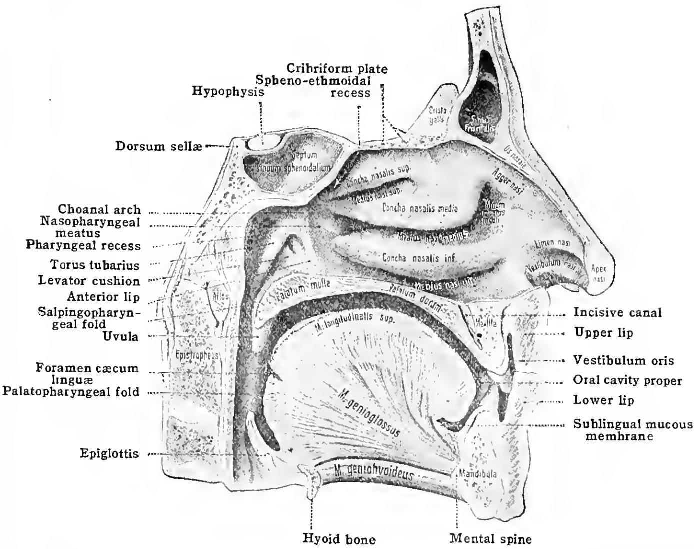
Subdivisions.—The oral cavity is subdivided by the alveolar and dental arches into an inner cavity, the *oral cavity proper* [cavum oris proprium], and an outer *vestibule* [vestibulum oris] adjacent to the lips and cheeks (fig. 848). When the upper and the lower teeth are in apposition, the vestibule communicates with the oral cavity proper (aside from the small interdental spaces) only through a space behind the last molar teeth on each side. Opening into the oral cavity are certain accessory glands, the salivary glands.

Fig. 847.—Coronal Section through Oral Region.



Structure.—Of the typical layers of the alimentary canal, only the mucous membrane can be recognised as a continuous layer in the mouth cavity. Even this is greatly modified and in structure somewhat resembles the skin, from which it is derived and with which it is continuous

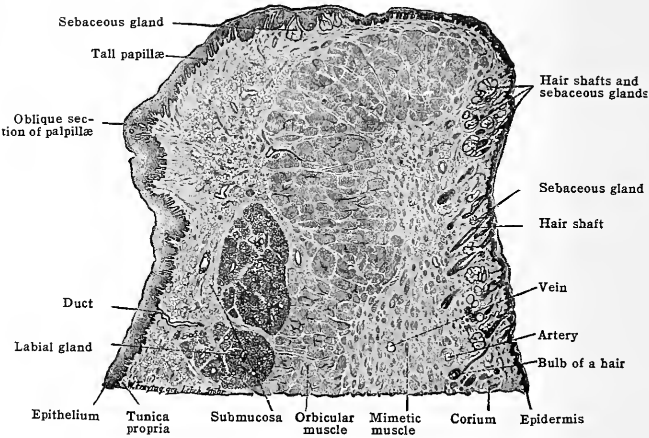
Fig. 848.—Mid-sagittal Section of the Head, through Oral and Nasal Regions. (Rauber-Kopsch.)



at the rima oris. The submucosa is a strong fibrous layer connecting the mucosa with adjacent structures, and lodging numerous racemose mucous glands. The muscles in the walls of the mouth cavity are not homologous with the typical muscularis of the alimentary canal. The outer fibrous tunic is also wanting.

The development of the oral cavity.—As stated in the section on MORPHOGENESIS, the oral cavity has its origin in a depression, the **oral fossa**, situated between the ventrally bent, developing head and the region occupied by the developing heart. This fossa is bounded anteriorly by the fronto-nasal process, and laterally by the maxillary and mandibular processes, portions of the first branchial arches. The fossa is lined by ectoderm. Its floor is in apposition with the cephalic end of the archenteron, lined by entoderm, the ectoderm of the oral fossa and the entoderm of the archenteron being in immediate contact and forming the **pharyngeal membrane.** The oral fossa deepens with further development, and becomes the oral sinus. The pharyngeal membrane becomes perforated in embryos about 2 mm. in length and disappears, leaving a free communication between the oral sinus and archenteron. On each side of the developing head and in a latero-ventral position there is early developed an area of thickened ectoderm, known as the nasal area. These areas soon develop into depressions, the nasal fossæ, and assume a position, one on either side of the fronto-nasal process; on each side of the fronto-nasal process there is developed a prominent protuberance, the globular process, each process forming the median wall of a nasal fossa. The lateral wall of each nasal fossa also thickens to form the lateral nasal process. With the further development, the ventral portion of each lateral nasal process fuses with the corresponding globular process, the maxillary processes also uniting with the globular processes, in this way separating the nasal fossæ from the oral sinus. With the further growth toward the median line of the maxillary processes the fronto-nasal process becomes narrower, ultimately forming the nasal septum and a small median portion of the upper jaw, the remainder of the upper jaw being formed by the maxillary processes, and the lower jaw having its origin in the mandibular processes.

FIG. 849.—SAGITTAL SECTION OF THE LOWER LIP. (Lewis and Stöhr.)



Variations.—The mouth is rarely absent, due to failure of the stomatodeal invagination, or imperforate, due to atresia of the pharyngeal membrane. Other variations will be mentioned in connection with the various mouth organs.

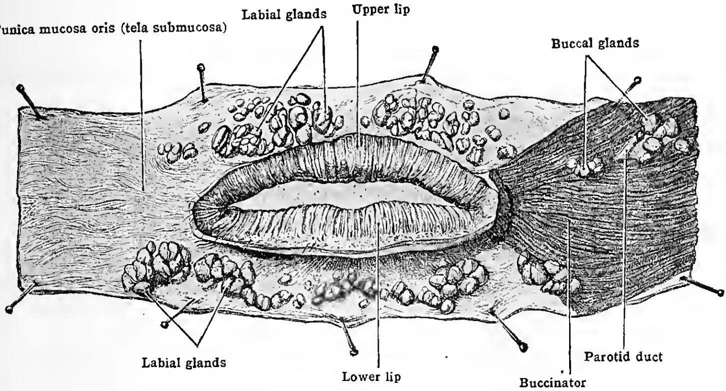
Comparative.—The phylogenetic origin of the mouth cavity from the integument is indicated not only by the ectodermal origin of its lining epithelium, but by its general structure and its appendages. Among the latter may be noted the teeth (representing modified dermal papillæ), sebaceous glands, and (in some rodents) even hairs in the mucosa lining pouches in the cheeks.

THE LIPS AND CHEEKS

The **lips** [labia oris] form the anterior wall of the mouth cavity. The *lower lip* [labium inferius] is marked off from the chin by the sulcus mentolabialis. The *upper lip* [labium superius] extends upward to the nose medially and the sulcus nasolabialis laterally. The *philtrum* is a median groove on the upper lip extending from the septum of the nose above to the *labial tubercle* [tuberculum labii superioris] below, at the middle of the rima oris. On each side of the rima oris the upper and the lower lips are continuous at the angle of the mouth [angulus oris], which is usually opposite the first premolar teeth. Laterally, the lips are continuous with the *cheeks* [buccæ], which form the lateral walls of the mouth cavity.

In **structure,** the *lips* (fig. 849) consist essentially in a middle layer of cross-striated muscle (orbicularis oris) covered externally by skin which is continuous through the rima oris with the mucosa forming the inner layer of the lips. The mucosa lines the vestibulum oris and is reflected upon the gums above and below. In the median line above and below, there extends from the lip to the gum a small fold of the mucosa [frenulum labii superioris vel inferioris]. The structure of the *cheeks* (figs. 847, 864) is similar to that of the lips but somewhat more complicated.

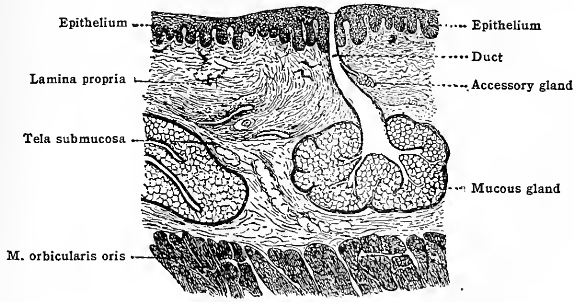
Fig. 850.—Labial and Buccal Glands Exposed by Dissection of the Skin from in Front. (From Toldt's Atlas.)



The muscular basis of the **cheek** is the buccinator muscle. External to this is a thick layer of fat [corpus adiposum buccæ] covered partly by the dermal muscles (platysma, zygomaticus, etc.) and lastly the skin. Internally the cheek is lined by the mucosa, continuous with that of the cheeks. The parotid duct opens into the vestibule opposite the second upper molar tooth.

Glands.—The *skin* of the lips and cheeks is well supplied with the usual sudoriparous and sebaceous glands. The mucosa likewise presents two kinds of glands, the sebaceous and the mucous glands. The *sebaceous* glands are relatively few in number and variable, being present in about 30 per cent. of cases in the adult (Stieda). They are similar in structure to those of

Fig. 851.—Section of Labial Mucosa, Showing Glands. × 16. (From Toldt's Atlas.)



the skin (though not associated with hair follicles), and when present are visible as small yellowish bodies in the mucosa. They occur chiefly near the free margins of the lips and along the cheek opposite the teeth.

The *mucous glands* are much more numerous and constantly present (figs. 850, 851). They are all of the racemose type. They are variable but small in size, and closely packed together in the submucosa of the lips [glandulæ labiales], where they may easily be felt. Those of the cheeks [gl. buccales] are less numerous. A few of them especially in the region of the molar teeth [gl. molares], are placed outside the buccinator. The ducts of the molar glands pierce this muscle near the parotid duct to open on the surface of the mucosa.

Vessels and nerves.—The mucosa of the lips and cheeks has a characteristic reddish hue, on account of the numerous blood-vessels which are visible through the thick but transparent stratified squamous epithelium (figs. 849, 851) The numerous papillæ of the lamina propria are highly vascular. The *blood-supply* of the lips and cheeks is derived chiefly from the labial (coronary) and buccal arteries. The rich *nerve-supply* (sensory) is from the infra-orbital, mental and buccal branches of the fifth. The lips are especially sensitive near the rima oris.

Development.—During the second month in the human embryo, ledges of epithelium grow into the substance of the mandibular and the fused fronto-nasal and maxillary processes. These ledges develop into grooves which separate the upper and the lower lips from the upper and the lower jaws, the grooves forming the oral vestibule.

The philtrum and labial tubercle are said to correspond to the lower part of the fronto-nasal process. A failure of union between the globular and the maxillary processes presents an arrest of development resulting in the malformation known as "hare-lip."

In the late fœtus and newborn, the red portion of the lips consists of an external smooth *pars glabra*, and an inner zone, *pars villosa*, which is covered with numerous villus-like projections. The largest of these reach a length of 1 mm. They also extend backward in an irregular band along the mucosa of the cheek. They disappear during the first few weeks of post-natal life.

In the infant, the corpus adiposum is especially well developed. On account of its supposed aid as a support for the buccinator in sucking, it has been called the "sucking pad."

The sebaceous glands of the mucosa are said not to appear until about the age of puberty.

Variations.—As is well known, the lips and cheeks are exceedingly variable in shape, size and structure in different individuals. There are also characteristic differences according to race and sex in the form and structure of the lips, rima oris, beard, etc. The "hare-lip" malformation was mentioned above.

Comparative.—Typical lips are found only in mammals, and are probably organs phylogenetically developed in connection with the process of suckling.

THE PALATE

The **palate** forms the roof of the mouth cavity proper, and consists of two portions, the anterior or hard palate and the posterior or soft palate.

The **hard palate** [palatum durum] (figs. 848, 852) is continuous in front and laterally with the alveolar processes of the upper jaw, and gives attachment posteriorly to the soft palate. It separates the mouth from the nasal cavity. It is supported by the palatine process of the maxilla and the horizontal part of the palate bone. The *oral surface* is concave from side to side, and also from before backward. It is covered by a thick, somewhat pale mucosa, which is firmly adherent to the periosteum through the submucosa. The submucosa contains numerous mucous *glands* [gl. palatinæ] (fig. 852), similar to those of the lips.

In the median line of the hard palate is a line or ridge, the *raphe* (fig. 852) terminating anteriorly in the small *incisive papilla*, which corresponds in position to the bony incisive foramen. Anteriorly there occur four to six more or less distinct *transverse ridges* [plicæ palatinæ transversæ]. Near the posterior margin of the hard palate there is on each side of the raphe a small pit (fig. 852), the *foveola palatina*, which is variable and inconstant.

The **soft palate** [palatum molle] (figs. 848, 892) separates the posterior portion of the mouth cavity from the nasal part of the pharynx. It is attached to the hard palate anteriorly and to the pharyngeal wall laterally. The posterior portion or *velum* projects backward and downward into the pharynx. Its free margin presents a median conical projection, the *uvula*, and splits laterally on each side to form two folds, the palatine arches, between which is located the palatine tonsil (fig. 852). The palatine arches and tonsil will be described later in connection with the pharynx.

Structure.—The soft palate is a fold of mucous membrane enclosing a fibrous aponeurosis, muscles, vessels, and nerves. It is marked in the middle line by a raphé indicating the line of junction of the two halves from which it was formed.

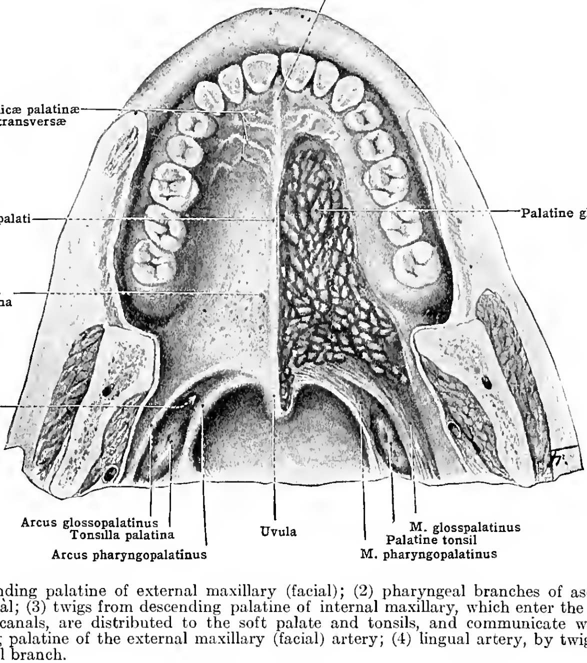
The posterior layer of the mucous fold which is directed toward the cavity of the pharynx is continuous with the nasal mucous membrane; the anterior layer lies in the posterior boundary of the mouth and is continuous with the mucous membrane of the hard palate. The structure of the mucosa is very similar to that of the lips (fig. 849). Mucous glands are numerous in both layers, but more especially in the anterior, and make up a large portion of the mucosa and submucosa (figs. 851, 852).

The aponeurosis is attached above to the posterior margin of the hard palate; laterally it is continuous with the aponeurotic layer of the pharyngeal wall; below, toward the lower margin of the velum, it gradually disappears. It gives attachment to fibres of the levator veli palatini and the pharyngo-palatinus (palato-pharyngeus) and to the tendon of the tensor veli palatini.

Muscles.—The muscles of the soft palate are described later (p. 1134) with those of the pharynx, with which they are closely associated.

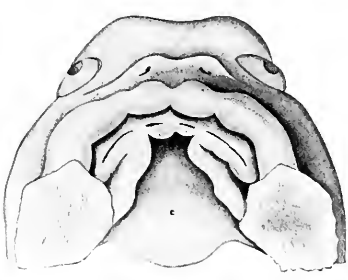
Vessels and nerves.—The arterial supply of the *hard palate* is derived chiefly from the major palatine branches of the internal maxillary. The arteries of the *soft palate* include:

FIG. 852.—ROOF OF MOUTH, SHOWING HARD AND SOFT PALATE DISSECTED ON ONE SIDE. (Rauber-Kopsch.)



(1) Ascending palatine of external maxillary (facial); (2) pharyngeal branches of ascending pharyngeal; (3) twigs from descending palatine of internal maxillary, which enter the smaller palatine canals, are distributed to the soft palate and tonsils, and communicate with the ascending palatine of the external maxillary (facial) artery; (4) lingual artery, by twigs from the dorsal branch.

FIG. 853.—DEVELOPING PALATINE SHELVES, VIEWED FROM BELOW. (McMurrich, from His.)



The *sensory nerves* to the palate are derived chiefly from the fifth through the sphenopalatine ganglion. The hard palate is supplied by the nasopalatine and anterior palatine branches; the soft palate chiefly by the median and posterior palatine branches. The *motor* nerves will be mentioned later in connection with the muscles.

The development of the palate.—The hard and soft palates arise (fig. 853) in two ridges of tissue, designated the **palate shelves**, which develop on the inner surfaces of the maxillary processes. These shelves grow toward the median line, and at the beginning of the third month of fœtal life meet beneath the nasal septum, uniting with each other and with the nasal septum, the union taking place from before backward. The incisive foramen indicates the place of meeting of the premaxillary and palate shelves, which closes the primitive communication between the oral and the nasal cavity. A want of union of the palate shelves presents an arrest of development known as cleft-palate. The *uvula* is similarly formed by the union of the posterior ends of the lateral palate anlages, and a failure to unite may produce a bifid uvula. The transverse *palatine ridges* are better developed in the infant than in the adult, and may assist in holding the nipple in sucking.

Variations.—*Cleft-palate* and *bifid uvula* were mentioned above. The transverse *palatine ridges* are quite variable in number and prominence. On each side of the *incisive papilla* there is often found a small pit or shallow tube, a vestige of the embryonal incisive canal (Merkel). Sometimes there is instead a single median pit, representing the lower end of the incisive (Stenson's) canal. These pits are remnants of the primitive embryonic communication between mouth and nasal cavities.

Comparative.—The palate is absent in fishes and amphibia, the choanæ opening directly into the primitive mouth cavity. In some birds, the palate shelves fail to unite, leaving a normal cleft-palate. The incisive (Stenson's) canal remains open permanently in some mammals (e. g., ruminants), bifurcating above and thus placing the mouth cavity in communication with the nasal cavity on each side in the vicinity of Jacobson's organ. The transverse palatine ridges are much better developed among many mammals, especially the carnivora.

THE TONGUE

The **tongue** [lingua] is a muscular organ covered with mucous membrane and located in the floor of the mouth. It is an important organ of mastication, deglutition, taste and speech. Upon its upper surface (figs. 854, 864) is a **V**-shaped groove (sulcus terminalis) indicating the division of the tongue into two parts. The larger anterior part, or *body* [corpus linguæ] belongs to the floor of the mouth, while the smaller posterior part, or *root* [radix linguæ], forms the anterior wall of the oral pharynx. The *inferior* surface (facies inferior) of the tongue is chiefly attached to the muscles of the floor of the mouth, from the hyoid bone to the mandible (fig. 858). Anteriorly and laterally, however, the inferior surface of the body is free and covered with mucosa. The superior surface of the body is called the *dorsum*. It is separated from the inferior surface by the *lateral margins*, which meet anteriorly at the *tip* [apex linguæ].

The **dorsum** of the tongue usually presents a slight *median groove* [sulcus medianus linguæ]. Its posterior end corresponds to a small pit of variable depth, the *foramen cæcum*, which is placed at the apex of the **V**-shaped *terminal sulcus*, The dorsum of the body has a characteristic rough appearance due to numerous small projections, the *lingual papillæ*.

Lingual papillæ.—Five or six varieties of papillæ are distinguished, between which intermediate forms occur. The *conical* [papillæ conices] and *thread-like* [papillæ filiformes] are most numerous, and are arranged more or less distinctly in rows parallel with the terminal sulcus (fig. 856). They are best developed toward the mid-line of the dorsum in its posterior part. As shown in vertical section (fig. 856), each papilla consists of an axial core of vascular fibrous tissue (from the lamina propria) often beset with smaller secondary papillæ. The stratified squamous epithelial covering often presents numerous thread-like prolongations from the apex of the papilla. The papillæ vary from 1 to 3 mm. in length.

The **fungiform** ("toad-stool shaped") papillæ are somewhat similar to the conical in structure, but larger and more prominent, with an expanded free portion and a slightly constricted stalk of attachment. They are relatively few in number and are scattered irregularly over the dorsum, being most numerous near the margins (fig. 864). They are easily distinguished in life by their larger size and reddish colour. A smaller, flattened variety of the fungiform is sometimes called the *lenticular* ('lens-shaped') papillæ. (This term, however, is applied by Toldt to certain small rounded elevations with underlying lymphatic nodules in the mucosa of the root of the tongue.)

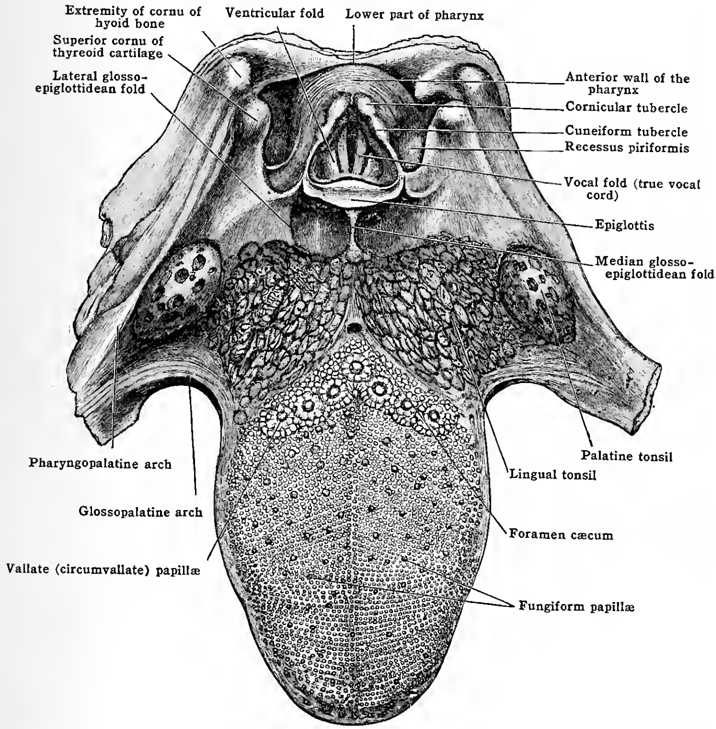
The **vallate** (circumvallate) papillæ, usually seven to eleven in number, are conspicuous and arranged in a **V**-shaped line parallel with and slightly anterior to the sulcus terminalis, (figs. 854, 857). They are, as a rule, shaped like short cylinders, 1 to 2 mm. in width, and somewhat less in height. As is shown in section (fig. 857), each is surrounded by a trench or fossa, into the bottom of which open ducts of the serous glands of von Ebner. On the sides of the fossæ are the *taste-buds*, as described in the section on Sense Organs.

The **foliate** papillæ are represented by a few (five to eight) parallel transverse or vertical folds of mucosa, along the margins of the tongue just anterior to the glosso-palatine arch on each side (fig. 864). They are variable in size and sometimes rudimentary. In structure they somewhat resemble the vallate papillæ (though of different form), their walls being studded with taste-buds.

The free **inferior surface** of the tongue (fig. 858) is covered by a thin smooth mucosa. In the median line is a prominent fold, the *frenulum*, which connects the tongue with the mandible and the floor of the mouth. On each side of the inferior surface, an irregular, variable, fringed fold, the *plica fimbriata*, extends from near the apex backward approximately parallel with the lateral margin of the tongue (fig. 858). Between the frenulum and the plicæ fimbriatæ, the lingual (ranine) veins are visible on each side beneath the mucosa.

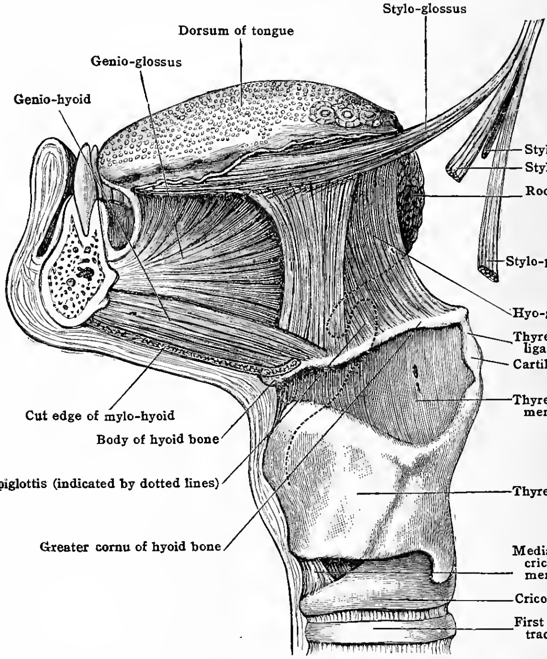
The **root** (or base) of the tongue [radix linguæ] belongs to the pharynx, but is here included with the mouth for convenience of description. Its free surface is directed posteriorly, and represents the continuation of the dorsum linguæ (fig. 854). Laterally it is continuous with the region of the palatine tonsils. Infe-

Fig. 854.—Dorsum and Root of the Tongue. (Papillæ diagrammatic.)



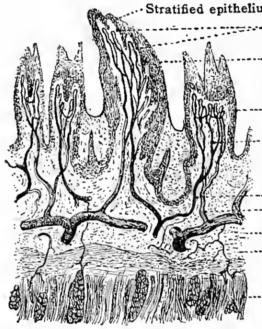
riorly it extends to the epiglottis, with which it is connected by a median and two lateral folds, between which are the depressions known as the *valleculæ*. The mucosa over the root of the tongue is irregular and warty in appearance due to the projections of the underlying nodular masses of lymphoid tissue, the *lingual follicles*. A *crypt* or tubular pocket of surface epithelium usually dips down into each of these follicles, as seen in surface view (fig. 854), and shown in section (fig. 859). The follicles vary from 34 to 102 in number, the average being 66 (Ostman), and are somewhat irregular in size and form. They are often arranged in more or less distinct longitudinal rows, with corresponding folds of the mucosa (Jurisch). The lingual follicles are collectively designated as the **lingual tonsil** [tonsilla linguæ]. Between the lingual follicles and around the periphery of the lingual tonsil there are found smaller ordinary nodules (without crypts) and indefinite masses of lymphoid tissue. The sulcus terminalis forms a fairly sharp boundary between the lymphoid mucosa of the root and the papillated mucosa of the body of the tongue (fig. 854).

Fig. 855.—Left Side of the Tongue, with its Muscles, etc.



Glands.—The glands of the tongue are of three types—mucous, serous and mixed—and are distributed as shown in fig. 860. The most numerous are those of the mucous type, which

Fig. 856.—Section of Lingual Papillæ. × 20. (From Toldt's Atlas.)



are typical for the mouth cavity in general and resemble those already described in the lips, cheeks and palate. They are spread over the entire surface of the root of the tongue, in the spaces between the lingual follicles, usually opening upon the surface but in many cases into the crypts. Anteriorly, they extend a short distance along the posterior portion of the lateral

FIG. 857.—VERTICAL SECTION OF A HUMAN VALLATE PAPILLA WITH LINGUAL GLANDS. × 25. (Lewis and Stöhr.)

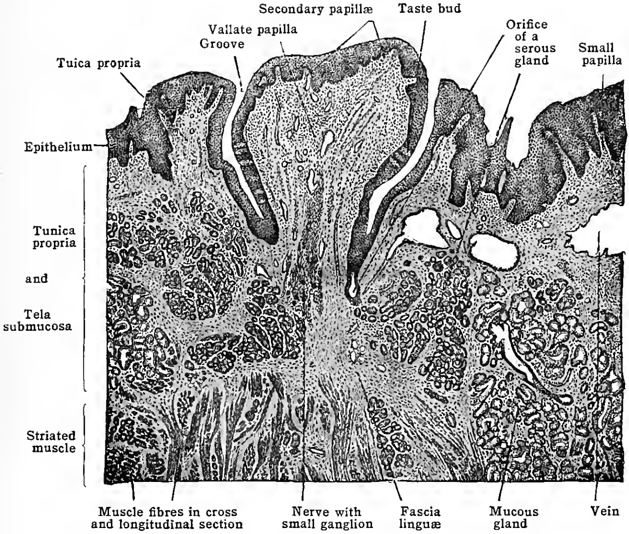


FIG. 858.—INFERIOR SURFACE OF THE TONGUE. (Modified from Spaltholz.)

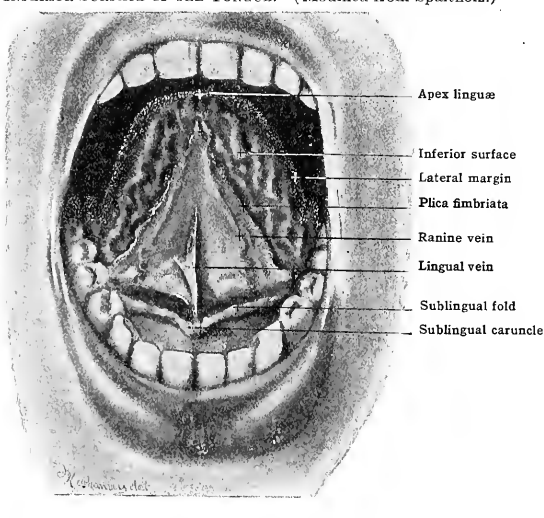
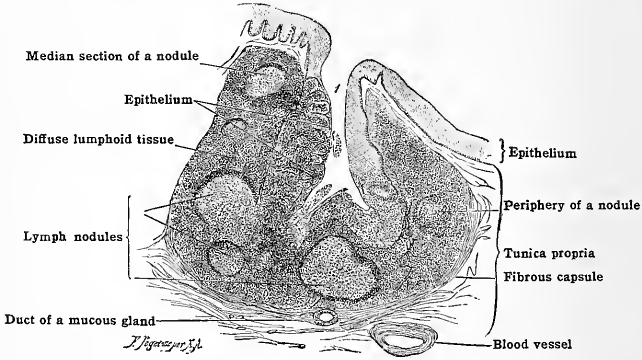


margin of the tongue, and also occupy small areas in and near the mid-line in front of the vallate papillæ.

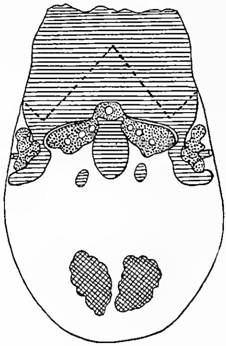
In the immediate region of the vallate papillæ, and in the small lateral areas corresponding to the foliate papillæ (i. e., in the regions of the taste-buds), the mucous glands are displaced by the **serous** glands (of von Ebner), which have a watery secretion (fig. 860). Finally, on the inferior surface of the tongue, on either side of the frenulum near the apex, are the **anterior lingual glands** (glands of Nuhn or Blandin). Each is about 15 mm. in length, and is composed of a group of racemose glands with three or four very small ducts opening on the surface of the tongue near the plica fimbriata. The anterior lingual glands are deeply placed and are covered not only by the mucosa, but also by some of the longitudinal muscle fibres (inferior longitudinal and styloglossus). This gland is of the mixed type, though chiefly mucous.

Fig. 859.—From a Section of the Lingual Tonsil of an Adult Man. × 20. 1. Pit containing leucocytes which have infiltrated its epithelium on the left side; that on the right is almost intact. (Lewis and Stöhr.)



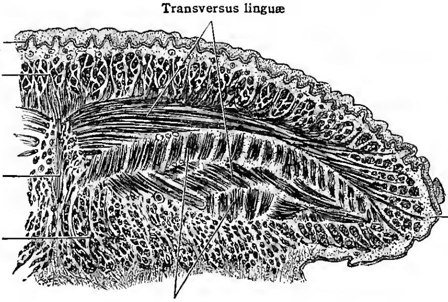
Muscles of the tongue.—A layer of fibrous connective tissue, the **lingual septum,** separates the halves of the tongue, extending in the median plane from the apex to the root, where it is attached below to the hyoid bone. The muscles of the tongue are classified as extrinsic and intrinsic. The **extrinsic muscles** (fig. 855) extend into the tongue from without. They are the hyoglossus, chondroglossus, genioglossus, styloglossus, and glossopalatinus (palatoglossus), all of which are described elsewhere (see Section IV.)

Fig. 860.—Diagram of the Distribution of the Lingual Glands. Horizontal lines indicate the mucous type; cross-hatched, the mixed type; and dotted areas, the serous type. (After Oppel.)



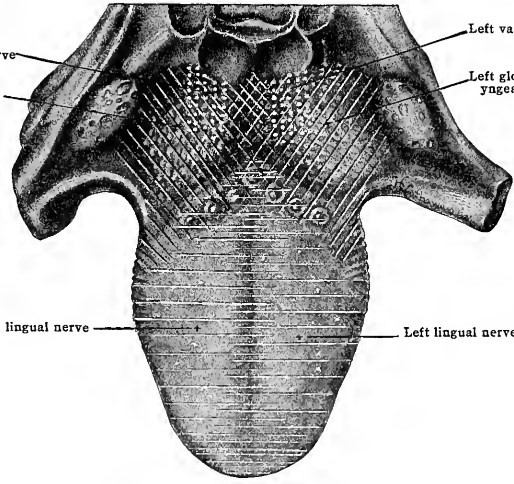
The intrinsic muscles.—The **longitudinalis superior** (fig. 861) is a superficial longitudinal stratum extending from the base to the apex of the tongue, immediately beneath the mucosa of the dorsum, to which many of its fibres are attached. The **longitudinalis inferior** (fig. 861) is composed of two muscle-bands extending from base to apex on the inferior surface of the tongue, and is situated between the hyoglossus and the genioglossus, some of its fibres near the apex mixing with the styloglossus, while dorsally some are attached to the hyoid bone. The **transversus linguæ** (fig. 861) consists of fibres which pass transversely, and is situated between the superior and inferior longitudinal muscles. The fibres arise from, or pass through, the septum linguæ, and are attached to the mucosa of the dorsum and lateral margins of the tongue. The **verticalis linguæ** (fig. 861) is composed of fibres which pass from the mucosa of the dorsum to the mucosa of the inferior surface of the tongue, interlacing with those of the other intrinsic and extrinsic muscles.

FIG. 861.—TRANSVERSE SECTION THROUGH THE LEFT HALF OF THE TONGUE. (Magnified.) (From a preparation by Mr. J. Pollard, Middlesex Hospital Museum.)



Vessels and nerves.—The lingual arteries furnish the principal blood-supply. The **lingual veins** carry the blood from the tongue to the internal jugular. The **lymphatics** form a network in the lamina propria, connected with a deeper network in the submucosa. The latter forms plexuses around the lingual follicles. The efferent lymph-vessels from the tongue empty chiefly into the superior deep cervical lymph-nodes. (For details concerning the blood- and lymph-vessels, see Sections V and VI.) The nerves are motor and sensory. The **hypoglossal nerve**

FIG. 862.—SCHEMATIC REPRESENTATION OF THE DISTRIBUTION OF TEE SENSORY NERVES IN THE MUCOUS MEMBRANE OF THE TONGUE. (Areas of distribution according to R. Zander. White dotted area indicates vagus; oblique lines, glosso-pharyngeal; horizontal lines lingual nerves.)

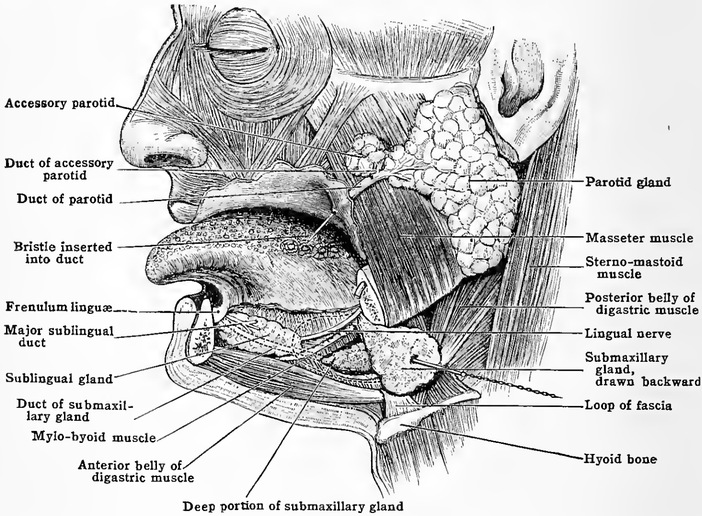


supplies the intrinsic and all the extrinsic muscles of the tongue except the glossopalatinus (palato-glossus), which is supplied from the pharyngeal plexus. The sensory nerves (fig. 862) are:—the **lingual nerve**, a branch of the mandibular division of the fifth, which, after joining with the chorda tympani from the seventh, is distributed to the anterior two-thirds of the tongue and represents the nerve of touch; the **lingual branches of the glossopharyngeal**, which are distributed to the root of the tongue, including also the vallate and foliate papillæ (nerve of taste); and **the superior laryngeal branch of the vagus**, which supplies a small area near the epiglottis.

Development.—The development of the tongue is quite complicated. In general, the *body* of the tongue is derived from the region corresponding to the ventral portion of the first arch, just behind the mandible. It does not develop from the tuberculum impar, however, which is a transitory structure (Hammar). The epithelium of the body of the tongue is probably of ectodermal origin. The *root* of the tongue develops from the corresponding lower portion of the second or hyoid arch, and its epithelium is endodermal in origin. The transverse groove between the two arches later becomes the *sulcus terminalis*. At the middle of this groove there is an ingrowth of the epithelium to form the anlage of the thyreoid gland. The *foramen cæcum* and the occasional *ductus lingualis* represent persistent portions of the thyreoid duct. The third arch does not appear to enter into the formation of the tongue, but forms the epiglottis (Hammar).

The *musculature* of the tongue appears to develop from the mesenchyme *in situ* although its innervation from the hypoglossal would indicate a derivation from the occipital myotomes. A pair of premuscle masses appears in the 9 mm. embryo, the individual extrinsic muscles being distinguishable at 14 mm., and the intrinsic at 20 mm. (W. H. Lewis). The *glands* appear in the fourth fœtal month as solid epithelial downgrowths which later acquire a lumen. The mucous glands appear first, the serous slightly later. Longitudinal folds in the mucosa of the

Fig. 863.—The Salivary Glands.



radix appear in the third or fourth fœtal month (Jurisch). The *lymphoid* tissue appears somewhat later as aggregations in the lamina propria, chiefly around the gland-ducts. From the beginning, the lymphoid structures are subject to marked individual variations. Characteristic, well-developed lingual follicles do not appear until some time after birth, however (Jurisch). Of the *lingual papillæ*, the fungiform appear at the end of the third fœtal month, followed shortly by the filiform and vallate. The formation of the papillæ is not completed at birth, however, since they later undergo changes in number, form, size and arrangement. The foliate papillæ appear about the fifth fœtal month. They are best developed in infants, undergoing retrogressive changes in the adult (Stahr). The same is true of the plicæ fimbriatæ.

Variations.—Of the manifold variations in the structure of the tongue, some have already been mentioned. Additional mucous glands sometimes occur along the margin of the tongue (completing Oppel's "glandular ring"). In "tongue-tied" individuals, the frenulum is abnormally short. A *forked* tongue (normal in some animals) is a rare congenital anomaly. Another rare variation is the so-called "*hairy*" tongue, due to hypertrophy of the filiform papillæ. While the **V**-shaped arrangement of the vallate papillæ is typical, the **Y**-form (two to four papillæ in the median line forming the stem of the **Y**) is nearly as frequent. Indeed, in some of the coloured races the latter type seems to predominate. The sulcus terminalis and foramen cæcum are often indistinct and sometimes absent.

Comparative.—The tongue of fishes and lower amphibia contains neither glands nor intrinsic musculature. Among higher vertebrates, the tongue varies exceedingly in form and structure, but always contains intrinsic musculature and mucous glands. The latter primitively form a ring around the margin and root of the tongue (Oppel). The serous glands occur only in mammals, and are associated closely with the papillæ bearing taste-buds.

The plica fimbriata in man is homologous with the 'sublingua' of lower mammals. According to Gegenbaur, the 'sublingua' represents the entire primitive vertebrate tongue, but this view is opposed by Oppel. Among various mammals, the number of vallate papillæ varies from one to thirty, but the **V**- or **Y**-arrangement is typical. The region of the foliate papillæ ('marginal organ') is typical for mammals, and is much better developed in some (e. g., rabbit) than in man. The mucosa of the root of the tongue is always different from that of the body. The lingual papillæ are especially developed in the tongue of carnivora.

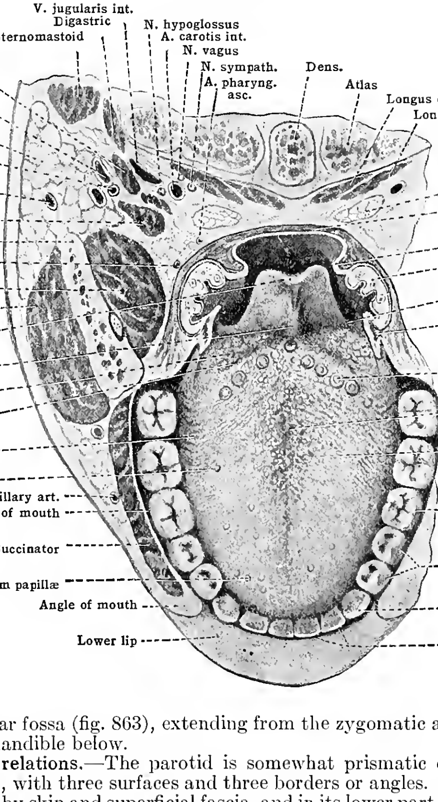
THE SALIVARY GLANDS

Numerous glands—labial, buccal, palatine and lingual—have already been mentioned, which pour their secretions into the mouth cavity. In addition to these, there are three larger pairs, the salivary glands proper. They include the parotid, the submaxillary, and the sublingual (the latter really a group of glands).

THE PAROTID GLAND

The **parotid gland** [gl. parotis] is the largest of the salivary glands, varying from 15 to 30 gm. in weight. It is located below and in front of the ear in the

Fig. 864.—Horizontal Section through Head at Level of Rima Oris. (After Henle, modified.)



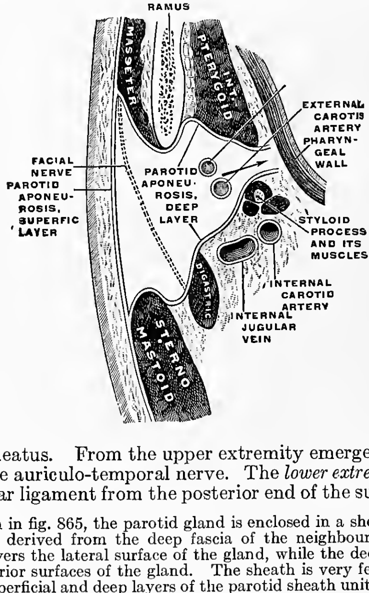
retromandibular fossa (fig. 863), extending from the zygomatic arch above to the angle of the mandible below.

Form and relations.—The parotid is somewhat prismatic or wedge-shaped (figs. 863, 864), with three surfaces and three borders or angles. The *lateral* surface is covered by skin and superficial fascia, and in its lower part by the platysma. The *anterior* surface overlaps the masseter and extends medialward in contact with the posterior border of the mandibular ramus and with the posterior aspect of the internal pterygoid muscle. An irregular ''pterygoid lobe'' may extend between the internal and the external pterygoid muscles. The *posterior* surface is in contact with the sternomastoid muscle laterally, and with the styloid process and associated muscles medially. Between the sternomastoid and styloid process it touches the posterior belly of the digastric, and is in relation with the internal carotid and jugular vessels. The various structures in contact with the parotid gland often make more or less distinct grooves upon its posterior and anterior surfaces.

Borders.—The *anterior* border usually extends from below obliquely upward and forward so as to give the whole superficial surface a triangular appearance. Near the upper end of the anterior border, the parotid duct leaves the gland, and just above this there is usually a small separate *accessory lobe* [gl. parotis accessoria], of variable form and size. The branches of the facial nerve also emerge from the anterior border. The *posterior* border extends along the anterior aspect of the sterno-mastoid muscle up to the mastoid process. The *medial* border is deeply placed (at the junction of the anterior and posterior surfaces), and approaches the wall of the pharynx.

The *upper extremity* of the parotid sends a process into the posterior part of the manibular fossa, behind the condyle of the mandible, and is related with the

Fig. 865.—Diagram of Horizontal Section Showing the Parotid Compartment and Relations. Arrow indicates opening in sheath. (Modified from Woolsey after Testut.)



external auditory meatus. From the upper extremity emerge the superficial temporal vessels and the auriculo-temporal nerve. The *lower extremity* is separated by the stylo-mandibular ligament from the posterior end of the submaxillary gland.

Fascia.—As shown in fig. 865, the parotid gland is enclosed in a sheath (called the parotid fascia or aponeurosis) derived from the deep fascia of the neighbourhood. The superficial layer of the sheath covers the lateral surface of the gland, while the deep layers correspond to the anterior and posterior surfaces of the gland. The sheath is very feeble or deficient at the medial angle. The superficial and deep layers of the parotid sheath unite below to form a thick fascial band extending from the angle of the mandible to the sterno-mastoid muscle.

Contents.—Within the sheath, the parotid gland is in intimate relation with numerous important structures. Extending along the medial border, and partly embedded in the gland, is the external carotid artery, dividing above into the superficial temporal and internal maxillary (including the origins of the deep auricular and transverse facial); and the posterior facial (temporo-maxillary) vein and branches. The auriculo-temporal nerve passes through the upper part of the gland, while the facial nerve passes somewhat horizontally through it, dividing into its temporo-facial and cervico-facial divisions. Finally, there are embedded in the gland two or three deep lymphatic nodes, which receive lymphatic vessels from the external auditory meatus, the soft palate and the posterior part of the nasal fossa; and several superficial nodes, which receive lymphatic vessels from the temple, eyebrows and eyelids, cheek and auricle.

Structure.—The parotid is a racemose gland of the serous type.

Duct, vessels and nerves.—The **duct of the parotid** (Stenson's) issues from the anterior border of the gland, crosses the masseter a finger's breadth below the zygoma, and turns abruptly medialward round its anterior border. It penetrates the fat of the cheek and the fibres of the buccinator muscle, between which and the mucous membrane it runs for a short distance before it terminates, sometimes on the summit of a little papilla, by a minute orifice. This opening is placed opposite the crown of the second upper molar tooth. The duct commences by numerous branches, which converge toward the anterior border of the gland, and receives in its passage across the masseter the duct of the accessory parotid gland. The canal is about the size of a crow-quill, length about 35 to 40 mm., diameter 3 mm. Its mucous membrane is covered for a short distance, beginning with its oral termination, by stratified pavement epithelium, for the remainder of the distance by columnar epithelium. The coat of the duct is thick and tough, and consists of fibrous tissue intermixed with nonstriated muscle-fibres.

The **arteries** are derived from those lying in the gland substance and from the posterior auricular artery.

The **veins** terminate in the posterior facial (temporo-maxillary) trunk.

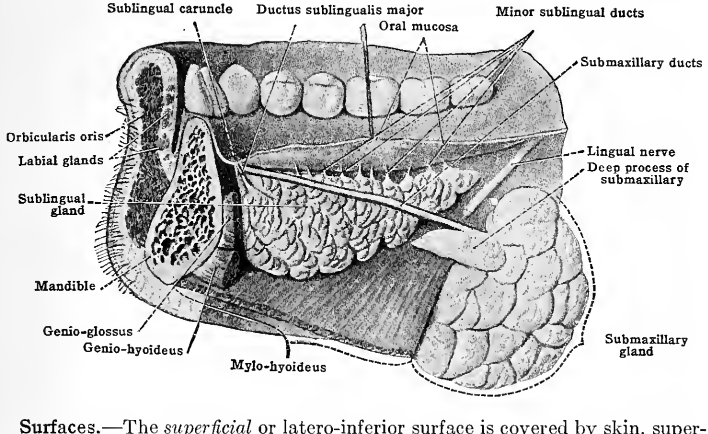
The **nerves.**—The parotid gland receives its secretory fibres from the otic ganglion, conveying impulses from the glosso-pharyngeal via the lesser petrosal and the auriculo-temporal; its sensory supply through branches of the fifth nerve; and its sympathetic supply from the carotid plexus. The **lymphatics** from the parotid gland terminate in the superficial and deep cervical glands, especially in the deeper group of parotid nodes embedded in the substance of the gland.

Variations.—The parotid is quite variable in size and in the form of its various processes, especially of the accessory lobe, as already mentioned. The lobulations are less distinct in infancy. Rarely the parotid is confined to the masseteric region, the retro-mandibular fossa being filled with a fatty tissue enclosing the vessels and nerves normally found with the gland.

THE SUBMAXILLARY GLAND

The **submaxillary gland** [gl. submaxillaris] weighs 7 to 10 grams, and is of about the form and size of a flattened walnut. It consists of a chief or superficial part, and a smaller deep process. The chief portion is located in the digastric triangle, and presents three surfaces—superficial, deep and lateral (figs. 847, 866).

FIG. 866.—MEDIAL VIEW OF THE SUBMAXILLARY AND SUBLINGUAL GLANDS. (Sobotta—McMurrich's Atlas.)



Surfaces.—The *superficial* or latero-inferior surface is covered by skin, superficial fascia, platysma and deep fascia (which forms an incomplete capsule around the gland). It is crossed by the facial vein and by cervical branches of the facial nerve. Several lymphatic glands, which receive vessels from the anterior facial region, lie upon or embedded in this surface.

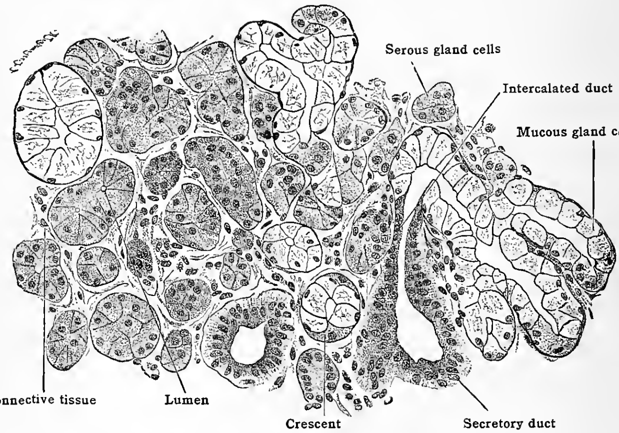
The *lateral* surface is the smallest of the three. It is in contact with the submaxillary fossa of the medial surface of the mandible, and with the lower part of the internal pterygoid muscle. The posterior aspect of the gland is deeply grooved by the external maxillary (facial) artery and is separated from the parotid gland by the stylo-mandibular ligament. The *deep* or medio-superior surface is in contact with the lower surface of the mylohyoid, and behind this with the hyo-glossus, stylohyoid and posterior belly of the digastric. Between this surface and the mylohyoid muscle are the mylohyoid nerve and artery and the submental artery.

The **deep portion** is a tongue-like process which passes from the deep surface of the submaxillary gland around the posterior border of the mylohyoid muscle, and extends forward in company with the duct, under cover of (above) the mylohyoid, and in relation with the hyoglossus and genioglossus muscles. At its commencement, the deep process lies just below the submaxillary ganglion and anteriorly it gives off the submaxillary duct as it approaches the sublingual gland.

Structure.—The submaxillary is a racemose gland belonging to the mixed type, some of the acini being serous, others mucous (fig. 867).

The **submaxillary** (Wharton's) **duct** springs from the deep surface of the superficial part of the gland; it passes forward and inward, along the medial surface of the deep lobe, and opens by a small orifice on the summit of a papilla [caruncula sublingualis] by the side of the frenulum of the tongue. It is crossed superficially by the lingual nerve. It lies at first between the mylo-

Fig. 867.—Section of the Submaxillary Gland of an Adult Man. × 252. (Lewis and Stöhr.)



hyoid and hyoglossus; next, between the mylohyoid and genioglossus; and lastly, under cover of the mucous membrane of the mouth, between the genioglossus and the sublingual gland. The duct is about 5 cm. in length, and has comparatively thin walls. It is lined by columnar epithelium.

Vessels and nerves.—The arteries to the gland are derived from the external maxillary (facial) and lingual, and they are accompanied by corresponding *veins*.

The **nerves.**—The submaxillary gland receives its secretory fibres from numerous small sympathetic ganglia situated on the submaxillary duct and in the hilus of the gland, these conveying impulses from the chorda tympani; its sensory branches probably come from the geniculate ganglion, and its sympathetic branches from the cervical sympathetic.

Variations.—Absence of the gland is a rare anomaly. A case is recorded (Turner) where the submaxillary was placed entirely under cover of the mylohyoid, being closely associated with the sublingual gland.

THE SUBLINGUAL GLAND

The **sublingual gland** [gl. sublingualis]—the smallest of the salivary glands (2 to 3 gm.) is in reality a group of glands forming an elongated mass in the floor of the mouth under the tongue (fig. 847). *Above*, it forms a distinct ridge, covered by a fold of mucosa (plica sublingualis) upon which its ducts open (fig. 866). It is flattened from side to side, its *lower* border resting upon the upper surface of the mylohyoid, its *lateral* surface in contact with the sublingual fossa of the mandible, and its *medial* surface with the geniohyoid, geniohyoglossus, lingual nerve, deep lingual artery and submaxillary duct (fig. 863). *Anteriorly* it touches its fellow of the opposite side, while *posteriorly* it is often related with the deep process of the submaxillary gland. It has no distinct capsule, thus differing from the submaxillary and parotid glands. In *structure*, it is a racemose mixed gland, but predominantly mucous.

Ducts.—The *minor sublingual ducts* [ductus sublinguales minores], ducts of Rivinus, vary from five to fifteen or more in number, and open on minute papillæ along the crest of the plica sublingualis (fig. 858). The anterior portion of the gland often forms a *larger* (*Bartholin's*) *duct* [ductus sublingualis major] which opens alongside the submaxillary duct on the *caruncula sublingualis* (figs. 858, 866).

Vessels and nerves.—The *arteries* are derived from the sublingual and submental, with corresponding *veins*. The *lymphatics* are tributaries of the superior deep cervical nodes.

Nerves.—The sublingual glands receive their secretory fibres from the submaxillary and associated sympathetic ganglia, conveying impulses from the chorda tympani; sympathetic branches come from the cervical sympathetic and sensory fibres probably from the geniculate ganglion, although this question needs further investigation.

Development of the salivary glands.—The salivary glands appear early as buds from the ectodermal epithelium extending into the adjacent mesenchyme of the mouth cavity. The *parotid* appears first on the side of the mouth cavity in an embryo of 8 mm., as a groove which becomes tubular and pushes back over the masseter to the ear region, developing branches (at first solid). Around the gland and between the branches is mesenchyme which becomes condensed to form the peripheral capsule. The *submaxillary* gland appears in the 13 mm. embryo as a ridge in the epithelium of the alveolo-lingual groove. The solid cord (lumen appearing later) grows forward to the region of its adult orifice. Its posterior end extends backward and gives off solid branches which later form the acini and duct system of the mature gland. The *sublingual* glands appear somewhat later (24 mm. embryo) as a series of separate anlages of variable number, budding off in the positions where the adult ducts empty. The major sublingual gland, if present, appears first. The histogenetic development of the salivary glands is not completed until some time after birth, probably about the time of weaning. However, mucin cells appear in the sublingual glands in the fœtus of four months and serous cells in the parotid of five months.

Variations.—The duct of Bartholin is present in about half of the cases, and the corresponding anterior part of the gland may be more or less separate [gl. sublingualis major]. The number of ducts may reach thirty (Tillaux). Rarely processes from the gland may penetrate the mylohyoid, appearing on its lower surface in one or more places (Moustin). Most of the variations in this and the other salivary glands are due to developmental irregularities.

Comparative.—Oral glands are not found in the lower aquatic vertebrates. Mucous glands occur in all terrestrial vertebrates, but true salivary (digestive) glands appear only in mammals. Although great variations occur in the different species of mammals, those in man (excepting the anterior lingual) are typical for the order. The sublingual gland, however, often occurs as two separate glands, corresponding to the sublingualis major and minor. The parotid gland apparently has no representative in forms below mammals. In some mammals (e. g., monkey) it has two main lobes—a larger superficial and a smaller deeper lobe between which lies the facial nerve (Gregoire). Other oral glands (e. g., orbital, zygomatic) appear in some mammals.

THE TEETH

The **teeth** [dentes] are highly specialized structures developed in the oral mucosa as organs of mastication and also (in man) of speech. The adult individual with perfect dentition has thirty-two teeth, arranged arch-like in the sockets (alveoli) of the maxilla and the mandible. Sixteen belong to the upper or maxillary arch; and sixteen to the lower or mandibular. The four central teeth in each dental arch are the *incisors;* the tooth next to these on each side is the *canine;* behind these are the two *premolars* (bicuspids); and lastly the three *molars*. This relation of teeth is expressed by the following dental formula:

$$\mathrm{i}\,\frac{2}{2},\ \mathrm{c}\,\frac{1}{1},\ \mathrm{pm}\,\frac{2}{2},\ \mathrm{m}\,\frac{3}{3}=32.$$

Form.—Each tooth [dens] has a *crown* [corona dentis], the portion exposed beyond the gum, and covered with enamel (figs. 871, 872). The root [radix dentis] is the portion covered with cementum and embedded in the bony socket. At the line of union of crown and root is the slightly constricted *neck* [collum dentis]. The surface of the tooth directed toward the lip (or cheek) is termed the *labial* (or buccal) surface [facies labialis; f. buccalis]; while that toward the tongue is the *lingual* surface [f. lingualis]. The crowns of the opposite arches meet at the *masticating* surface [f. masticatoria]. The surfaces in contact with the adjacent teeth of the same arch [facies contactus] are, for the incisors and canines, termed *medial* and *lateral*, while those for the premolars and molars are termed *anterior* and *posterior*.

Structure.—As shown in longitudinal section (fig. 873), each tooth has a central *cavity* [cavum dentis] or pulp cavity, which is filled with *pulp* [pulpa dentis]. The pulp is a soft fibrous tissue richly supplied with vessels and sensory nerves which enter the *root canal* through the apical *foramen* [foramen apicis dentis]. The body of the tooth, both crown and root, is composed of a dense modified variety of bone called *dentine* [substantia eburnea]. It is yellowish in colour. The striated appearance of the dentine is due to numerous fine canals, the *dentinal*

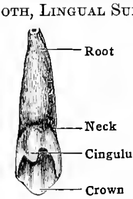

Fig. 872.—A Molar Tooth in Section.

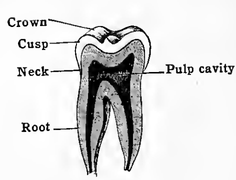
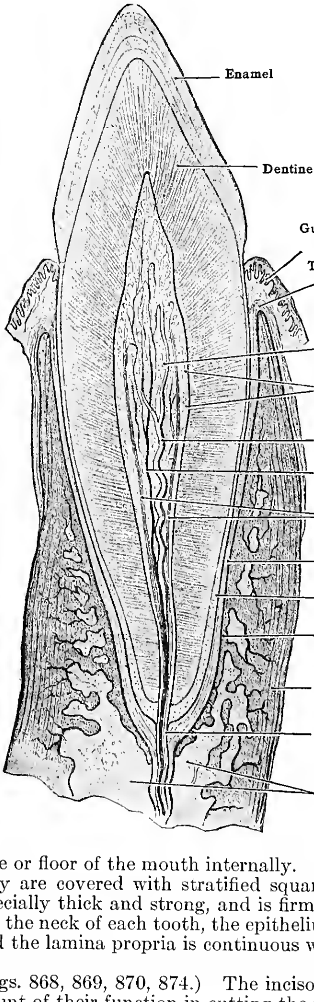


tubules. These contain 'Tomes' fibrils,' which are long protoplasmic branches of the *odontoblasts*, a layer of cells on the surface of the pulp. At the outer surface of the dentine are numerous small, irregular *interglobular spaces*, corresponding in the root to Tomes' 'granular sheath' (fig. 873). The dentine of the crown is covered with a layer of white *enamel* [substantia adamantina], which is the hardest substance in the body. It is composed of numerous minute hexagonal *prisms* [prismata adamantina] which are arranged perpendicular to the surface and are of epithelial origin. In adult teeth, the enamel is often worn through in places, exposing the yellowish dentine. The dentine of the root is covered by a thin layer of *cementum* [substantia ossea], a layer of bone which is very thin at the neck, but becomes thicker toward the root apex (fig. 873). Surrounding the root is the *alveolar periosteum*, a fibrous membrane connecting the cementum firmly with the bony lining of the socket. For further details of the minute structure of teeth, works on histology may be consulted.

Gums.—Covering the alveolar portions of the maxilla and mandible are the **gums** [gingivæ]. They are continuous with the mucosa of the vestibule exter-

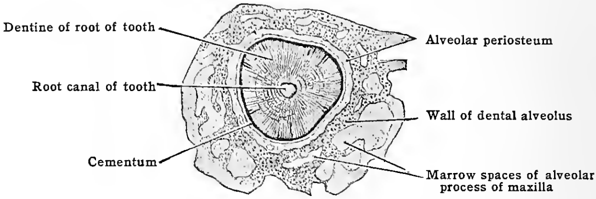
Fig. 873.—Vertical Section of an Inferior Canine Tooth, in Situ. × 4. (From Toldt's Atlas.)



nally and of the palate or floor of the mouth internally. Like the mucosa of the mouth elsewhere, they are covered with stratified squamous epithelium. The lamina propria is especially thick and strong, and is firmly attached to the subjacent bone. Around the neck of each tooth, the epithelium of the gum forms an overlapping collar and the lamina propria is continuous with the alveolar periosteum (fig. 873).

The incisors.—(Figs. 868, 869, 870, 874.) The incisor teeth [dentes incisivi] are so named on account of their function in cutting the food. The *crown* has a characteristic chisel shape. The *masticating* surface is narrow and chisel-edged. In recently erupted teeth, the cutting edge is elevated into three small cusps, which soon wear down, leaving a straight edge. These cusps correspond to three indistinct ridges on the labial surfaces. The lateral angle of the crown is usually more rounded than the medial. The *labial* surfaces are slightly convex, the *lin-*

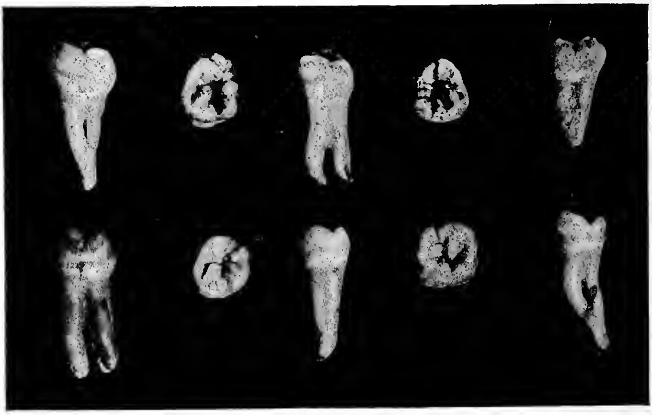
Fig. 874.—Cross-Section of the Medial Upper Incisor, in Situ. × 4. (From Toldt's Atlas.)



gual slightly concave. The *contact* surfaces are somewhat triangular. The *roots* of the incisors are single, though often longitudinally grooved, indicating traces of a division. They are somewhat conical, but flattened from side to side, expecially the lower set, and are slightly curved lateralward.

The upper or **maxillary incisors** are much larger than the lower. They are lodged in the premaxilla, and are inclined downward and forward. They overlap the lower incisors in mastication, hence the masticating surface is worn off and rounded at its posterior edge, while the anterior edge becomes sharp and chisel-like. The lingual surfaces of the crowns terminate near the gum in a low, inverted **V**-shaped ridge, the basal ridge or *cingulum.* At the apex of

Fig. 875.—Variations in the Form of the Upper Third Molar. (Broomell and Fischelis.)



the **V**, near the gum, there is often (especially on the lateral incisor) a small *lingual cusp.* The medial upper incisor is distinguished from the lateral by its much larger size.

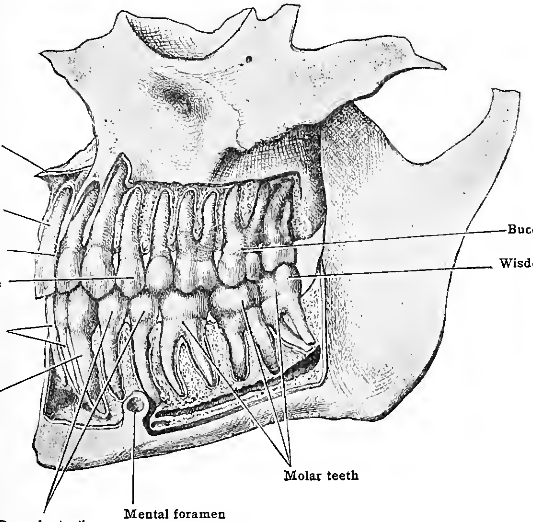
The lower or **mandibular incisors** are smaller than the upper, the cutting edges being only about half as wide. Being overlapped by the upper set, the lower incisors have the masticating surface worn off anteriorly, leaving a sharp cutting edge posteriorly. The lower incisors are vertically placed, and the crown becomes narrower toward the neck. A cingulum is rarely visible. The medial lower incisor, unlike the upper, is slightly smaller than the lateral.

The canines.—(Figs. 868, 869, 870, 871.) The canine teeth [dentes canini] so-called from their prominence in the dog-tribe, are the longest of all the teeth (fig. 868). The *crown* is thicker and more conical than in the incisors. The *masticating* surface forms a median angular point, on either side of which the cutting edge slopes to the lateral angle. The medial limb of the cutting edge is usually somewhat shorter than the lateral, rendering the crown asymmetrical. The *labial* surface is convex, the *lingual* somewhat concave. The *root* is single, long, flattened from side to side and grooved on the sides as in the incisors. The canine root is usually slightly curved lateralward. The bony alveolar protuberances [juga alveolaria] are more prominent than those of any other teeth.

The **upper canine** slants forward and overlaps the lower, as in the incisors. The upper canine also presents a well-marked *cingulum*, and usually a distinct *lingual cusp* (fig. 871) below which a slight median ridge extends along the lingual surface. On the **lower canine,** these structures are poorly marked or absent. The lower canine is somewhat smaller than the upper, and its root is occasionally bifid.

The premolars.—(Figs. 868, 869, 870, 876, 877.) The premolars [dentes premolares] are so named on account of their position in front of the molars. The

Fig. 876.—Dissection Showing the Roots of the Teeth. Teeth in Occlusion. × 1 (From Toldt's Atlas.)



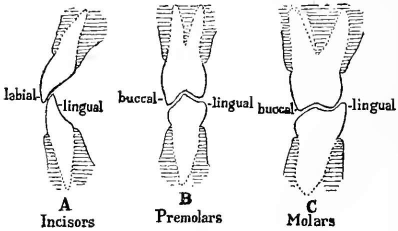
crown presents on the masticating surface two prominent cusps, on account of which the premolars are often called 'bicuspids.' The *buccal* and *lingual* surfaces are convex especially from side to side, so that the crown is somewhat cylindrical in form, with flattened, quadrilateral anterior and posterior *contact* surfaces. The *root* is (usually) single and more or less flattened antero-posteriorly, and usually somewhat curved backward.

The **upper premolars** are distinguished from the lower by a greater antero-posterior flattening of the crown and by a deep groove separating the cusps (excepting at their anterior and posterior margins) on the masticating surface. In the *first* upper premolar the lingual cusp and surface are decidedly smaller than the buccal; and the root is frequently bifid or double (occasionally even triple). In the *second* upper premolar the lingual cusp and surface are as large as the buccal; and the root, though deeply grooved, is rarely bifid.

In the **lower premolars,** the crowns are more cylindrical in form, and the cusps are united by a median ridge so that the masticating surface presents two small pits. The roots are more rounded and tapering, and rarely grooved. In the *first* lower premolar (like the corresponding upper) the lingual cusp and surface are much smaller than the buccal, the lingual cusp sometimes being rudimentary; while in the *second* they are more nearly equal. The second lower premolar is often slightly larger than the first, while in the upper premolars the converse is true. It should be noted, however, that the premolars are quite variable in all respects, and it is therefore often difficult to identify the individual isolated teeth.

The molars.—(Figs. 868, 869, 870, 872, 875, 876.) The molars [dentes molares] or 'grinders' are characterized by their large size, and by the presence of three to five masticating cusps (hence sometimes called 'multicuspids'). The *crowns* are massive, somewhat resembling rounded cubes, and the lingual and buccal surfaces present vertical grooves continuous with the fissures separating the cusps. The *pulp cavity* (fig. 872) has slight extensions corresponding to the cusps, and also communicates with the canals of the *roots*, which are usually two or three in number, and more or less curved.

Fig. 877.—Diagram Showing the Articulation of the Teeth. (Poirier-Charpy.)

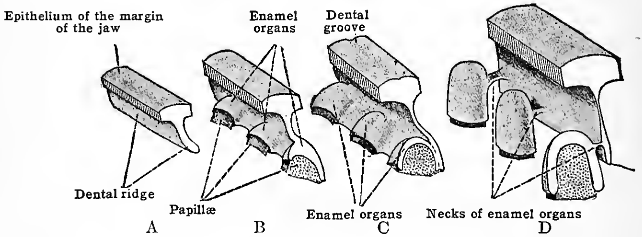


The upper molars are most easily distinguished from the lower by the presence of a triple root. The masticating surface is nearly square with rounded angles. They each have typically four cusps, separated by grooves resembling a diagonally placed H (fig. 852). The crowns of the upper molars are obliquely placed so as to slant downward and slightly lateralward.

Each upper molar has three roots, two buccal and one lingual or palatal. They are all (especially the buccal) in more or less close relation with the floor of the maxillary antrum (of Highmore) (fig. 876). The buccal roots are flattened antero-posteriorly, and longitudinally grooved, and bent backward. The palatal root is more rounded, with a groove on the lingual surface, and usually bent medialward. Either of the buccal roots may fuse with the palatal, or there may be an extra fourth root.

As to the *individual* upper molars, the *first* has almost invariably four typical cusps (rarely only three, or with an additional fifth rudimentary). The *second* upper molar has only three cusps in about half of the cases (in Europeans), and four in the remainder. The *third*, or wisdom tooth [dens serotinus] is exceedingly variable in size and form (fig. 875). It has three cusps much more frequently than four, and its three roots are often more or less fused into a conical mass. It is usually much smaller than the other molars, and is absent in nearly one-fifth of all cases.

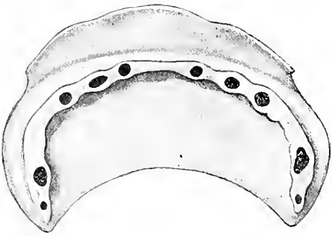
Fig. 878.—Diagrams Showing the Early Development of Three Teeth, One of which is Shown in Vertical Section. (Lewis and Stöhr.)



The lower molars have usually four or five cusps (two lingual, and two or three buccal) the fissures separating them being cross-shaped or stellate (fig. 864). The crowns incline upward and slightly medialward. They have each two roots, anterior and posterior, flattened antero-posteriorly, and usually somewhat curved backward. The roots, especially the anterior, may be longitudinally grooved. The anterior has two root-canals, the posterior usually only one. The apices of the roots of the lower molars, especially of the third, approach the mandibular (inferior dental) canal (fig. 876).

Of the *individual* lower molars, the *first* is usually slightly the largest, and has five cusps in the great majority of cases (variously estimated at from 60 to 95 per cent.), otherwise four, The four main cusps (two buccal and two lingual) are separated by a cruciform fissure, which bifurcates posteriorly to embrace the small fifth cusp (which is placed slightly to the buccal side) when present. The *second* lower molar has usually four cusps (75 to 85 per cent. of cases), otherwise five, the fifth usually small or rudimentary. The roots are sometimes confluent. The lower *third* or wisdom tooth, like the upper, is usually small and exceedingly variable (fig. 875). It has usually four or five cusps; but the number may be increased to six or seven,

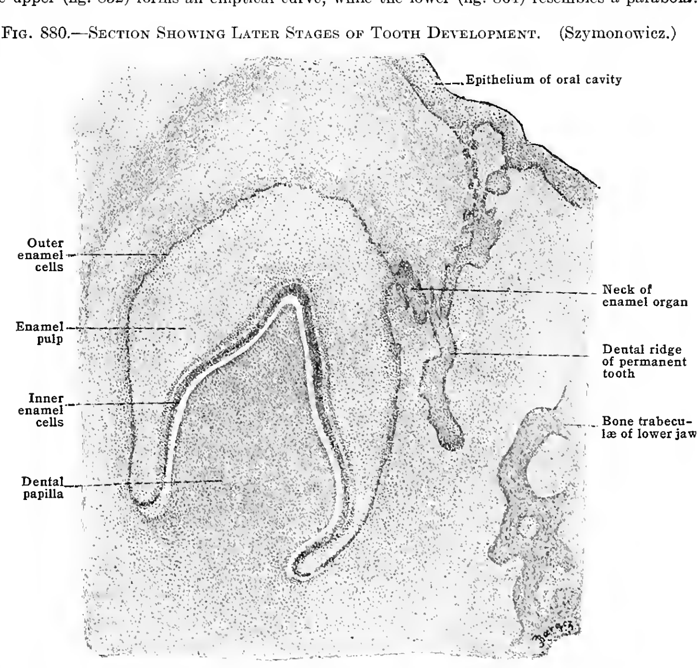
FIG. 879.—MODEL OF ECTODERM OF JAW OF HUMAN EMBRYO 40 MM. LONG, SHOWING DENTAL RIDGE WITH ENAMEL ORGANS FOR THE FIRST TEETH. (Kingsley, after Röse.)



or reduced to three, two, or one. The roots are often short and fused into a conical mass in which sometimes only a single canal is present.

The dental arches.—On comparing the upper and the lower dental arches, it is seen that the upper (fig. 852) forms an elliptical curve, while the lower (fig. 864) resembles a parabola.

FIG. 880.—SECTION SHOWING LATER STAGES OF TOOTH DEVELOPMENT. (Szymonowicz.)

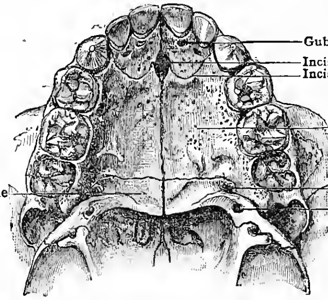


The upper arch is slightly larger (due chiefly to the slant of the teeth, as previously explained) so that it slightly overlaps the lower when the teeth are in occlusion. Thus, as shown in fig. 876, the upper incisors (and canines) overlap the lower. The buccal cusps of the lower premolars and molars fit into the groove between the upper buccal and lingual cusps; while the upper lingual cusps correspond to the groove between lower buccal and lingual cusps. This arrangement favors a more perfect mastication (see fig. 877).

Moreover, when viewed from the side (fig. 876), it is seen that in general, the corresponding teeth of the upper and the lower arches are not opposite, but alternate with each other. This is due chiefly to the great width of the upper central incisor. The lower molars, however, especially the third, are wider (antero-posteriorly) than the upper, so that the two arches are nearly equal in length. The interdental line between the two arches is not straight, but slightly convex downward (fig. 876). In both arches, the crowns of the incisors and canines are taller than those of the premolars and molars.

Vessels and nerves.—The vessels and nerves of the teeth are distributed partly to the pulp and partly to the surrounding alveolar periosteum. The *arteries* are all derived from the internal maxillary. Those for the upper teeth are the posterior superior alveolar and the anterior superior alveolar (from the infraorbital). Similar branches to the lower jaw are given off by the inferior alveolar. They give off twigs to the gums (rami gingivales), the alveolar

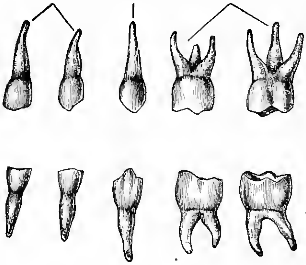
Fig. 881.—Hard Palate of a Child of Five Years, Showing Deciduous Teeth.



periosteum (rr. alveolares), and the pulp cavities (rr. dentales). A dental branch enters each root canal through the apical foramen, and breaks up into a rich peripheral capillary plexus under the odontoblast layer. From this plexus, the corresponding *veins* arise. There is a plexus of peridental *lymphatics*, which anastomose with those of the surrounding gums, and drain chiefly into the submaxillary nodes. Lymphatics have also recently been demonstrated in the pulp of the tooth (Schweitzer).

The nerves are sensory branches derived from the trigeminus. Those for the upper teeth are from the anterior, middle, and posterior superior alveolar (fig. 735); while those for the lower teeth are from the inferior alveolar (fig. 736). These nerves give numerous branches to

Fig. 882.—The Deciduous Teeth, External View.



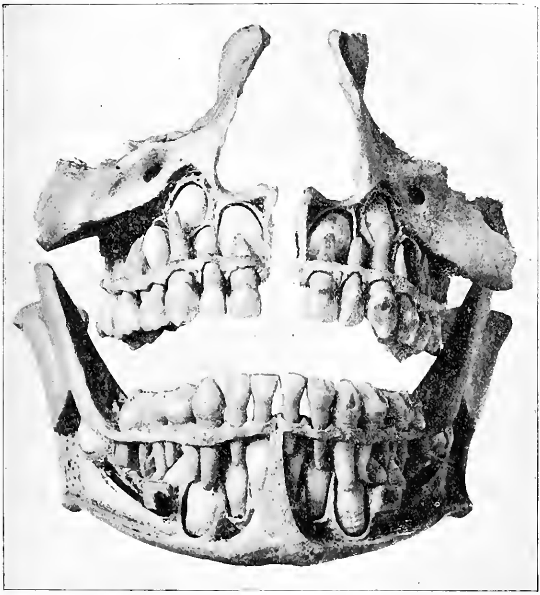
the gums, alveolar periosteum, and pulp cavities. The latter enter with the corresponding vessels, and their distribution within the tooth is a subject of controversy. They may be followed easily to a plexus under the odontoblasts; but whether they end freely, or in connection with the odontoblasts (which by some are considered as peripheral sensory cells), or send fine terminal branches out into the dentinal canals is still uncertain.

Development of the teeth.—The teeth represent calcified papillæ of the oral mucosa, the enamel being a derivative of the ectodermal epithelium, and the remainder of the tooth coming from the underlying mesenchyme. The first trace of the teeth appears in the human embryo of about 11 mm., in the form of an epithelial shelf, the *dental ridge*, extending into the mesenchyme corresponding to the future alveolar portions of the jaws (figs. 878, 879). From the dental ridge there is later produced a series of cup-shaped enlargements, the *enamel organs*, which become constricted off except for a slender neck attaching each to the common ridge. By the end of the third fœtal month, the twenty enamel organs of the temporary or deciduous teeth are formed. The concavity of each enamel organ is filled by the *dental papilla* of mesenchyme.

A somewhat later stage in the organogenesis of a tooth is shown in fig. 880. The mesenchymal cells on the surface of the dental papilla, next to the enamel organ, form a single layer of columnar cells, the *odontoblasts*. These cells form the dentine upon their outer surfaces, gradually retreating toward the center of the tooth as the dentine increases in thickness. The first dentine formed is irregular, enclosing the spatia interglobularia. The odontoblasts remain through life just beneath the dentine on the surface of the pulp, sending slender processes up into the dentinal tubules as previously noted in the structure of the adult tooth. The remainder of the dental papilla becomes the pulp, receiving its vascular and nerve supply at the point opposite the enamel organ, corresponding to the future root.

The *enamel organ* (fig. 880) is differentiated into three layers: a thin *outer* layer attached by the neck to the dental ridge; a thick *middle* layer (forming the spongy "enamel pulp"); and a single *inner* layer of cylindrical enamel cells, the *adamantoblasts*. The latter form the *enamel prisms*, which are deposited gradually upon the outer surface of the dentine.

Fig. 883.—Dissection Showing the Teeth at about Six Years. (Broomell and Fischelis.)



Surrounding the entire developing tooth there is formed a strong, fibrous connective-tissue membrane, the *tooth-sac*. The deeper part of this sac later becomes the *alveolar periosteum* around which the bony alveoli are formed. This bone may entirely surround the tooth-sac, excepting at the summit, where a foramen persists through which a process of connective tissue (*gubernaculum dentis*) connects the tooth-sac with the overlying gum (see figs. 114, 881). Upon the inner surface of the tooth-sac, next to the root, the bony *cementum* is deposited upon the dentine. The root gradually elongates, and is usually not completed until long after the eruption. The remaining superficial portion of the tooth-sac undergoes pressure atrophy and absorption. The remnants of the enamel organ, however, persist and form a thin tough cuticle [cuticula dentis], Nasmyth's membrane, which is soon worn off when the crown is exposed at the surface.

From the remainder of the dental ridge, which lies on the lingual side of the deciduous teeth (fig. 878), the *permanent teeth* are later derived in a very similar manner. (Rudimentary indications of a *prelacteal* dental ridge have also been described.) The anlages of the permanent teeth therefore lie to the lingual side of the deciduous (fig. 883). From the posterior end of the dental ridge a process extends into the jaw behind the deciduous teeth, and from this process the permanent molars (which have no deciduous predecessors) are formed. At birth, although no teeth have yet been cut, there are present in the gums the anlages of not only all of the deciduous teeth, but also all of the permanent teeth, with two exceptions. Those of the second molars do not appear until six weeks after birth, and of the third molars not until the fifth year. The remnants of the dental ridges become broken up into small masses of epithelial cells, which persist for a variable time.

The deciduous teeth.—The deciduous [dentes decidui], temporary or milk teeth are twenty in number, corresponding to the following formula:

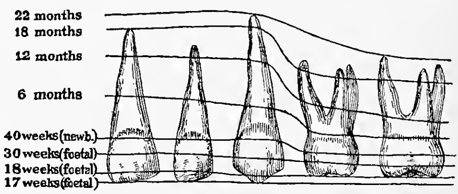
$$\text{di}\,\frac{2}{2},\ \text{dc}\,\frac{1}{1},\ \text{dm}\,\frac{2}{2}=20.$$

The deciduous teeth (figs. 882, 883) are much smaller in size than the permanent teeth, and their necks are more constricted. The enamel of the crown cap is thicker. In general, their form and structure otherwise is very similar to that

Fig. 884.—Pulp-cavity of the Upper First Molar, from the Fifth to the Ninth Year (Broomell and Fischelis.)

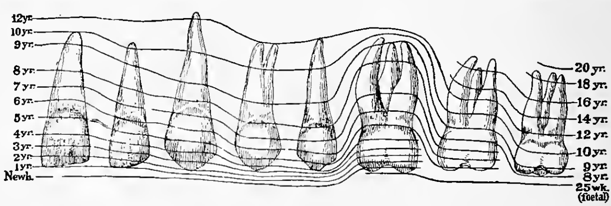
already described in the case of the permanent incisors and canines. The molars, however, are different. Their cusps on the masticating surface are very sharp and irregular. There are usually three cusps on the first upper molar and four on the second; four cusps on the first lower molar and five on the second. The roots

Fig. 885.—Showing the Extent of Calcification of Deciduous Teeth. (Peirce.)



correspond to those of the permanent molars (three above and two below), but they are much more divergent, to allow room for the development of the corresponding subjacent permanent premolar teeth. The first molar is always considerably smaller than the second.

Fig. 886.—Showing the Extent of Calcification of the Permanent Teeth. (Peirce.)



Calcification in the dentine and enamel of the teeth does not begin until the anlages of the crowns are well formed. The process of calcification follows that of the development of the tooth in general, beginning in the superficial portion of the crown and gradually spreading toward the root. Calcification in the *deciduous* teeth begins during the fifth fœtal month, and at birth the crowns are nearly completed (fig. 885). Of the *permanent* set of teeth, only the first molar has begun to calcify at birth (fig. 886). Calcification of the other permanent teeth begins during the second year; excepting the second molar, which begins during the fifth, and the third molar, which begins about the eighth year. There are, however, great variations in the time at which the calcification of the various teeth begins. As a rule, the calcification of the roots is not completed at the apices until some time after the crowns are exposed in eruption.

Eruption of the teeth.—On account of pressure due to growth and expansion at the root of the tooth (and probably other obscure factors), the crowns are pushed toward the surface. The overlying portion of the tooth-sac, together with corresponding portions of the temporary alveolar bone, are absorbed, and the crown is "cut," i. e., breaks through the surface of the gum in eruption. In the case of the permanent teeth, this is normally preceded by a shedding of the deciduous teeth. The latter have been loosened by the absorption of their roots, which is perhaps due largely to the activity of certain *odontoclasts* (like the osteoclasts of bone) which are found in the region of absorption.

Time and order of eruption.—The *time* of the eruption of the various teeth is subject to great variation, so that no two investigators agree upon it. Aside from the wisdom teeth, the time of eruption is most variable in the canines and premolars, and least variable in the first permanent molars (Röse). The eruption averages four and one-half months earlier in the male, and is also earlier in well-to-do and city children (Röse). The *order* in which the teeth appear is less variable. The average time at which the various deciduous and permanent teeth appear is indicated approximately in the following table.

A. Deciduous Teeth

	Months after Birth (Average)
Lower central incisors	7 (6–8)
Upper central incisors	8–9
Upper lateral incisors	9–10
Lower lateral incisors	12–14
First molars	14
Canines	18
Second molars	22–24

B. Permanent Teeth

The average time at which the teeth in the lower jaw undergo eruption is shown in the table below. The corresponding teeth in the upper jaw appear a little later:—

	Years
First molars	6–7
Central incisors	7
Lateral incisors	8
First premolars	9–10
Second premolars	9–10
Canines	11
Second molars	12
Third molars (wisdom teeth)	17–25

Variations.—The great variability of the teeth has already been emphasized, and numerous variations described in connection with the various individual teeth and their development. In *number*, the teeth may be reduced, due to absence (oftenest of the third molar) or incomplete development with failure of eruption. An *increase* in the normal number is less common[1] It may be only apparent, due to the retention of a deciduous tooth. There may rarely, however, be a true extra third incisor or premolar, or a fourth molar. Aberrant teeth may occur either on the labial or palatal side of the dental arch. A third dentition appears rarely in old age. In *form*, there is much greater variation as before mentioned. All intermediate forms between rudimentary and fully developed teeth may occur. Fusion between neighbouring teeth is sometimes found, and deformities in the dental arches necessarily accompany palatal defects involving the alveolar arches.

Comparative.—As the oral mucosa represents an invagination of the integument, so the teeth are morphologically equivalent to dermal papillæ. The close relationship between the teeth and the dermal appendages is clearly shown among many of the lower vertebrates, but most clearly in the Selachians (which include sharks and allied forms). In fig. 887, which illustrates a sagittal section through the lower jaw of a young dogfish, it is clearly evident that the external placoid scales or 'dermal teeth' are continuous with the equivalent oral teeth at the oral margin of the jaw. Both the dermal teeth and the oral teeth are composed of dentine which presents an enlarged base and a somewhat conical apex. The base is embedded in the fibrous lamina propria (often in bony plates) while the apex projects through the epithelium and is covered with a thin cuticular layer the "enamel membrane." True enamel is usually rudimentary or absent in the primitive teeth of lower vertebrates, and represents a secondary acquisition. The dentine is in all cases derived from the connective tissue, and the enamel from the epithelium.

The process of development of the primitive oral teeth is also illustrated in fig. 887. Just within the oral margin there is a shelf-like downgrowth of the ectodermal epithelium, forming a primitive germinal ridge. Along this ridge may be seen the anlages of several rows of teeth in various stages of development. As fast as the mature teeth at the oral margin are worn off, new teeth pass up from below to replace them. Thus the primitive form of dentition is *polyphyodont*, with many sets of teeth developed successively throughout life. As we pass up the vertebrate scale there is a tendency to a reduction in the number of sets, although there is a wide variation among the various forms. In most mammals, as in man, the number of sets of teeth has been reduced to two, or *diphyodont* dentition, with only traces of an earlier (prelacteal) and also a later (post-permanent) set. In some mammals (monotremes, cetacea) the dentition has been reduced to a single set, *monophyodont,* while in birds all except rudimentary traces of dentition have been lost.

As may be further observed in fig. 887, the primitive teeth are of a recurved conical form, and serve primarily for grasping and holding the food. The specialization of the teeth for purposes of mastication is in general a secondary acquisition amongst higher vertebrates.

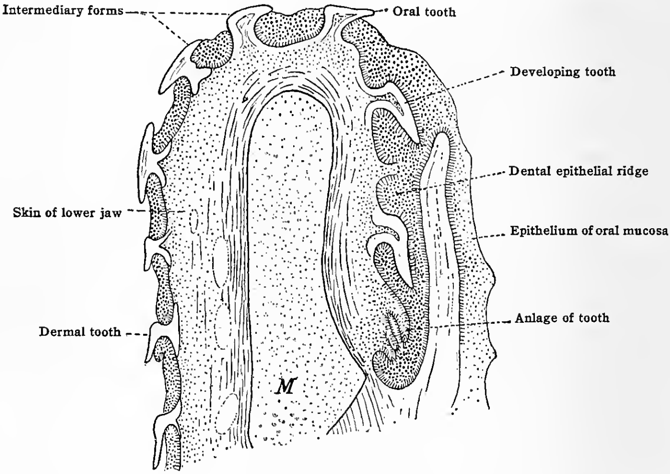
It is also noteworthy that the primitive teeth, as found among nearly all forms below the mammals, are practically alike in form, i. e., *homodont.* Among mammals, however, there is a marked specialization of the teeth, or *heterodont* dentition. The mammalian teeth are usually differentiated into four distinct classes, incisors, canines, premolars and molars, similar to those found in man.

The typical or complete mammalian dentition, however, contains a larger number of teeth than found in man, and is represented by the formula

$$\text{i}\,\frac{3}{3},\ \text{c}\,\frac{1}{1},\ \text{pm}\,\frac{4}{4},\ \text{m}\,\frac{3}{3}=44.$$

Thus it is evident that there has been a reduction in the incisors and premolars in the human species, and there has been considerable discussion of the question as to which teeth of the

FIG. 887.—SECTION THROUGH LOWER JAW OF DOG-FISH, SHOWING THE DEVELOPMENT OF THE ORAL TEETH, AND THE TRANSITION TO DERMAL TEETH. M, mandible. (After Gegenbaur.)



primitive series have been lost. This reduction in the number of teeth is probably correlated with the general reduction in the jaws, which are relatively much larger and stronger in the savage races and lower animals. The third molar, or wisdom tooth, is probably now on the road to extinction, due to a continuation of the same evolutionary process.

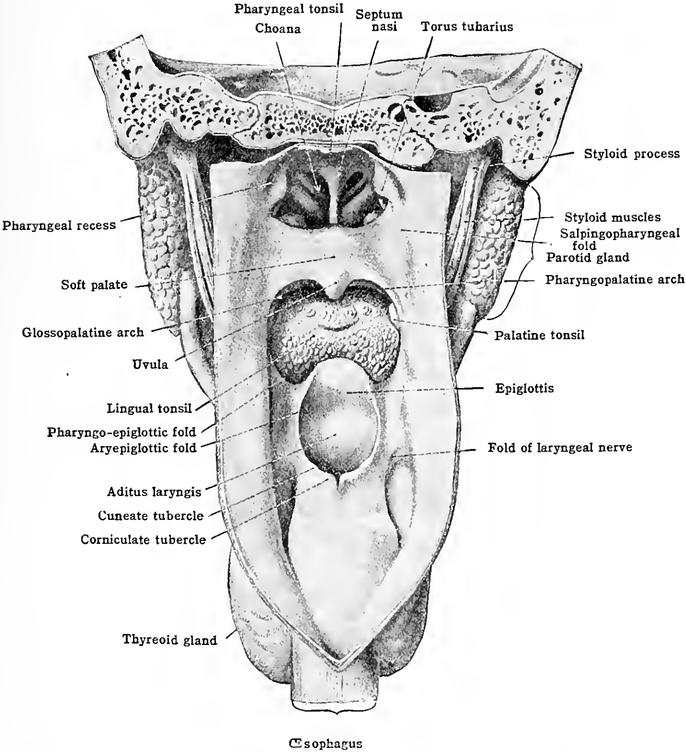
Another interesting problem, concerning which there has been much speculation, is the origin of the multicuspidate mammalian molar. It has clearly been derived from the primitive conical type of the homodont dentition, but as to the method of evolution there is a difference of opinion. According to one view (the 'concrescence' theory), the molar has been derived by a process of fusion, each cusp representing a primitive conical tooth. Another view (the 'differentiation' theory) is that the molar represents a single primitive tooth, upon the crown of which the various cusps have been differentiated. According to a third view, which is a compromise, the tritubercular (tricuspid) form of tooth, which is that found in the earliest fossil mammals, was derived by a process of concrescence of three primitive teeth, while from this tricuspid form the multicuspidate molar has been derived by a process of differentiation.

THE PHARYNX

The **pharynx** is a vertical, tubular passage, flattened antero-posteriorly, and extending from the base of the cranium *above* to the beginning of the œsophagus *below.* *Posteriorly,* it is in contact with the bodies of the upper six cervical vertebræ. *Laterally,* it is in relation with the internal and common carotid arteries, the internal jugular vein, the sympathetic and the last four cranial nerves. *Anteriorly*, it communicates above with the nasal cavity, beneath this with the oral cavity, and below with the laryngeal cavity. The pharynx is correspondingly divided into three parts: the *nasal pharynx* [pars nasalis], which is exclusively respiratory in function; the *oral pharynx* [pars oralis], which is both respiratory and alimentary; and the *laryngeal pharynx* [pars laryngea], which is almost entirely alimentary.

Size and form.—The average length of the pharynx is about 12 cm. (5 inches). It is widest at the nasal pharynx, with a constriction (isthmus) connect-

FIG. 888.—THE INTERIOR OF THE PHARYNX, VIEWED FROM BEHIND. (Sobotta-McMurrich.)



ing it with the widened oral pharynx, and is again somewhat narrowed at the junction of oral and laryngeal pharynx (fig. 888). It is narrowest at the point where it joins the œsophagus below. In sagittal section (fig. 848), it is evident that the anterior and posterior walls are closely approximated in the laryngeal pharynx, and have only a small space between them in the oral pharynx. The nasal pharynx, however, has a considerable antero-posterior depth, and by its bony walls is always kept open for respiratory purposes.

Structure.—The pharynx approaches the typical structure of the alimentary canal, yet differs from it in several important respects. The lining *mucosa* is continuous with that of the various cavities which open into the pharynx. Above, it is closely adherent to the base of the cranium, where it is thick and dark in colour. It becomes thinner where it approaches the openings of the auditory tubes and choanæ; and below it is paler and thrown into longitudinal folds. The epithelium of the greater part of the nasal pharynx (from the orifice of the auditory tube upward) is stratified ciliated columnar, while that of the remainder of the pharynx is stratified squamous.

External to the mucosa, there is a characteristic fibrous membrane, the *pharyngeal aponeurosis* [fascia pharyngobasilaris], which is well marked above, but below it loses its density and gradually disappears as a definite structure. Above, it is attached to the basilar portion of the occipital bone in front of the pharyngeal tubercle. Its attachment may be traced to the apex of the petrous portion of the temporal bone, and thence to the auditory (Eustachian) tube and medial lamina of the pterygoid process. It descends along the pterygo-mandibular ligament to the posterior end of the mylohyoid ridge of the lower jaw, and passes thence along the side of the tongue to the stylohyoid ligament, the hyoid bone, and thyreoid cartilage.

External to the pharyngeal aponeurosis is a thick *muscular* layer, made up of various cross-striated muscles, as will be described later. Outside of the muscular layer is a thin fibrous tunica adventitia, connected with the adjacent prevertebral fascia by a loose, areolar tissue. This loose tissue allows movement of the pharynx, and also favours the spreading of post-pharyngeal abscesses.

The **nasal pharynx** (figs. 848, 888) belongs, strictly speaking, with the nasal fossa as a part of the respiratory rather than the digestive system. Its **anterior wall** is occupied by the two *choanæ* (posterior nares), with the nasal septum between them. The *floor* is formed by the upper surface of the soft palate and in a direct posterior continuation of the floor of the nasal fossæ. Posteriorly, however, the floor presents a more or less narrowed opening, the *pharyngeal isthmus*, which communicates with the oral pharynx below. The isthmus is formed anteriorly by the uvula, laterally by the posterior (pharyngo-palatine) arches. These slope backward and downward to the posterior wall of the pharynx, which forms the posterior boundary of the isthmus. The floor and isthmus change their form and position greatly during the action of the palatal muscles, as will be mentioned later.

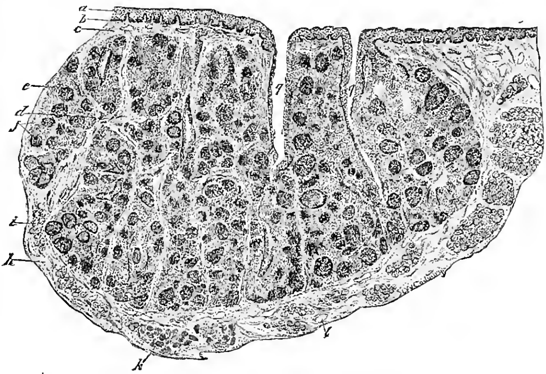
The **lateral wall** of the nasal pharynx presents above and behind, corresponding to its widest point, a wide, slit-like lateral extension, the *pharyngeal recess* [recessus pharyngeus] or fossa of Rosenmueller (fig. 888). Below and in front of this recess, the greater part of the lateral wall is occupied by the aperture of the auditory (Eustachian) tube [ostium pharyngeum tubæ]. This is a somewhat triangular, funnel-shaped opening, with an inconspicuous *anterior lip* [labium anterius], a more distinct *posterior lip* [labium posterius], which presents posteriorly a rounded prominence (due to the projecting cartilage of the auditory tube), called the *torus tubarius*. The prominence of the posterior lip facilitates the introduction of the Eustachian catheter, in connection with which the location of the aperture in the mid-lateral wall just above the level of the floor of the nasal fossa should be carefully noted. On the lower aspect of the triangular aperture is a slightly rounded fold, the *levator cushion*, which is a prominence caused by the levator palati muscle. A fold of mucosa descending from the posterior lip of the aperture to the lateral pharyngeal wall is the *plica salpingo-pharyngea* (due to the m. salpingo-pharyngeus). An inconspicuous *plica salpingo-palatina* descends from the anterior lip to the soft palate.

The **posterior wall** (fig. 848) of the nasal pharynx slopes from below upward and forward, passing (at the level of the anterior arch of the atlas) into the *roof* [fornix pharyngis]. The roof is attached chiefly to the basi-occipital and basi-sphenoid bones, extending laterally to the carotid canal of the pyramid, and anteriorly to the base of the nasal septum. In the posterior wall of the nasal pharynx there is found in the mucosa a variable and inconstant blind sac, the *pharyngeal bursa*.

The mucosa of the roof, and to a certain extent also of the posterior wall, especially in children, is thrown into numerous folds, which may be irregular or radiate from the neighbourhood of the bursa. There is often a median longitudinal groove (or sometimes ridge) at the posterior (inferior) end of which is the bursa. These folds of the mucosa contain much lymphoid tissue, both diffuse and in the form of numerous characteristic lymphoid nodules, with crypt-like invaginations of the surface epithelium. This area constitutes the **pharyngeal tonsil** [tonsilla pharyngea] (fig. 890), which is well-developed in children (often abnormally enlarged, producing 'adenoids'), but usually, though not always, atrophied in the adult. According to Symington, the involution of the pharyngeal tonsils begins at 6 or 7 years, and is usually completed at 10 years. In the region of the pharyngeal tonsil and elsewhere, the mucosa presents numerous small racemose mucous glands, especially thick in the palatal floor of the nasal pharynx and similar to those of the oral cavity.

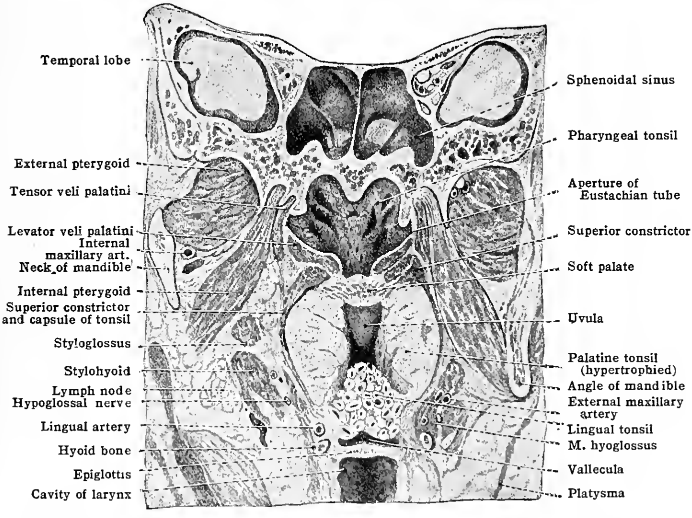
The **oral pharynx** (figs. 848, 864, 888) is continuous *above* through the pharyngeal isthmus with the nasal pharynx and *below* with the laryngeal pharynx. Its *posterior* wall presents no special features. The *anterior* wall is deficient above, where there is a communication with the mouth cavity through the *isthmus*

FIG. 889.—VERTICAL SECTION OF A HUMAN PALATINE TONSIL. *a*, Stratified epithelium; *b*, basement membrane; *c*, tunica propria; *d*, trabeculæ; *e*, diffuse lymphoid tissue; *f*, nodules; *h*, capsule; *i*, mucous glands; *k*, striated muscle; *l*, blood vessel; *q*, pits. (From Radasch.)



faucium. The faucial isthmus is bounded above by the uvula, laterally by the anterior (glosso-palatine) arches, and below by the dorsum of the tongue in the region of the sulcus terminalis. Below the faucial isthmus, the anterior wall of

FIG. 890.—PORTION OF A CORONAL SECTION THROUGH THE PHARYNGEAL REGION, SHOWING WALDEYER'S TONSILLAR RING. (Palatine tonsils hypertrophied.)



the oral pharynx is formed by the root of the tongue, which has been described previously. The *lateral* wall of the oral pharynx on each side presents the *palatine tonsil,* enclosed in a somewhat triangular *tonsillar fossa* [sinus tonsillaris] limited anteriorly and posteriorly by the anterior and posterior palatine arches, and below by the root of the tongue.

The **palatine arches** are folds of the mucosa formed at the sides of the free posterior border of the soft palate, as already mentioned in connection with that organ. The *anterior arch* (or pillar) [arcus glossopalatinus] extends from the soft palate downward and forward to the lateral margin of the tongue, just behind the papillæ foliatæ. It is a fold of mucosa due to the underlying glosso-palatine muscle, and inconspicuous except when this muscle is in action, or when the tongue is depressed. It forms the lateral boundary of the faucial isthmus. The *posterior arch* [arcus pharyngopalatinus] is a more prominent fold which extends from the soft palate in the region of the uvula downward and backward to join the postero-lateral aspect of the pharyngeal wall. It forms the lateral boundary of the pharyngeal isthmus, and encloses the pharyngo-palatine muscle, whose action will be explained later.

The **palatine tonsil** [tonsilla palatina] (figs. 864, 889, 890, 891) is a flattened ovoidal body, usually visible through the mouth cavity and faucial isthmus, and located on each side of the oral pharynx. The tonsil is extremely variable in size, but in the young adult averages about 20 mm. in height, 15 mm. in width (antero-posteriorly) and 12 mm. in thickness.

The **lateral** or attached **surface** of the tonsil is covered by a thin but firm fibrous *capsule*, which is continuous with the pharyngeal aponeurosis, and in contact with the middle constrictor muscle of the pharynx (fig. 864). Just outside the constrictor, the tonsil is in relation with the ascending pharyngeal and ascending palatine arteries, but is separated by a considerable space from the external and internal carotids. Rarely, however, the lingual or external maxillary may extend up higher than usual, so as to be in close relation with the lower aspect of the tonsil. Further lateralward, the palatine tonsil is in relation with the internal pterygoid muscle, and on the surface corresponds to a point somewhat above and in front of the angle of the mandible. The posterior border of the tonsil is thicker than the anterior, and forms a somewhat flattened surface in contact with the pharyngo-palatine muscle (fig. 891).

The **medial** or free **surface** of the tonsil is covered with mucosa and presents a variable number (12 to 30) small pits which are the openings into the tubular or slit-like *crypts* [fossulæ tonsillares]. These crypts are somewhat more numerous in the upper part of the tonsil, and are sometimes branched or irregular in form. Usually they end blindly in the substance of the tonsil, surrounded by lymphoid tissue in characteristic nodular masses (fig. 889). The lymphocytes normally migrate through the stratified squamous epithelium lining the crypts (occasionally eroding passages of considerable size), and escape into the pharyngeal and mouth cavities, where they form the so-called *salivary corpuscles.* Around the periphery of the palatine tonsil, within the capsule, are many mucous glands (fig. 889), similar to those described in connection with the lingual and pharyngeal tonsils. The ducts of the mucous glands sometimes enter the crypts, but usually pass to the surface chiefly around the margins of the palatine tonsil.

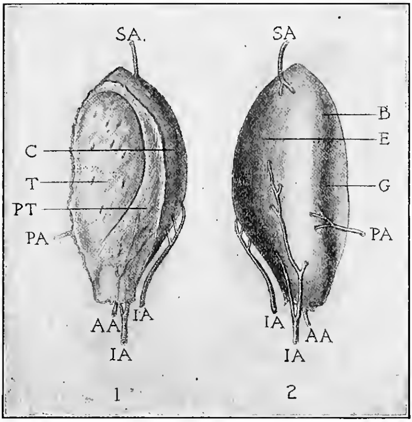
Tonsillar plicæ and fossæ.—Connected with the tonsil are certain important folds and fossæ. The *plica triangularis* (fig. 891) is a fold of variable extent and appearance, placed just behind the anterior arch, wider below and narrower above. According to Fetterolf, it is a prolongation of the tonsillar capsule, covered with mucosa. It may be adherent to the anterior part of the medial surface of the tonsil, or it may be free, in which case it covers a recess called the *anterior tonsillar fossa.* Occasionally there is a similar plica and fossa at the *posterior* border of the tonsil. Above the tonsil there is similarly a *supratonsillar fossa* [fossa supratonsillaris], which is also inconstant and exceedingly variable in size and shape. Killian found a supratonsillar fossa or canal in 41 of 105 cadavers.

Tonsillar vessels.—The *arteries* to the tonsil include the *anterior* tonsillar (from the dorsalis linguæ); the *inferior* tonsillar (from the external maxillary); the *posterior* tonsillar (from the ascending pharyngeal) and the *superior* tonsillar (from the descending palatine). These pierce the capsule and supply the gland. The *veins* form a plexus around the capsule and empty into the lingual vein and the pharyngeal plexus. The *lymphatic* relations of the palatine tonsil are important. *Afferent* vessels are received from adjacent areas of the mucosa in the pharynx, mouth and lower part of the nasal cavity (v. Lenart). These are connected with an extensive lymphatic plexus around the lymph follicles within the tonsil. *Efferent* lymphatic vessels pass chiefly to the upper deep cervical lymphatic nodes. One of these, located just behind the angle of the mandible, is so closely connected with the tonsil, and so constantly enlarged following tonsillar infection, that it has been called the *tonsillar lymph gland* (Wood). There are also communications with the submaxillary and superficial cervical lymphatic nodes. The tonsillar lymphatic vessels connect also with those of the lingual tonsil in the root of the tongue.

The tonsillar ring.—The two palatine tonsils, together with the lingual tonsil below and the pharyngeal tonsil above, form an almost complete ring of characteristic tonsillar tissue surrounding the pharynx and known as Waldeyer's 'tonsillar ring' (fig. 890). It is a highly specialized development of the diffuse lymphoid tissue which is found everywhere in the mucosa of the alimentary and respiratory tracts. It may be noted that the 'tonsillar ring' corresponds to the anterior limit of the embryonic foregut, hence the epithelium is of endodermic origin. The arrangement of the tonsils, together with their lymphatic connections, has suggested the widely accepted view that they are to be considered as protective mechanisms whose function is to intercept infectious material which has entered the mouth or nasal cavities. This theory is supported by the experiments of v. Lenart, who found that substances injected into the nasal mucosa are intercepted partly in the tonsils, and partly in the cervical lymph

FIG. 891.—THE LEFT PALATINE TONSIL, SHOWING THE ARTERIAL SUPPLY.

1, Mesial aspect. 2, Postero-lateral aspect. E, lateral surface. B, posterior surface. T, medial surface. G, groove for pharyngo-palatine muscle. C, capsule. PT, plica triangularis. Arteries: AA, anterior tonsillar (from dorsal lingual); PA, posterior tonsillar (from ascending pharyngeal); SA, superior tonsillar (from descending palatine); IA, inferior tonsillar (anterior from dorsal lingual; posterior from tonsillar branch of internal maxillary). (Fetterolf: Amer. J. Med. Sc., 1912.)



nodes. Oppel, however, opposes this view, holding that the function of the tonsils, as of lymphoid tissue elsewhere, is merely the production of lymphocytes.

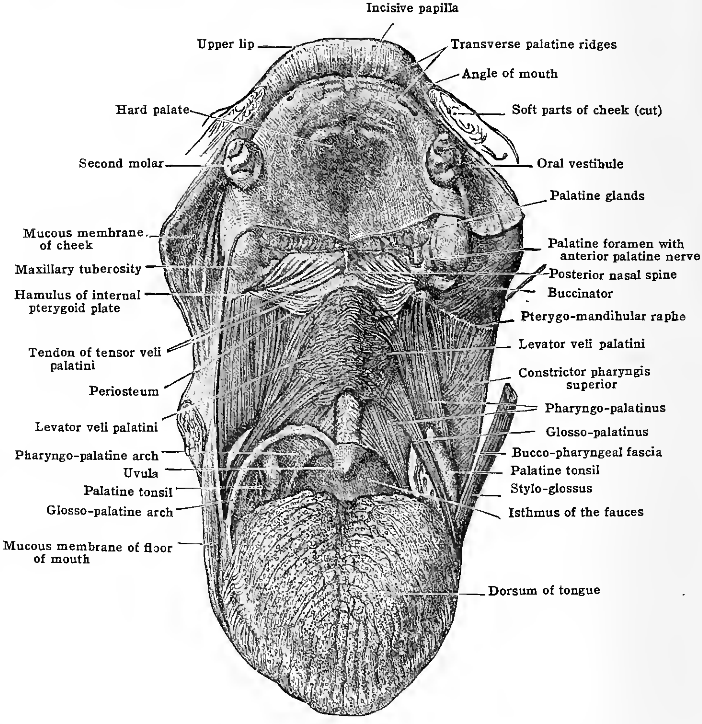
Development of the tonsil.—According to Hammar, the palatine fossa (sinus tonsillaris) is a derivative of the second inner branchial groove and is visible in the human embryo of 17 mm. There appears in the floor of the fossa a tubercle (tuberculum tonsillare) which later becomes atrophied, excepting a portion which is converted into the plica triangularis. The primitive tonsil becomes divided into two lobes, upper and lower, by a fold (plica intratonsillaris) which later usually disappears. In the fœtus of about 100 mm. (crown-rump length) the epithelium of the floor grows into the subjacent mesenchyme in the form of somewhat irregular solid sprouts of epithelium. These later become hollow and form the crypts. Around them, in about the sixth fœtal month, the lymphoid tissue begins to accumulate, at first diffusely, later forming characteristic follicles. The lymphocytes arise *in situ* from the connective-tissue cells (Hammar) or by immigration from the blood-vessels (Stöhr). Retterer's claim that the tonsillar lymphoid cells are derived from the epithelial cells has not been confirmed.

The later fœtal development of the tonsil is subject to considerable individual variation. The supratonsillar fossa is a remnant of the upper part of the primitive sinus tonsillaris, which may be transformed into a canal by growth of adenoid tissue around it. It is inconstant and quite variable in size and extent. A portion of the sinus may likewise persist anteriorly (anterior tonsillar fossa) between the tonsil and the plica triangularis, but this portion is usually obliterated by fusion of the plica with the tonsil. The occasional retro-tonsillar fold and fossa are said to arise secondarily (Hammar).

Variations in the tonsil.—The palatine tonsil, like the lingual and pharyngeal tonsils, is an exceedingly variable organ. Many of the variations are developmental in origin, as above indicated, and are therefore *congenital*. Furthermore, the tonsils, like all lymphoid structures, are subject to marked *age* variations. Though fairly well formed at birth, they are yet somewhat undeveloped. They rapidly increase in relative size and complexity, however, being best developed in childhood. After the age of puberty, they usually undergo certain retrogressive changes, become smaller in size, and in old age become almost entirely atrophied and lost. They are also markedly subject to inflammatory hypertrophy, especially in children. Variations in the relations of the *blood-vessels* were mentioned above.

The laryngeal pharynx (fig. 848) is the lower portion leading from the oral pharynx above into the œsophagus below (at the level of the lower border of the cricoid cartilage, usually opposite the sixth cervical centrum). It is wide above

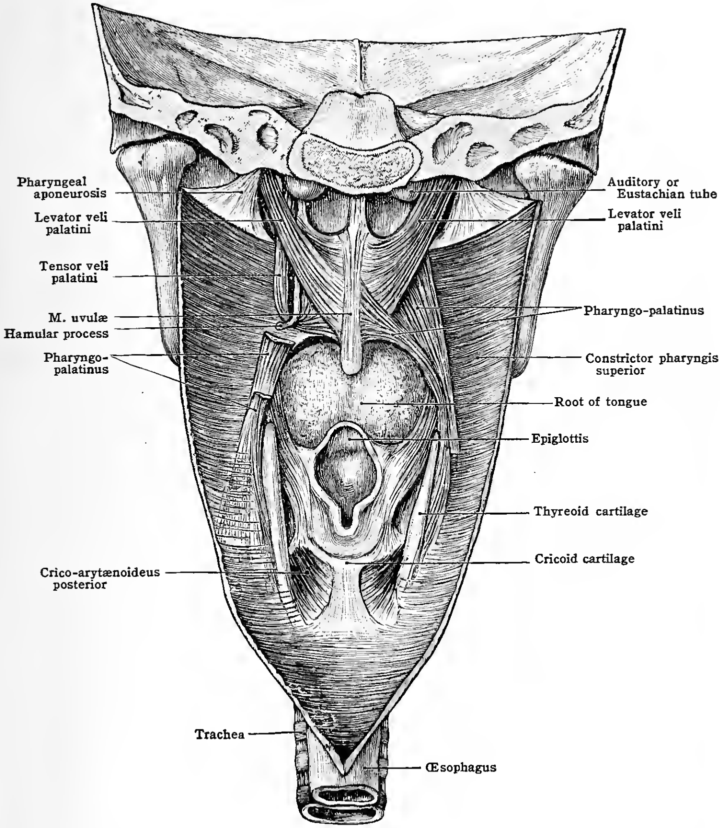
Fig. 892.—The Muscles of the Soft Palate and the Palatal Arches as Seen from in Front. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



and narrow below (fig. 888). Its *posterior* walls are continuous with those of the oral pharynx and in relation with the vertebral centra. Its *lateral* walls are attached to the hyoid bone and the posterior part of the medial surface of the thyreoid cartilage. *Anteriorly* it is in relation with the larynx. In the median line above is the epiglottis, below which is the superior aperture of the larynx. Still lower is the posterior wall of the larynx, containing the arytænoid and lamina of the cricoid cartilage. Laterally, are the pharyngo-epiglottic folds, and below these on each side a deep, elongated fossa, the *recessus piriformis*, bounded laterally by the medial surface of the thyreoid cartilage. The *mucosa* of the laryngeal pharynx is similar to that of the oral pharynx, and contains racemose mucous glands, which are especially numerous in its anterior wall.

Muscles of the pharynx and soft palate.—These muscles (figs. 892, 893, 894), which are here grouped together for convenience of description, are chiefly sphincter-like constrictors in function. They include the constrictors of the faucial isthmus (mm. glossopalatini), the constrictors of the pharyngeal isthmus (mm. pharyngopalatini), the three pharyngeal constrictors, and also the levator and the tensor veli palatini, the m. uvulæ and the stylo-pharyngeus. The stylo-pharyngeus and pharyngo-palatine muscles form an incomplete longitudinal layer within the more circularly arranged constrictors of the pharynx.

Fig. 893.—View of Muscles of Soft Palate, as Seen from Behind, Within the Pharynx. (Modified from Bourgery.)

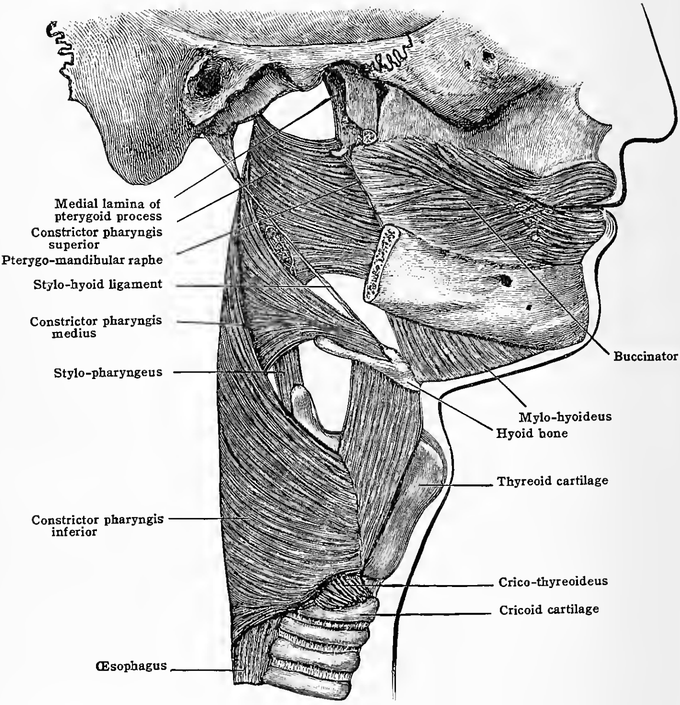


The muscles are arranged in layers either behind or in front of the aponeurosis, and in a horizontal section of the soft palate the following layers are met with from behind forward: (1) The mucous membrane on the pharyngeal surface; (2) the posterior layer of the pharyngo-palatinus (palato-pharyngeus); (3) the m. uvulæ; (4) the levator veli palatini; (5) the anterior layer of the pharyngo-palatinus; (6) the palatal aponeurosis with the tensor veli palatini; (7) the glosso-palatinus palato-glossus); and (8) the mucous membrane on the oral aspect.

The **glosso-palatinus** (palato-glossus) is a cylindrical muscle extending between the soft palate and the lateral border of the tongue. *Origin.*—From the oral surface of the palatal aponeurosis. *Insertion.*—(1) The superficial layer of muscles which covers the side and adjacent part of the under surface of the tongue; (2) the transversus linguæ. *Structure.*—At its origin the muscle forms a thin sheet, but the fibres, passing lateralward, quickly concentrate to form a cylindrical bundle, which passes downward beneath the mucous membrane of the pharynx and in front of the tonsil, forming the glosso-palatine arch of the fauces. It reaches the side of the tongue at the junction of its middle and posterior thirds, and some of its fibres continue forward to join with those of the stylo-glossus and hyo-glossus, while the majority pass medially to become continuous with the transversus linguæ. *Nerve-supply.*—From the pharyngeal branches (plexus) of the vagus. *Action.*—(1) To draw the sides of the soft palate downward; (2) to draw the sides of the tongue upward and backward. The combination of these actions tends to constrict the faucial isthmus. (The origin and insertion of the glosso-palatinus as given above are often described as reversed.)

The **pharyngo-palatinus** (palato-pharyngeus)—named from its attachments—is a thin sheet. *Origin.*—(1) From the aponeurosis of the soft palate by two heads which are separated by the insertion of the levator veli palatini; (2) by one or two narrow bundles from the lower part of the cartilage of the auditory (Eustachian) tube (*salpingo-pharyngeus*). *Insertion.*—(1) By a narrow fasciculus into the posterior border of the thyreoid cartilage near the base of the superior cornu; (2) by a broad expansion into the fibrous layer of the pharynx at its lower part.

Fig. 894.—The Muscles of the Pharynx, Lateral View.



Structure.—The upper head of the muscle consists of scattered fibres which blend with the opposite muscle across the middle line; the lower head is thicker, and follows the curve of the posterior border of the palate. The two heads with the fasciculus from the auditory (Eustachian) tube form a compact muscular band in the posterior palatine arch; the fibres mingle with those of the stylo-pharyngeus, at the lower border of the superior constrictor, and then expand upon the lower part of the pharynx. *Nerve-supply.*—From the pharyngeal branch (plexus) of the vagus. *Action.*—(1) Approximates the posterior arches of the fauces; (2) depresses the soft palate; (3) elevates the pharynx and larynx. (The origin and insertion above given are often described as reversed.)

The **inferior constrictor** is thick and strong. It *arises* from the thyreoid cartilage immediately behind the oblique line and superior tubercle (thyreo-pharyngeus), and from a tendinous arch extending between the inferior tubercle of the thyreoid and the cricoid cartilage and also from the lateral surface of the cricoid cartilage (cricopharyngeus) (fig. 894). The fibres spread backward and medialward, the lowest horizontally, whilst those above ascend more and more obliquely, and are *inserted* into the fibrous raphé of the pharynx. Some of the lowest fibres are continuous with the muscular fibres of the œsophagus, and the upper overlap the middle constrictor (fig. 894). The *nerve-supply* of all three constrictors is from the pharyngeal nerve.

Near the upper border the superior laryngeal nerve and artery pierce the thyreo-hyoid membrane to reach the larynx. The inferior laryngeal nerve ascends beneath the lower border immediately behind the crico-thyreoid articulation.

The **middle constrictor** is a fan-shaped muscle which *arises* from the lesser cornu of the hyoid bone and from the stylo-hyoid ligament (chondro-pharyngeus), and from the whole length of the greater cornu (cerato-pharyngeus). The diverging fibres are *inserted* into the median raphé, and blend with those of the opposite side. The lower fibres of the muscle descend, beneath the inferior constrictor, to the lower part of the pharynx; the upper overlap the superior constrictor, and reach the basilar process of the occipital bone, whilst the middle fibres run transversely (fig. 894).

The glosso-pharyngeal nerve passes downward above its upper border, the stylo-pharyngeus passes between it and the superior constrictor, and near its origin it is overlapped by the hyoglossus and crossed by the lingual artery.

The **superior constrictor** is quadrilateral in shape, pale, and thin (fig. 894). It *arises* from the lower third of the hinder edge of the median lamina of the pterygoid process and its hamular process (pterygo-pharyngeus), from the pterygo-mandibular ligament (bucco-pharyngeus), from the posterior fifth of the mylo-hyoid ridge of the mandible (mylo-pharyngeus), and from the side of the root of the tongue (glosso-pharyngeus). The fibres pass backward to be *inserted* into the median raphé, the highest reaching the pharyngeal tubercle. The Eustachian tube and the levator veli palatini are placed above the superior arched border, and the space (*sinus of Morgagni*) between this and the basilar process, devoid of muscular fibres, is strengthened by the pharyngeal aponeurosis, this portion of it being semilunar in shape.

The **stylo-pharyngeus** *arises* from the base of the styloid process internally. It passes downward and medialward to reach the pharynx between the superior and middle constrictors. Its fibres spread out as it descends beneath the mucous membrane. At the lower border of the superior constrictor some of its fibres join fibres of the pharyngo-palatinus (palato-pharyngeus), and are *inserted* into the posterior border of the thyreoid cartilage (fig. 894); the rest blend with the constrictors. The *nerve-supply* of the stylo-pharyngeus is from the glosso-pharyngeal nerve.

The **levator veli palatini**—named from its action on the velum of the soft palate—is somewhat rounded in its upper, but flattened in its lower, half. *Origin.*—(1) The inferior surface of the petrous portion of the temporal, anterior to the orifice of the carotid canal; (2) the lower margin of the cartilage of the auditory (Eustachian) tube. *Insertion.*—The aponeurosis of the soft palate; the terminal fibres of the muscles of each side meet in the middle line in front of the m. uvulæ. *Structure.*—Its origin is by a short tendon; the muscle then becomes fleshy, and continues so to its insertion. *Nerve-supply.*—From a pharyngeal branch (plexus) of the vagus. *Action.*—(1) To raise up the velum of the soft palate, and bring it in contact with the posterior wall of the pharynx; (2) to narrow the pharyngeal opening and to widen the isthmus of the auditory (Eustachian) tube. (According to Cleland, it closes the pharyngeal opening of this tube.)

The **tensor veli palatini**—named from its action on the velum of the soft palate—is a thin, flat, and narrow sheet. *Origin.*—(1) The scaphoid fossa of the sphenoid; (2) the angular spine of the sphenoid; (3) the lateral side of the membranous and cartilaginous wall of the auditory (Eustachian) tube. *Insertion.*—(1) Into the transverse ridge on the under surface of the horizontal plate of the palate bone; (2) the aponeurosis of the soft palate.

Structure.—Its belly as it descends between the pterygoideus internus and the internal pterygoid plate is muscular. On approaching the hamular process it becomes tendinous, and continues so to its insertion. A bursa is interposed between the hamular process and the tendon. The belly of the muscle is at nearly a right angle with its tendon. *Nerve-supply.*—From the mandibular division of the trigeminus through the tensor palati branch of the otic ganglion. *Actions.*—(1) Tightens the soft palate; (2) opens the auditory (Eustachian) tube during deglutition.

The **m. uvulæ.**—so named by reason of its position in the uvula. *Origin.*—(1) From the aponeurosis of the soft palate and tendinous expansions of the two tensores veli palatini. *Insertion.*—Into the uvula. *Structure.*—The muscle consists of two narrow parallel strips lying on each side of the middle line of the palate. *Nerve-supply.*—From the pharyngeal branch of the vagus. *Action.*—To draw up the uvula.

Origin of the muscles.—According to W. H. Lewis, the tensor palati is a derivative of the mandibular arch (probably split off from the pterygoid mass); the levator palati and m. uvulæ come with the facial musculature from the hyoid arch; the glosso-palatine, stylo-pharyngeus and pharyngeal constrictors probably from the third visceral arch, in a pre-muscle mass visible in a 9 mm. embryo. The adult innervation of the pharyngeal muscles does not agree entirely with this, however. The pharyngeal muscles (as above stated) are innervated chiefly from the vagus, whereas if derived from the third arch their innervation from the glosso-pharyngeus would be expected.

Process of swallowing.—In the act of swallowing, practically all of the muscles of the mouth, tongue, palate and pharynx are involved. By compression of the lips and cheeks, together with elevation of the tongue, the food is forced backward through the faucial isthmus into the oral pharynx. Constriction of the faucial isthmus by the glosso-palatine muscles assists in preventing a return to the mouth. By the action of the levator palati, tensor palati, and pharyngo-palatine muscles, the soft palate is retracted and tightened, with constriction of the pharyngeal isthmus, so as to prevent the passage of the food upward into the nasal pharynx. The pharynx is drawn upward by the stylo-pharyngeus, and the pressure produced by the pharyngeal constrictors (the contraction beginning above and extending downward) forces the food downward through the laryngeal pharynx and into the œsophagus. Passage of the food into the larynx is prevented by constriction of the superior aperture of the larynx.

Vessels and nerves.—The vessels of the tonsil and the motor nerves of the various muscles have already been mentioned. In general, the *arteries* to the pharynx are derived chiefly from the ascending pharyngeal, the ascending palatine branch of the external maxillary, and the descending palatine and pterygo-palatine branches of the internal maxillary. The *veins* form a venous plexus between the pharyngeal constrictors and the pharyngeal aponeurosis, and also an external plexus, communicating with the pterygoid plexus above and with the posterior facial or internal jugular vein below. The *lymphatic* vessels pass chiefly to the deep cervical nodes, those from the upper portion (including the pharyngeal tonsil) ending partly in the retro-pharyngeal glands. The *nerves* of the pharynx, both motor and sensory, are derived chiefly from the glosso-pharyngeal and vagus, by way of the pharyngeal plexus.

The development of the pharynx.—The pharynx is developed chiefly (if not entirely) from the anterior end of the archenteron. In this portion of the archenteron, with the development of the branchial arches, there are formed on each side four entodermal pouches or grooves (with a rudimentary fifth), the branchial clefts (see p. 17). With further development the first pair of branchial clefts form the tympanic cavities and the auditory or Eustachian tubes; the lower portion of each second branchial cleft persists as a fossa in which a palatine tonsil is developed; the remains of the third and fourth pairs are found on each side in the vallecula and piriform sinus of the larynx. The origin of the pharyngeal tonsil may be observed in the third month of fœtal life in the form of small folds of mucous membrane which, during the sixth month, become infiltrated with diffuse adenoid tissue, lymph-nodules differentiating in this toward the end of fœtal life. The pharyngeal bursa, which is not a constant structure (Killian), may be observed as a small diverticulum of the pharyngeal wall, closely connected with the anterior extremity of the notochord. The diverticulum develops independently of Rathke's pouch (which gives rise to the anterior portion of the hypophysis), and is also apparently distinct from Seesel's pocket.

The entire pharynx, like the associated facial region, is relatively small and undeveloped in the fœtus and newborn, but develops rapidly during infancy. The development of the muscles and of the palatine tonsils has already been considered.

Variations.—Variations in the palatine and pharyngeal tonsils and in the pharyngeal bursa have already been mentioned. Remnants of the visceral clefts may persist as aberrant diverticula or as 'branchial fistulæ' connected with the pharynx. Many additional *muscles* have been described, chiefly longitudinal muscles arising from the base of the cranium either by splitting of those normally present, or as separate slips. A detailed description of these may be found in Poirier-Charpy's work. Abnormally extensive fusion of the posterior arches of the palate with the walls of the pharynx may produce a congenital stenosis of the pharyngeal isthmus.

Comparative.—The pharynx is not distinctly separated from the mouth cavity in the lower vertebrates. It is the region containing the branchial or visceral clefts and is thus both respiratory and alimentary in function. The *nasal* pharynx, including the apertures of the auditory tubes, becomes distinct along with the nasal cavity when the palate is formed (from the reptiles upward). In the air-breathing vertebrates, the laryngeal aperture appears in the ventral wall of the pharynx just anterior to the beginning of the œsophagus. Of the *tonsils*, the *pharyngeal* are the most primitive, being present in the roof of the pharynx in amphibia, well-developed in reptiles, birds, and mammals (Killian). The *palatine* tonsils, on the other hand, are characteristic of mammals, being rarely absent, however (e. g., rat, guinea pig). From the embryological point of view, Hammar has classified the palatine tonsils in the various mammals under (1) the primary type (including rabbit, cat, and dog), in which the tonsil is formed from the embryonic tonsillar tubercle (described above under development of tonsil); and (2) the secondary type (including pig, ox, sheep and man), in which the tonsillar tubercle disappears and the tonsil is developed from the wall of the surrounding tonsillar sinus. Typical epithelial crypts (highly branched in the ox) are found only in the secondary type. The tonsil may form a single (lymphoid) lobe (cat, pig, rabbit) or may develop typically two lobes (ox, sheep, man), separated by the intratonsillar fold. There are great variations among different species as to relative size, number and character of folds, crypts, etc. The intimate relation of the epithelium with the underlying lymphoid tissue is characteristic and constant.

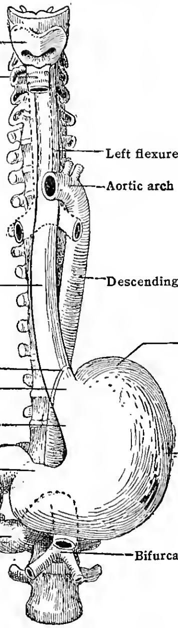
THE ŒSOPHAGUS

The **œsophagus** (figs. 895, 896) is that portion of the alimentary tract which extends between the pharynx and the stomach. It is more constricted than the rest of the canal, being narrowest at its commencement opposite the lower border of the cricoid cartilage. It is again somewhat contracted behind the left bronchus, and at its passage through the diaphragm, which is opposite the tenth or eleventh thoracic vertebra. It has an average length of 25 cm. (varying from 20 to 35 cm.). The average distance from the rima oris to the beginning of the œsophagus is about 15 cm. In its course downward the œsophagus follows the curves of the vertebral column until it finally passes forward in front of, and slightly to the left of, the aorta to gain the œsophageal opening in the diaphragm. In addition to these curves it presents two lateral curvatures, one convex toward the left side at the root of the neck and in the upper part of the thorax, and the other concave toward the left in the lower part of the thorax where it leaves the vertebral column. It lies in the middle line at its commencement (usually opposite the sixth cervical vertebra), and again, at a lower level, opposite the fifth thoracic vertebra.

After death the œsophagus is somewhat flattened from before backward, but it is more rounded during life. It is closed except during the passage of food, etc.

The *peristaltic movements* of the œsophagus can readily be observed by means of the Rœntgen-rays. Solids often lodge a short time at the level of the arch of the aorta, but pass quickly through the cardiac orifice. A swallow of liquid, on the other hand, is usually detained at the lower end of the œsophagus (probably by sphincteric action of the cardia) for about seven seconds before passing into the stomach (Pfahler).

FIG. 895.—THE ŒSOPHAGUS AND STOMACH. (Testut.)

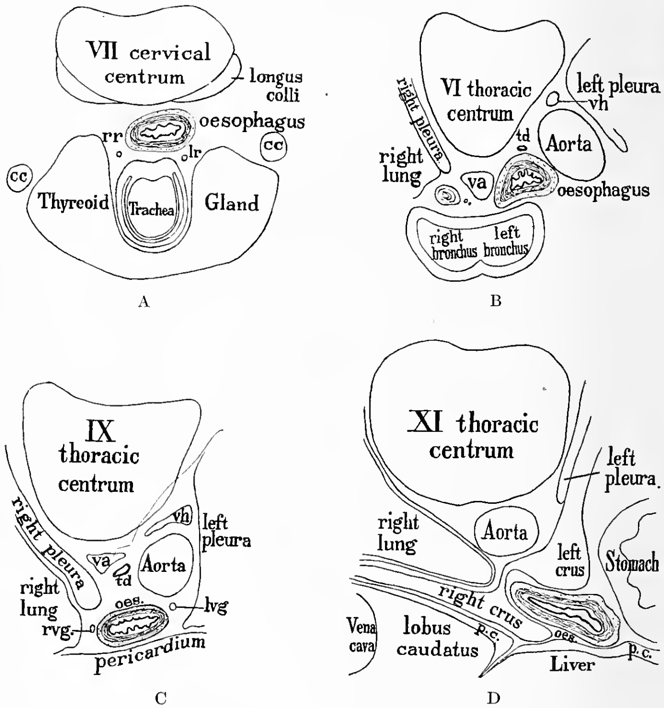


The œsophagus is divided into three parts: cervical, thoracic and abdominal.

Cervical portion.—The œsophagus has anteriorly the trachea, the posterior portion of the left lateral lobe of the thyreoid gland, and the left recurrent nerve, branches of the inferior thyreoid artery, and the carotid sheath. *Posteriorly*, it rests upon the vertebral column, the longus colli muscles, and prevertebral fascia. *On its right side* are placed the right carotid and right recurrent nerve; and *on the left side* the left inferior thyreoid vessels, left carotid artery, left subclavian, and the thoracic duct. The recurrent nerves pass upward on each side to gain the interval between the trachea and œsophagus. The left nerve, as already described, lies in front of the tube, and the right along its right border.

Thoracic portion.—The œsophagus descends in the thorax through the superior and the posterior mediastina. In the *superior mediastinum* its anterior relations are the trachea, with the deep cardiac plexus in front of its bifurcation, the left subclavian and carotid arteries crossing its left border obliquely, the left recurrent nerve, and the arch of the aorta. To the *left* are the left carotid and subclavian arteries, the end of the arch of the aorta, and the left pleural sac. To the *right* it is in relation with the right vagus nerve and the right pleural sac. *Posteriorly*, it rests upon the vertebral column, the left longus colli muscle, and it overlaps the thoracic duct. As it enters the *posterior mediastinum* it passes behind the left bronchus (or bifurcation of the trachea) and the right pulmonary artery, resting posteriorly on the vertebral column and thoracic duct. In the posterior mediastinum it has *anteriorly* the pericardium, which separates it from the left atrium and a portion of the diaphragm; *posteriorly* it rests upon the vertebral column, accessory hemiazygos and hemiazygos veins, the right aortic intercostal arteries, the thoracic duct, and the descending aorta. To the *right* is the right pleural sac, the vena azygos, which it partly overlaps, and below, the thoracic duct. To the *left* in the upper part is the descending thoracic aorta, and, below, the left pleural sac is separated from it by a little loose areolar tissue. It is surrounded by the œsophageal plexus formed by the vagi nerves, and, as they emerge from the lower part of the plexus, the left vagus lies in front of the œsophagus and the right vagus behind.

Fig. 896.—Cross-sections Illustrating the Relations of the Œsophagus at Various Levels.



Abdominal portion.—The œsophagus lies in the epigastric region of the abdomen. *Anteriorly* is the left lobe of the liver. To the *left* the left lobe of the liver and the fundus of the stomach. To the *right* the caudate (Spigelian) lobe of the liver, and *posteriorly* the decussating fibres of the crura of the diaphragm and the left inferior phrenic artery. The abdominal portion is very short, usually not more than 2 cm. (4/5 inch) in length (see figs. 896 D, 907).

Structure.—The thick-walled œsophagus presents the four typical tunics of the alimentary canal (fig. 897). The mucosa and the muscularis are the most important, the submucosa and the external adventitia being accessory layers. The **mucosa** (fig. 897) is thick and strong, of reddish colour in its upper portion and more greyish below. It presents deep longitudinal folds to allow for distention, and when empty the lumen is therefore stellate in cross sections. The lining epithelium is stratified squamous. The lamina propria presents numerous papillæ, and is limited externally by a *muscularis mucosæ*. This is a comparatively thick layer (except at the upper end) and is composed of smooth muscle fibres, longitudinally arranged.

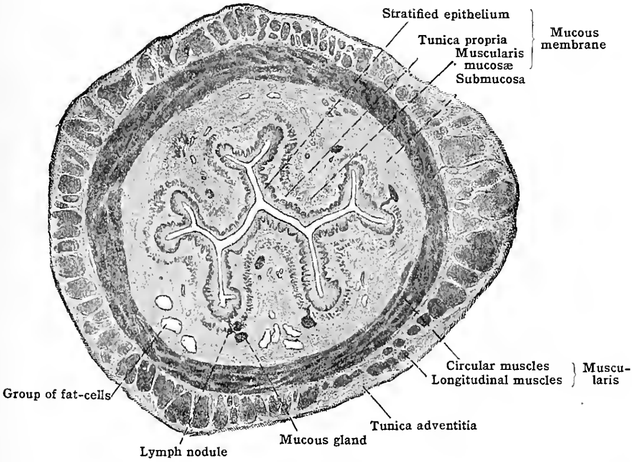
The submucosa (fig. 897) is a thick, very loose fibrous layer connecting the mucosa with the muscularis. It contains numerous vessels and nerves, and *mucous glands*. The latter [gl. œsophageæ] are of the racemose type, like those of the mouth, and are variable in number. There are also two sets of *superficial* glands, confined to the lamina propria, and resembling the fundus glands of the stomach. The upper set (Rüdinger-Schaffer glands) are found in 70 per cent. of cases, occurring above the level of the fifth tracheal ring. The lower set (œsophageal cardiac glands) form a ring around the œsophagus just above the cardiac aperture. A few small lymph nodes also occur in the submucosa, often around the ducts of the mucous glands.

The **muscularis** (fig. 897) is a thick reddish tunic with two distinct layers, approximately equal in thickness. The fibres of the *inner* layer are arranged circularly and are continuous with the inferior constrictor above and with the oblique fibres of the stomach below. The fibres of the *outer* layer are longitudinal and commence above as three flattened bands: a strong anterior band arising from the ridge on the back of the cricoid cartilage, and two lateral bands blending with the fibres of the stylo-pharyngeus and the pharyngo-palatine. These all unite into a continuous layer which below passes into the muscular coat of the stomach. The upper third or fourth of the œsophagus contains exclusively cross-striated muscle fibres, like those of the pharynx. Below this, there is a zone of intermingled smooth and cross-striated fibres. The lower half of the œsophagus muscle is usually composed exclusively of smooth fibres.

Around the muscular coat is a thin loose *fibrous* layer [tunica adventitia] connecting the œsophagus with neighbouring structures.

Vessels and nerves.—The *arterial* supply of the œsophagus is derived from the inferior thyreoid, the œsophageal branches of the aorta, the intercostals, the inferior phrenic and the

FIG. 897.—TRANSVERSE SECTION OF THE UPPER THIRD OF THE HUMAN ŒSOPHAGUS. × 5. (Lewis and Stöhr.)



left gastric arteries. Branches pierce the wall and supply the various coats. The *veins* accompany the arteries. They form on the outer surface of the œsophagus a venous plexus opening into the gastric coronary vein below and the azygos and thyreoid veins above (thus establishing a communication between portal and systemic veins). There are also numerous *lymphatics* in the œsophagus arising chiefly in the mucosa and draining into the lower deep cervical, posterior mediastinal and superior gastric nodes. The *nerves* form two sympathetic plexuses, the submucous and the myenteric, from which the walls are supplied as will be described later for the stomach and intestine. Branches are received from the sympathetics, and from the vagus, including the recurrent nerve.

Development.—The embryonic œsophagus is at first relatively very short, but lengthens rapidly in connection with the descent of the stomach. The upper end is still high in children, corresponding to the higher vertebral level of the larynx. The lining epithelial cells are primitively cylindrical in form, and irregular ciliated areas are found from the third fœtal month up to birth (F. T. Lewis). In the embryo of about 20 mm., there is a proliferation of the epithelium, associated with the formation of vacuoles, but the lumen does not appear to be normally occluded. The primary longitudinal folds of the mucosa appear early (third month) and at the lower end seem to participate in the rotation of the stomach (F. P. Johnson). The superficial œsophageal glands appear about the fourth month (78 mm.), the deep glands at 240 mm. (Johnson). Of the muscular layers, the circular appears first (at about 10 mm.) the longitudinal slightly later (17 mm.).

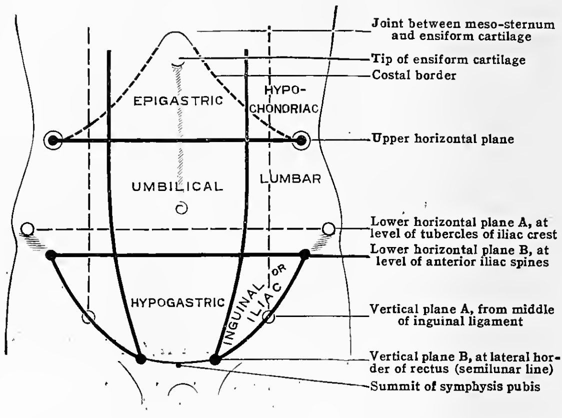
Variations.—Usually a bundle of smooth *muscle* connects the œsophagus with the left bronchus [m. broncho-œsophageus], and another similarly with the left mediastinal pleura [m. pleuro-œsophageus]. More rarely there are similar bands connecting with the trachea, pericardium, etc. Pouch-like *dilatations* of the œsophagus may occur, especially in the upper part of its posterior wall or at the lower end. According to C. R. Robinson, the latter include (1) *ampulla phrenica*, just above the diaphragm, and (2) *antrum cardiacum*, in the abdominal portion of the œsophagus. *Diverticula* also occur, some of which may be derived from the embryonic vacuolization of the epithelium previously described, as may likewise the occasional congenital *atresia*. Abnormal *strictures* of the œsophagus may occur, oftenest at the upper end, at the left bronchus, and near the lower end. Finally, the œsophagus may be in part either double or absent, and may communicate by fistula with the trachea.

Comparative.—The *length* of the œsophagus varies with the length of the neck, being shortest in fishes and amphibia where the œsophagus is not well marked off from the stomach. The *lining epithelium* is stratified squamous in mammals and birds, but often ciliated in lower forms. *Mucous glands* are absent in fishes, but occur typically in all higher forms. They are found best developed toward the lower end of the œsophagus, except in mammals, where they are usually more numerous at the upper end. *Dilatations* may occur normally, as in the crop of birds, which is richly supplied with glands. The *musculature* of the œsophagus is primitively entirely smooth (Oppel) as found in amphibia, reptiles and birds. A secondary replacement by cross-striated muscle is found to a variable extent in the majority of mammals and fishes.

THE ABDOMEN

The **abdomen** properly consists of that part of the body situated between the thorax and the pelvis. It is bounded *above* by the diaphragm; *below*, by the brim of the true pelvis; *behind*, by the vertebral column, diaphragm, quadratus lumborum and psoas muscles, and by the posterior portions of the ilia. *At the sides* it is limited by the anterior parts of the ilia and the hinder segments of the muscles which compose the anterior abdominal wall, viz., the transversus, internal oblique,

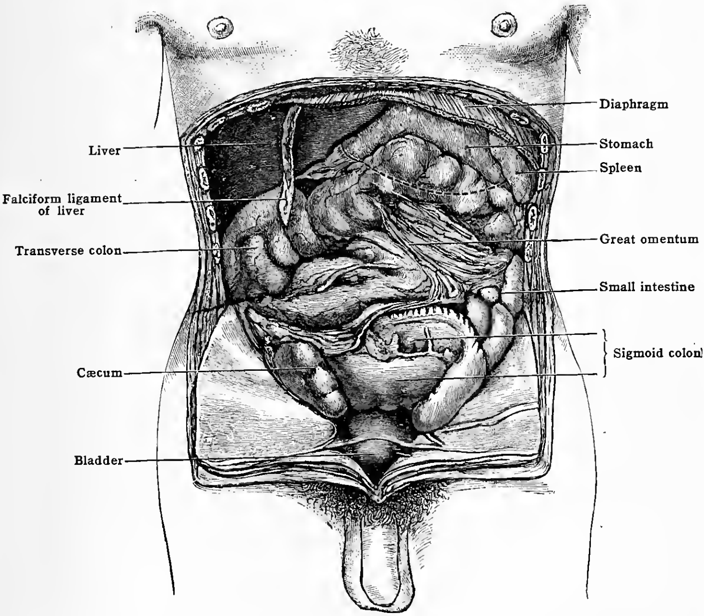
Fig. 898.—Diagram of the Abdominal Regions.



and external oblique. *In front*, besides these muscles, there are the two recti and pyramidales muscles. External to the peritoneum the abdomen is lined by a special layer of fascia.

It is customary for anatomists and physicians to divide, for purposes of description, the ventral surface of the abdomen, by means of two horizontal and two vertical lines, into nine regions (fig. 898). A complete uniformity in the use of the boundary lines marking these regional subdivisions has not as yet been attained, although the variations in the schemes used are not marked as concerns the main features. It should be borne in mind that it is necessary that the boundary lines used should be converted into planes carried through the whole depth of the abdomen and defined on the dorsal as well as the ventral surface, and that the relations defined can only be approximate, owing to the wide range of the physiological variation in the position of the abdominal contents. The nine regions or subdivisions may be outlined as follows:—The upper horizontal line or plane passes through the lowest point of the tenth costal cartilages, about 5 cm. above the umbilicus, and dorsally through the second or third lumbar vertebra. The lower horizontal line and plane passes through the level of the anterior superior iliac spines, and dorsally about 2.5 cm. below the promontory of the sacrum. Cunningham has proposed that this line be passed through the tuberculum cristæ, therefore in a plane slightly higher than the interspinous plane. For the longitudinal lines and planes it has been customary to run vertical lines parallel with the mid-body line or mid-sagittal plane, and from the middle of the inguinal ligaments. The outer border of each rectus would seem, however, preferable as a guide for these longitudinal lines and planes, which may be easily localised above by the lateral infra-costal furrow and below by the pubic spines, leaving thus on each side an inguinal region which includes the whole of the inguinal canal. The boundary lines here indicated may be made intelligible by a reference to fig. 898. The regions thus outlined are known as the right and left hypochondriac and epigastric regions, found above the upper horizontal line; the right and left lumbar and the umbilical regions, found between the two horizontal lines; the right and left

FIG. 899.—THE ADBOMINAL VISCERA IN SITU, AFTER REMOVAL OF THE ANTERIOR ABDOMINAL WALL. (After Sarazin.)



inguinal or iliac and the hypogastric regions, found below the lower horizontal lines. (According to the BNA, the lumbar regions are termed 'lateral abdominal'.)

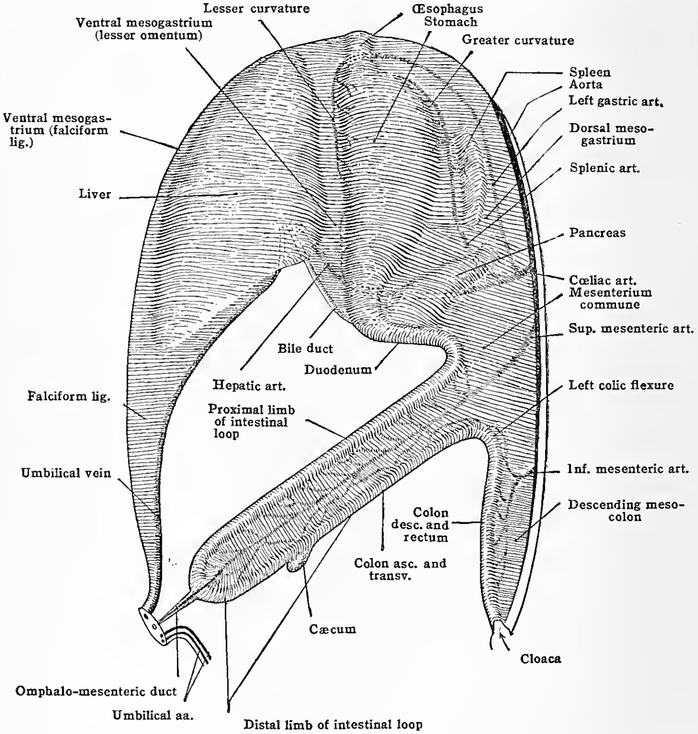
On freely laying open an abdomen from the front, the general form of the space is seen to be an irregular hexagon, the sides of which are formed as follows:—The upper two by the margins of the costal cartilages with the ensiform cartilage between; the two lateral sides by the edges of the lateral boundary; and the two lower by the two inguinal ligaments which meet at the pubes.

In this irregular hexagon the following organs can be observed without disarranging their normal position (fig. 899). Above, on the right side, under the costal cartilages, can be seen the liver, which extends from the right across the median line to a point below the left costal cartilages. Below the liver, and lying to the left side, can be seen the anterior surface of the stomach; from the lower border of the stomach the omentum extends downward, and shining through it can be seen the middle part of the transverse colon. On each side and below the irregularly folded omentum are exposed the coils of the small intestine; in the right iliac fossa a part of the cæcum appears; and in the left iliac fossa the lower (iliac) part of the descending colon and the beginning of the sigmoid colon.

To the left of the stomach and under cover of the lower ribs of the left side the edge of the spleen may possibly be observed; and just below the edge of the liver, and about the level of the tip of the ninth rib, the gall-bladder may be seen. The dome of the urinary bladder may be noticed just behind the symphysis pubis and in the median line. The disposition of the viscera in the fœtus is shown in fig. 953.

General morphology—Before taking up the various individual organs included in the abdominal and pelvic portions of the alimentary canal, a brief consideration of their general morphology is desirable. The primitive canal, as already described in the embryo (in the

FIG. 900.—DIGRAMMATIC REPRESENTATION OF AN EARLY STAGE IN THE DEVELOPMENT OF THE ALIMENTARY CANAL AND THE PERITONEUM. (After Sobotta-McMurrich.)



section on MORPHOGENESIS), and as found in the lower vertebrates is a comparatively straight, simple tube extending ventral to the body axis from mouth to anus. In the abdominal region (and primitively throughout the whole trunk), the canal lies within the body cavity, which is lined by parietal peritoneum. The visceral peritoneum is reflected from the mid-dorsal line as a double layer, the *primitive dorsal mesentery*, within which the vessels and nerves pass to the walls of the canal. Within the dorsal mesentery are also the spleen and pancreas. In the anterior (upper) region of the abdomen there is also a similar primitive *ventral* mesentery, which contains the liver.

The relations above mentioned are indicated diagrammatically in fig. 900, which represents a comparatively early stage in the development of the intestinal canal. The liver is already almost completely separated from the diaphragm (with which it was intimately associated in the earlier septum transversum). The ventral mesentery persists in the form of (1) the gastro-hepatic or lesser omentum, connecting the stomach with the liver; and (2) the falciform ligament, connecting the liver with the ventral body wall.

The stomach undergoes a rotation on its longitudinal axis so that its anterior border (lesser curvature) is turned to the right, and its posterior border (greater curvature) to the left (fig. 901). Thus the posterior mesentery of the stomach [mesogastrium], bulges to the left and forward, carrying with it the spleen and pancreas. The portion of the mesentery corresponding to the pancreas, and that from the spleen to the root of the mesentery, become fused with the posterior body wall. The portion of the primitive mesogastrium between the stomach and spleen persists as the *gastro-splenic omentum* (or ligament), while the lower portion arches forward and downward as an extensive fold, the *great omentum.* The portion of the peritoneal cavity left behind the stomach is termed the *bursa omentalis,* or lesser sac, the remainder of the peritoneal cavity being the greater sac.

Along with the pancreas, the duodenum becomes adherent to the posterior wall. The remainder of the intestine forms a loop (fig. 901), the upper portion of which forms the jejuno-ileum, the lower portion the large intestine. The intestinal loop rotates counter-clockwise, so that the cæcum and ascending colon are carried over to the right side of the body cavity, where (with the corresponding portion of the primitive mesentery) they become adherent to the posterior body wall (fig. 901). The mesentery of the transverse colon persists (though fused partly with the great omentum, as explained later under development). The descending colon becomes displaced to the left side, and (together with its mesentery) becomes adherent to the posterior wall of the abdomen. The mesentery of the sigmoid colon usually persists (in part), while that of the rectum is obliterated. Through these modifications of the peri-

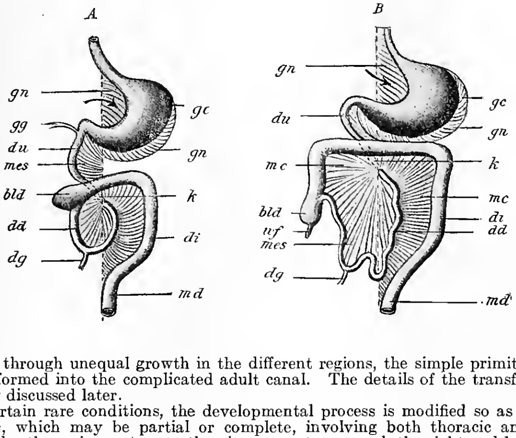
bld, cæcum; dd, small intestine; dg, yolk-stalk; di, colon; du, duodenum; gc, greater curvature of the stomach; gg, bile duct; gn, mesogastrium; k, point where the loops of the intestine cross; mc, mesocolon; md, rectum; mes, mesentery; wf, vermiform appendix. (McMurrich after Hertwig.)



toneum, and through unequal growth in the different regions, the simple primitive intestinal tube is transformed into the complicated adult canal. The details of the transformation will be more fully discussed later.

Under certain rare conditions, the developmental process is modified so as to produce a *situs inversus,* which may be partial or complete, involving both thoracic and abdominal viscera. Under these circumstances, the viscera are transposed, the right and left sides being reversed.

THE PERITONEUM

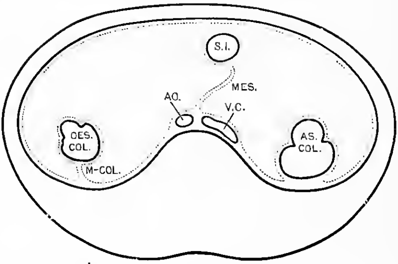
The **peritoneum,** as has been shown, is a serous membrane which lines the cavity of the abdomen from the diaphragm to the pelvic floor, and invests or covers to a varying extent the viscera which that cavity contains. Viewed in its very simplest condition, it may be regarded as a closed sac, the inner surface of which is smooth, while the outer surface is rough and is attached to the tissues which surround it.

In the male subject the peritoneum forms actually a closed sac; but in the female its wall exhibits two minute punctures, which correspond to the openings of the Fallopian tubes. That part which lines the walls of the abdomen is termed the *parietal* peritoneum; that which is reflected on to the viscera is the *visceral* peritoneum. The disposition of the peritoneum may first be studied by noting its arrangement as made evident in transverse sections of the abdomen at certain levels.

The first section to be described shows the peritoneum in its simplest condition. This is a transverse section through the body, at about the level of the upper surface of the fourth lumbar vertebra, and therefore about the site of the umbilicus (fig. 902).

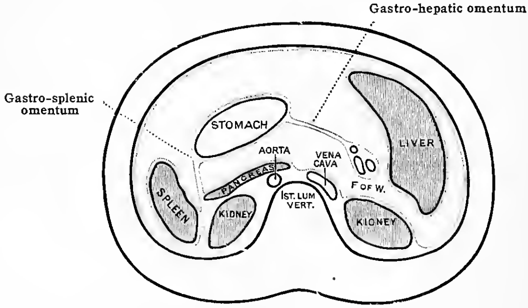
Starting on the inner surface of the anterior abdominal wall, the peritoneum is seen to cover the transversalis fascia, and indirectly the anterior abdominal muscles; then, passing

Fig. 902.—Diagram of Cross-section of the Abdomen, Showing the Peritoneal Relations at the Level of the Umbilicus. *AO*, Aorta. *AS. COL.*, Ascending colon. *DES. COL.*, Descending colon. *MES.*, Mesentery. *M. COL.*, Descending mesocolon. *SI*, Small intestine. *V.C.*, Vena cava inferior.



to the left, it lines the side of the abdomen, until it reaches the descending colon. This it covers, as a rule, in front and on the sides, though occasionally it forms a mesocolon. Then it passes over the bodies of the vertebræ with the large vessels upon them, and leaves the back of the abdomen to run forward and enclose the small intestine, returning again to the spine. The two layers thus form the mesentery, having between them a middle layer [lamina mesenterii propria] containing the terminal branches of the superior mesenteric vessels. It then passes over the right half of the posterior abdominal wall, covering the ascending colon in front and at the sides only (unless there be a mesocolon), and then passes on to the side and front of the abdomen to the point from which it was first traced.

Fig. 903.—Diagram of Cross-section of the Abdomen, Showing the Peritoneal Relations at the Level of the Foramen of Winslow. (F. of W.)

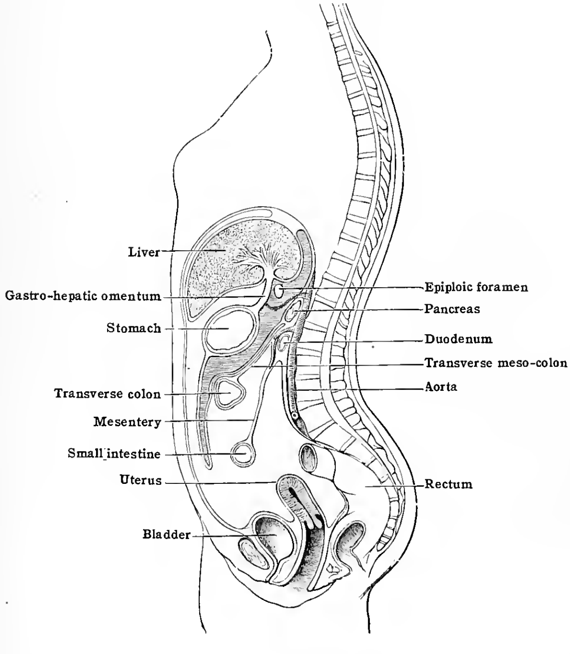


In tracing the peritoneum in a section of the body opposite the stomach (fig. 903), on a level with the first lumbar vertebra, its course becomes more complicated and difficult to follow.

In the section already given the peritoneum as a simple closed sac can be readily conceived; but at the level now exposed the serous membrane has been so introverted that there appear to be two sacs, one leading from the other, and known respectively as the greater and the lesser sac of the peritoneum. They communicate through the epiploic foramen (of Winslow). The lesser sac [bursa omentalis] is situated behind the stomach, so that on first opening the abdomen no trace of it is to be seen. It extends downward [recessus inferior] between the layers of the great omentum (though this part of the lesser sac is largely obliterated by adhesion in the adult). It extends upward [recessus superior] behind the caudate lobe of the liver. The vestibule [vestibulum bursæ omentalis] is the portion which lies just behind the lesser omentum, and communicates with the greater sac through the epiploic foramen. In general, the lesser sac is limited *anteriorly* by the liver, stomach, and omenta; *posteriorly* by the posterior abdominal wall, and below, behind the great omentum, by the transverse meso-colon. Its disposition on vertical section is shown in fig. 904.

The **epiploic foramen (foramen of Winslow)** (figs. 903, 906) is situated just below the liver; it looks toward the right, and will readily admit one or two fingers. It is bounded *superiorly* by the caudate lobe of the liver; *inferiorly*, by the duodenum (pars superior); *posteriorly*, by the vena cava; and *anteriorly* by the right margin of the gastro-hepatic or lesser omentum, containing the structures passing to and from the liver. Starting at the epiploic foramen, the lesser sac will be found to turn to the left.

Fig. 904.—Diagram of a Sagittal Section of the Trunk, Showing the Relations of the Peritoneum. (Allen Thompson.)



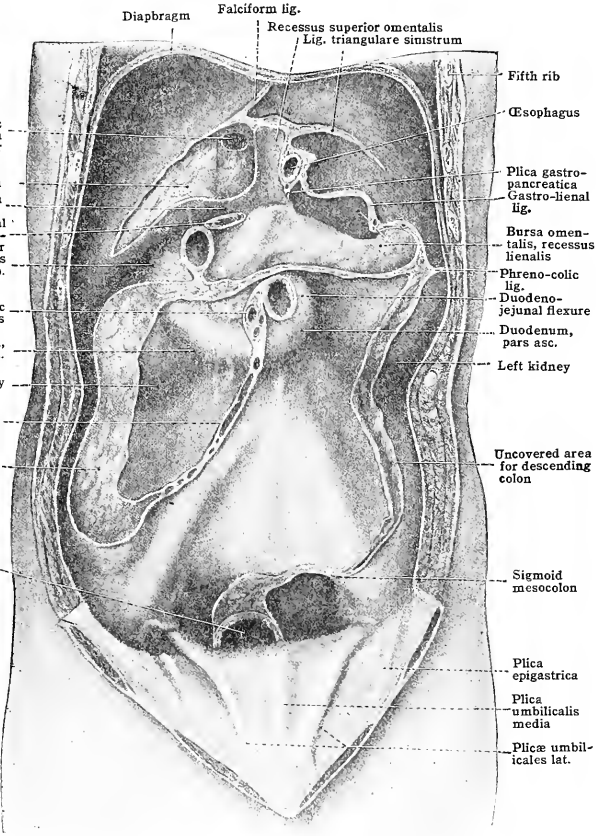
If, now, the peritoneum be viewed in a transverse section of the body at the level named, viz., through the first lumbar vertebra, it will be found that the section has probably passed through the epiploic foramen (fig. 903). Starting at the front of the abdomen and going to the right, the peritoneum is seen to line the anterior abdominal wall, to pass over the side of the abdomen, and to cover the front of the right kidney; it then extends on to the vena cava, when it becomes a part of the lesser sac; then along the back of the lesser sac, over the aorta and pancreas, which separate it from the vertebral column; next it reaches the anterior of the two internal surfaces of the spleen internal to the hilus. Here it meets with another layer of peritoneum, and helps to form the gastro-splenic ligament [lig. gastrolienale]. Leaving the spleen, it changes its direction forward and to the right, and runs to the stomach, forming the posterior, layer of the gastro-splenic ligament; it covers the posterior surface of the stomach, and leaves its mesial border (lesser curvature) to form the posterior layer of the lesser omentum, and then passes upward and to the right to the liver. In this transverse section it is only seen passing on the right margin of the lesser omentum, where it forms the anterior boundary of the epiploic foramen. Here it bends sharply around the omental margin enclosing the hepatic vessels continuing to the left as the anterior layer of the lesser omentum; and then passing to the left reaches the stomach, which it covers in front. It then forms the anterior layer of the gastro-splenic ligament, and once more reaches the spleen. It passes right around the spleen to the back of the hilus, where it is reflected on to the left kidney as the lieno-renal ligament (fig. 903). Hence the peritoneum passes along the side and front of the abdomen to the point from which it started. In this section the liver is so divided as to appear separated from all connection with the other viscera and the abdominal wall, and to be surrounded by peritoneum.

The course of the peritoneum in a **longitudinal section of the body** will now be considered (fig. 904). Starting at the umbilicus and passing downward, the peritoneum is seen to line the anterior abdominal wall. Before reaching the pelvis it covers also the urachus, the deep epigastric arteries, and obliterated hypogastric arteries, which form ridges beneath it. For some little way above the os pubis the peritoneum is loosely connected with the abdominal wall, a circumstance which is made use of in supra-pubic cystotomy. Moreover, as the distended bladder rises from the pelvis it can detach the serous membrane to some extent from the anterior abdominal wall. In extreme distension of the bladder the peritoneum may be lifted up for some 5 cm. vertically above the symphysis. On reaching the os pubis it is reflected on to the upper part of the bladder, covering it as far back as the base of the trigone; thence it is reflected on to the rectum, wihch it covers in front and at the sides on its upper part, rarely forming a distinct mesorectum. Between the bladder and rectum it forms in the male the **recto-vesical pouch.** The mouth of this pouch is bounded on either side by a crescentic fold, the plica semilunaris. In the female the peritoneum is reflected from the bladder on to the uterus, which it covers; it then extends so far down in the pelvis as to pass over the upper part of the vagina behind; thence it extends to the rectum. The peritoneum which invests the uterus is reflected laterally to form the broad ligaments. The fold between the vagina and rectum forms the **recto-vaginal pouch,** or pouch of Douglas. The membrane has now been traced back to the spine.

Following it upward, the sigmoid colon will be found to be completely covered by peritoneum, a mesocolon attaching the gut to the abdominal wall (shown in fig. 905). A little higher up in the median line the peritoneum passes forward, to enclose the small intestine, and, returning to the spine, forms the mesentery (fig. 904). It now passes over the third part of the duodenum to the pancreas, from which point it again passes forward to form the lower layer of the transverse mesocolon. It invests the transverse colon below and partly in front, and then leaves it to pass downward to take part in the great omentum. Running downward some distance, it returns and forms the anterior layer of the omentum. On reaching the stomach it goes over the anterior surface, and at the upper border forms the anterior layer of the lesser or gastro-hepatic omentum, which extends between the stomach and the liver. It invests the inferior surface of the liver in front of the transverse fissure, and, turning over its anterior border, covers the upper surface. At the posterior limit of the upper surface it leaves the liver and goes to the diaphragm, forming the superior layer of the coronary ligament. It covers the anterior part of the dome of the diaphragm, and, once more reaching the anterior abdominal wall, can be followed to the umbilicus, where it was first described. This completes the boundary of the greater sac. On reference to the diagram (fig. 904) the student might be led to suppose that the two sacs are quite separate. This, of course, is not the case; but in a longitudinal section of the body made anywhere to the left of the epiploic foramen (foramen of Winslow), it is impossible to show the direct connection between the two sacs. (See fig. 905.)

The peritoneum has only been traced in this longitudinal section so far as it concerns the greater sac. It now remains to follow upon the same section (fig. 904) such part of the membrane as forms the **lesser sac.** The peritoneum here will be seen to cover the posterior surface of the stomach; thence from the lesser curvature it runs upward to the liver, forming the posterior layer of the lesser or gastro-hepatic omentum. It reaches the liver behind the transverse fissure. It covers only a part of its posterior surface (caudate lobe), and is reflected on to the diaphragm, forming the lower layer of the coronary ligament. It now goes downward over the posterior part of the dome of the diaphragm to the spine, separated from the latter by the great vessels. On reaching the anterior border of the pancreas it passes forward, and forms the upper layer of the transverse meso-colon. It then covers the upper half of the transverse colon, and, descending, forms the innermost layer of the great omentum. (The inner layers of the great omentum are usually fused in the adult, however, thus obliterating this portion of the lesser sac.) It now ascends, and, arriving at the greater curvature of the stomach, passes on to its posterior wall. At this point its description was commenced. The general relations of the greater and the lesser sac are also evident in fig. 905 showing the lines along which the parietal peritoneum is reflected from the posterior abdominal wall as the visceral peritoneum, forming the various mesenteries and covering the various abdominal organs.

Fig. 905.—Reflections of the Peritoneum on the Posterior Abdominal Wall. (From Rauber-Kopsch, modified.)



The precise manner in which certain organs—such as the liver, the cæcum, the duodenum, and the kidneys—are invested by peritoneum is described in the accounts of those viscera. To such accounts the reader is referred for a description of the many 'ligaments' (such as those of the bladder and liver) which are formed by the peritoneum.

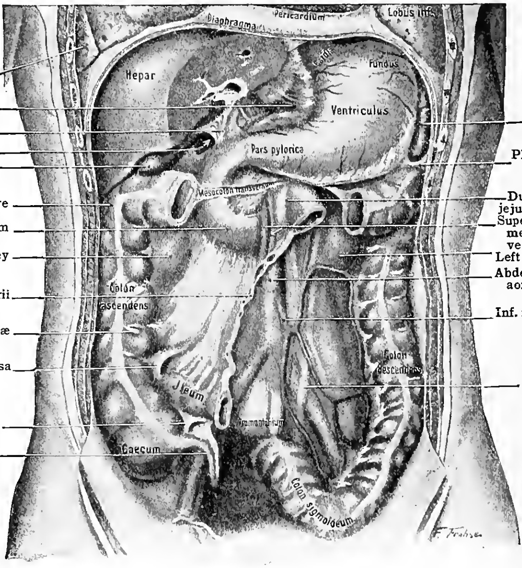
The great omentum.—As is evident from its development, the great omentum [omentum majus] is formed of four layers of peritoneum, though this is quite impossible to demonstrate in an adult, the individual layers having become adherent.

The great omentum acts as an apron, protecting the intestines and providing them with a heat-economising covering of fat. It is nearly quadrilateral in shape, and is variable in extent. In fig. 904 the great omentum is shown to be connected with the greater curvature of the stomach, on the one hand, and the transverse colon, on the other. Originally it extended backward above the transverse colon and mesocolon to the posterior abdominal wall. The line along which it fuses with the transverse colon and mesocolon during development is shown in fig. 904.

Mr. Lockwood has made some investigations on the lengths of the transverse meso-colon and great omentum in thirty-three cases. In twenty, under the age of forty-five, only one subject had a great omentum long enough to be drawn beyond the pubic spine; in five, the omentum reached as far as the pubes. In the cases beyond forty-five years it was the exception rather than the rule to find an omentum which could not be pulled beyond the lower limits of the abdomen.

The **lesser omentum** [omentum minus] consists of a double layer of peritoneum extending between the stomach and the liver. If the two anterior layers of the great omentum are traced upward, they are seen to enclose the stomach, and then

FIG. 906.—ABDOMINAL VISCERA, ANTERIOR VIEW, AFTER REMOVAL OF A PART OF THE LIVER AND INTESTINES. (Rauber-Kopsch.)



join together again at the lesser curvature to form the lesser omentum (fig. 904). It is connected above with the portal (transverse) fissure and the fissure for the ductus venosus; below, with the lesser curvature of the stomach; the left extremity encloses the œsophagus; the right border contains the hepatic vessels and is free, forming the anterior boundary of the epiploic foramen (see fig. 906).

The lesser omentum is divided into two parts. The portion connecting the portal fissure of the liver with the first part of the duodenum, and enclosing the root structures of the liver, is called the *hepato-duodenal ligament* [lig. hepatoduodenale]. The portion of the lesser omentum connecting the lesser curvature of the stomach with the fissure of the ductus venosus is the *gastro-hepatic* ligament [lig. hepatogastricum].

The **gastro-splenic ligament** [lig. gastrolienale] connects the left extremity of the stomach with the spleen, continuing the layers of peritoneum which enclose the stomach (fig. 903).

The gastro-phrenic and phreno-colic ligaments.—As the peritoneum passes from the diaphragm to the stomach it forms a small fold just to the left of the œsophagus. This is the gastro-phrenic ligament. A strong fold of the membrane also extends from the diaphragm (opposite the tenth and eleventh ribs) to the splenic flexure of the colon, and is known as the phreno-colic (costo-colic) ligament [lig. phrenicolienale]. (See figs. 905, 906.)

Minute anatomy.—The peritoneum, like all serous membranes, consists of two layers; a lining layer composed of simple squamous epithelium (mesothelium), and an underlying layer of fibrous connective tissue. The latter is highly elastic, and denser in the parietal than in the visceral layer. It often contains fat. In mesenteries and similar structures, the connective tissue is usually very scanty, except surrounding the vessels and nerves. Ruptures often occur in the omenta, which thus become fenestrated in structure. The visceral peritoneum is usually closely attached to the organs for which it forms the outer serous tunic, but the parietal peritoneum is often loosely attached to the adjacent wall by a fatty subserous layer [tela subserosa]. Smooth muscle occurs frequently in the various peritoneal folds.

The peritoneal cavity contains normally a very slight amount of watery fluid, which serves to lubricate the smooth peritoneal surface and thus to eliminate friction between adjacent surfaces during the movements of the alimentary canal.

Vessels and nerves.—The peritoneum is in general somewhat sparsely supplied with *blood-vessels* from various adjacent trunks. *Lymph-vessels* also occur, but they probably do not connect directly with the peritoneal cavity by stomata (as is found in the frog and as claimed by some to occur in man). They communicate with the lymphatics of neighbouring regions. The *nerves* are also comparatively scarce. They are partly of sympathetic origin (vasomotor), and partly sensory nerves from the intercostal (7th to 12th), and lumbar nerves. The sensory nerves are more frequent in the parietal peritoneum and end in the connective tissue, either freely or in special end-organs (varying from simple end-bulbs to Pacinian corpuscles).

Development.—The principal features in the development of the peritoneum have already been mentioned in the section on MORPHOGENESIS and in the remarks on the general morphology of the intestinal canal (p. 19). Further details will be included later under the development of the intestine, etc.

Variations.—Variations in the form and relations of the peritoneum are exceedingly common, and are most commonly of developmental origin. Variations in the form and relations of the various abdominal organs necessarily involve corresponding modifications in the peritoneum. The diaphragm may be incompletely formed, leaving the peritoneal cavity in communication with the pleural, or more rarely the pericardial cavity. The primitive dorsal mesentery of the intestine [mesenterium commune] may persist unmodified (in about 2 per cent. of adults), or the various secondary changes may be inhibited at any stage. Thus the stomach or the intestinal loop may fail, either wholly or partly, to undergo their characteristic rotations. The adhesions of the various mesenteries may be incomplete, or they may be more extensive than usual. For example, the sigmoid mesocolon may be more or less completely obliterated by adhesion, and numerous unusual peritoneal pockets or ligamentous bands may be formed in this way in various localities. Variations thus due to extensions of the normal developmental process are sometimes difficult to distinguish from pathological adhesions caused by peritonitis.

Comparative.—As previously mentioned, the primitive body cavity in vertebrates extends throughout the trunk region. In the cyclostomata, this primitive relation persists, the pericardial cavity remaining in communication with the general body cavity. In all higher forms, however, the pericardial cavity becomes entirely separated. In amphibia the lungs lie in the general (pleuroperitoneal) body cavity; in the reptiles and birds, they are partially separated; but a complete separation of the pleural cavities occurs only with the formation of the definite diaphragm in mammals.

The formation in the peritoneal cavity of a complete dorsal mesentery, and an incomplete ventral mesentery (in the hepatic region) is typical for all classes of vertebrates. Slight modifications in the form of the mesenteries depend chiefly upon the different degrees of complexity in the development of the various parts of the intestinal tract. The marked changes associated with extensive secondary adhesions of the primitive peritoneal structures are found only among the higher mammalia, especially in man.

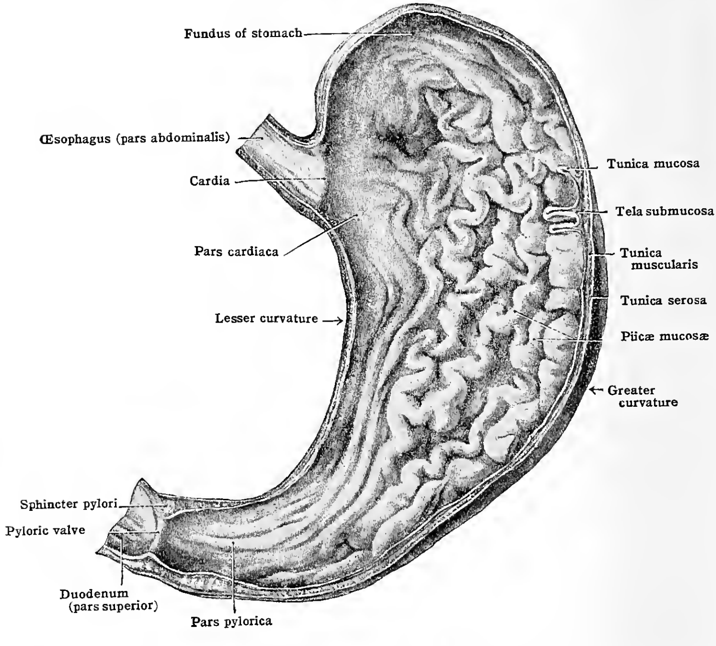
THE STOMACH

The **stomach** [ventriculus; gaster] is a dilation of the alimentary canal succeeding the œsophagus. In the stomach the food is mixed with the gastric juice and reduced to a viscid, pulpy liquid, the chyme [chymus], which undergoes a certain amount of digestion and absorption before passing into the duodenum.

The stomach (figs. 906, 907) is a somewhat pear-shaped organ located in the upper, left side of the abdominal cavity. It presents a *body* [corpus ventriculi], with an enlarged upper end or *fundus*, on the right side of which is the *cardia*, the aperture communicating with the œsophagus. The body of the stomach is extremely variable in form, as will be explained later, but is in general divisible into a more expanded upper two-thirds, the *cardiac portion* [pars cardiaca], which is nearly vertical, and a more constricted lower third, the *pyloric portion* [pars pylorica], which turns horizontally toward the right. The pyloric portion often presents toward its lower end a slight, variable dilation, the *antrum pylori*, succeeded by a short constricted *pyloric canal* (Jonnesco). At the lower end of this canal the *pylorus* forms the aperture leading into the duodenum, and contains a thick sphincter derived from the circular fibres of the muscular layer. The stomach has two borders and two surfaces. The medial (or upper) border forms the *lesser curvature* [curvatura ventriculi minor], which is concave (except near the pylorus) and gives attachment to the lesser omentum. The lateral (or lower) border forms the *greater curvature* [curvatura ventriculi major], which is convex, and gives attachment to the great omentum. The curvatures separate the *anterior surface* [paries anterior], which faces forward and upward, from the *posterior surface* [paries posterior], which is placed backward and downward.

Dimensions.—The dimensions of the stomach are subject to great variation and therefore only a gross approximation can be given. The *length* of the lesser curvature averages about 10 cm. (7.5 cm. to 15 cm.), and that of the greater

Fig. 907.—Longitudinal Section of Stomach, Showing the Interior of the Posterior Half. (Rauber-Kopsch.)



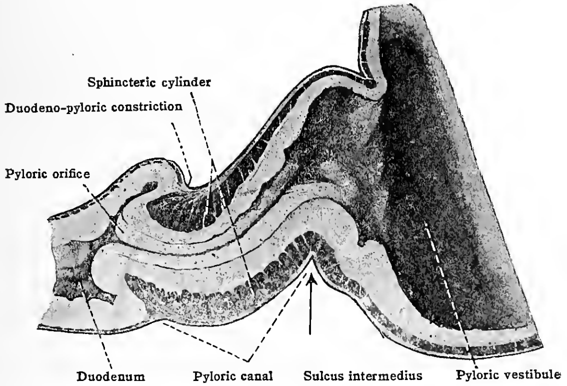
curvature is three or four times as great. The *diameter* varies exceedingly according to the amount of contents. When nearly empty, it presents, especially in the pyloric portion, a narrow tubular form, with a diameter of about 4 cm. or 5 cm. (fig. 1108, Section XIII). The diameter of the pylorus, which is the narrowest point in the alimentary canal when constricted is only about 1.5 cm. It is distensible, however, as hard bodies with diameters of 2 cm. or more may readily pass through.

The average *capacity* of the stomach is between one and two litres, being subject to extreme individual variations. In the newborn, it averages about 30 cc. (25 to 35 cc.), increasing very rapidly in the early postnatal months and reaching an average of 270 cc. at one year (Lissenko). The average *weight* of the adult stomach is about 135 gm.

Position and relations of the stomach.—The position and relations of the stomach, like its form and structure, are subject to many variations in different individuals, and in the same individual according to changes in physiological condition, posture, etc. It is therefore difficult to give a concise and accurate description.

The normal **position** of the stomach has long been disputed. It is generally recognised that the long axis is oblique, extending from above downward, forward and to the right. Some, however, especially among the older anatomists, have maintained that the gastric axis normally approaches more nearly to the *horizontal* type, with the pylorus but little below the cardia (approximately the position shown in figs. 915, 916). Others, especially among the more recent anatomists, have maintained that the axis of the stomach is normally more nearly *vertical* in position (see fig. 1125, Section XIII). The results of an extended and careful study, both in formalin-hardened bodies and by means of the Rœntgen-rays in the living body, demonstrate that there is much variability in the position of the stomach. Both the horizontal and the vertical types may occur as the extremes of normal variation, but the more usual type is the intermediate *oblique* position. The gastric axis, however, is not straight, but somewhat curved and bent in a reverse L-shape. The larger cardiac portion is approximately vertical (especially when the trunk is in the upright posture) the smaller pyloric portion more nearly horizontal (figs. 895, 906, 918, 919). In the empty stomach, the pylorus opens into the duodenum from left to right. In distention, however, the pylorus is carried in front of the duodenum. In extreme distention, it is carried to the right and downward so as to open upward and to the left.

Fig. 908.—Longitudinal Section of the Pyloric Portion of the Stomach. (Cunningham, Trans. Royal Soc. Edinb., vol. 45.)

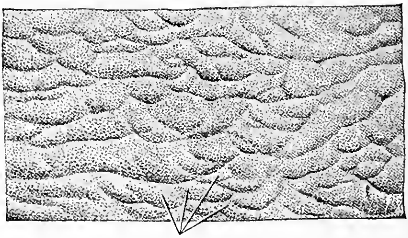


In **surface relation** (fig. 914), the stomach lies within the left hypochondriac and the epigastric regions. Often, however, especially when distended, it extends into the umbilical and even the right hypochondriac region. When empty, it usually lies almost entirely in the left half of the body, with the pylorus not more than 1 cm. or 2 cm. to the right of the mid-sagittal plane. When distended, the long axis of the stomach is lengthened and the pylorus is displaced 5 cm. or more to the right and downward. In distention, the stomach expands in all directions (except posteriorly), and does not appear to rotate as is sometimes stated. The position of the stomach, especially when distended, also varies appreciably according to the *posture* of the body. It sags downward when the body is in the upright position, and to the right or left when the body is placed on the corresponding side. The *cardia* lies on the left side of the 10th or 11th thoracic vertebra, and corresponds to a surface point behind the left 7th costal cartilage about 2.5 cm. from its sternal end. The *pylorus* usually lies opposite the right side of the 1st lumbar vertebra, about midway between ensiform cartilage and umbilicus, or in Addison's 'transpyloric line,' midway between the suprasternal notch and the symphysis pubis, when the body is recumbent; but descends to the 2d or lower in upright posture. The *fundus* corresponds to the left dome of the diaphragm (which separates it from the lung and heart), opposite the sixth sterno-costal junction. The fundus of course rises and falls with respiratory movements of the diaphragm, the excursion being from 2 to 6 cm.

The relations of the stomach with *surrounding organs* are indicated diagrammatically in figs. 915 and 916. The *anterior surface* is in contact on the right with the left lobe of the liver, the pylorus reaching the quadrate lobe; on the left it is in contact with the diaphragm (separating it from the heart and left lung); and below with the anterior body wall by a triangular area of variable size. The *posterior surface* is in relation (separated by the lesser sac) with the pancreas, above which are areas of contact with the diaphragm, spleen, left kidney and suprarenal body; below the pancreas, the stomach is in contact with the transverse mesocolon, and through this with the transverse colon and coils of small intestine. The relation with the duodeno-jejunal angle is indicated in fig. 895. Further details concerning topography of the stomach are given in section XIII on CLINICAL AND TOPOGRAPHICAL ANATOMY.

Peritoneal relations.—The stomach is covered by peritoneum in its whole extent, except immediately along the curvatures and upon a small triangular space at the back of the cardiac orifice, where the viscus lies in direct contact with the diaphragm and possibly with the upper part of the left suprarenal gland. It is enclosed between two layers. These two layers at its lesser curvature come together to form the gastro-hepatic portion of the lesser omentum, and at the greater curvature extend downward to form the great omentum (figs. 903, 904). At the left of the œsophagus the two layers pass to the diaphragm, forming the gastro-phrenic ligament; and at the fundus they pass on to the spleen, forming the gastro-splenic ligament.

FIG. 909.—SURFACE VIEW OF GASTRIC MUCOSA. × 4. (Sobotta-McMurrich.)



The posterior surface of the stomach is in relation with the lesser sac (bursa omentalis), forming part of its anterior wall. The anterior surface of the stomach is in relation with the greater sac of the peritoneal cavity.

Minute anatomy.—The stomach is composed of the four typical layers of the alimentary canal—mucosa, submucosa, muscularis and serosa. The *mucosa* (figs. 907, 908, and 909) is thrown into a series of coarse *folds* (plicæ mucosæ), chiefly longitudinal, which disappear when the stomach is distended. Along the lesser curvature, the ridges are more regular (corresponding to Waldeyer's 'Magenstrasse') and form a longitudinal grooved channel from cardia to pylorus. Upon closer examination (fig. 909) the inner surface of the mucosa presents a somewhat warty ('mammilated') appearance, due to numerous small elevated areas [areæ gastricæ], varying from 1 to 6 mm. in diameter. When examined with a lens, it is seen that each area is beset with numerous small *pits* [foveolæ gastricæ], separated by partitions which sometimes (especially in the pyloric region) bear villus-like prolongations [plicæ villosæ]. The average number of foveolæ is estimated at 87 per sq. mm., or more than 6 millions for the entire stomach (Toldt). Into each pit or foveola open 3 to 5 gastric glands. The entire surface is covered with a simple columnar mucigenous epithelium.

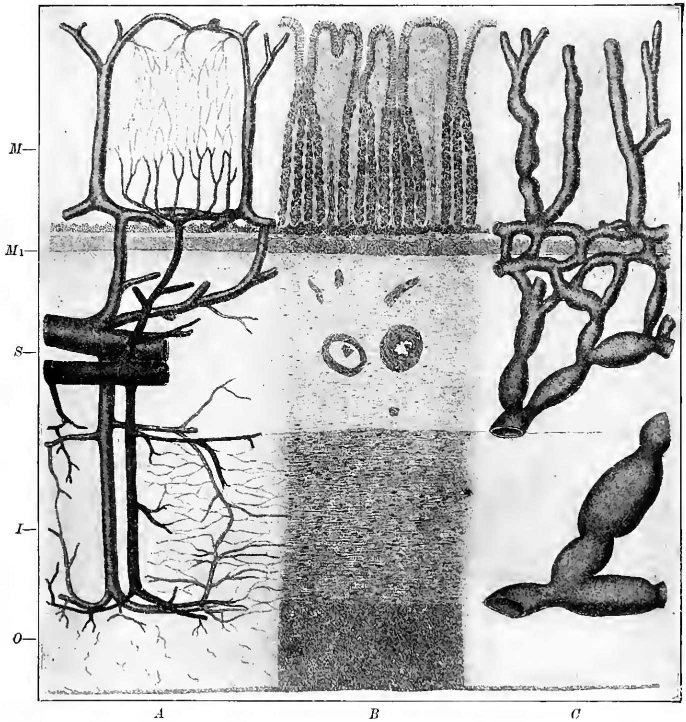
The relations of the mucosa in section are shown in fig. 910. The thickness of the mucosa varies, being greatest (about 2 mm.) in the pyloric region, decreasing to less than .5 mm. in the cardiac region (Kölliker). The *lamina propria* is crowded with *glands*, of which three varieties are distinguished. The *cardiac* glands are tubulo-racemose (chiefly mucous) glands occupying a narrow zone a few millimeters in width adjacent to the cardiac orifice. The *fundic* glands [gl. gastricæ propriæ] occupy the greater part of the stomach, and are simple (partly branched) tubular glands (fig. 910). They contain three varieties of cells—mucous cells, peptic cells, and parietal cells. The parietal cells may secrete an organic chloride compound, but the HCl of the gastric juice is formed *not* in the gland tubules but at the surface of the mucosa (Harvey and Bensley). The *pyloric* glands [gl. pyloricæ] are branched tubular glands occupying the pyloric region. Whether they are merely mucous or also secrete pepsin is still in dispute.

The interstitial tissue of the lamina propria contains diffuse lymphoid tissue and a few small *lymph nodules*, especially in the pyloric region. The *muscularis mucosæ* is a thin sheet of smooth muscle lying just below the fundus of the glands and is composed of an inner circular and an outer longitudinal layer.

The *tela submucosa* (fig. 910) is a very loose areolar, vascular layer which permits the wrinkling of the mucosa according to the degree of distention.

The *tunica muscularis* contains three layers of smooth muscle (figs. 911, 912, and 913). The outer or *longitudinal* layer [stratum longitudinale] is thickest along the lesser curvature, and is continuous with the longitudinal fibres of the œsophagus and the duodenum. On the anterior and posterior walls of the antrum pylori, the longitudinal fibres form thickened bands,

FIG. 910.—DIAGRAMMATIC SECTION OF THE STOMACH WALL SHOWING (*A*.) The Blood vessels, (*B*) the Tunics, and (*C*) the Lymphatics. *M*, Mucosa. M_1, Muscularis mucosæ. *S*, Submucosa. *I*, Circular, and *O*, longitudinal muscle layer. (Szymonowicz, after Mall.)



the *ligamenta pylori*. The middle or *circular* layer [stratum circulare] is continuous with the circular fibres of œsophagus and duodenum and surrounds the entire stomach. It is especially thickened in the region of the pyloric canal, at the lower end of which it forms a thickened ring-like band, the pyloric *sphincter* [m. sphincter pylori]. The inner or *oblique* layer [fibræ obliquæ] is composed of fibres continuous with the deepest circular fibres of the œsophagus. They form an incomplete layer which encircles the fundus and passes obliquely downward around the body of the stomach toward the greater curvature.

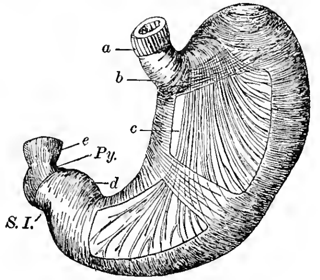
The external *tunica serosa* is formed by the peritoneum, and has the smooth shiny appearance and the structure typical for a serous membrane.

Blood-vessels.—The stomach receives its blood-supply from many branches. From the cœliac axis there is the left gastric artery, which runs along the lesser curve from left to right, anastomosing with the right gastric branch of the hepatic. Along the greater curve run the right and left gastro-epiploic arteries, anastomosing at the middle of the border, the left being a branch of the splenic, the right a branch of the hepatic, through the gastro-duodenal artery. The stomach also receives branches from the splenic (vasa brevia) at the fundus. The vascular arches along the curvatures of the stomach are comparable to those in the intestinal mesentery (Mall).

The blood of the stomach is returned into the portal vein. The coronary vein and pyloric vein open separately into the portal vein; the right gastro-epiploic vein opens into the superior mesenteric, the left into the splenic.

The arrangement and distribution of the blood-vessels within the stomach wall are illus-

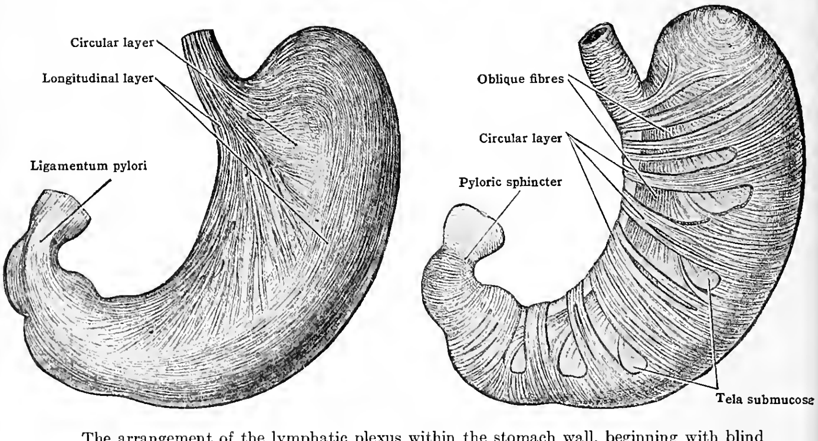
Fig. 911.—A Dissection of the Musculature of the Stomach. (Lewis and Stöhr, after Spalteholz.) *a* and *e*, Longitudinal layer. *b* and *d*, Circular layer. *c*, Oblique layer. *Py*, Pylorus. *S.I.*, Sulcus intermedius.



trated in fig. 910. The rich capillary plexus in the mucosa supplies the glands and also serves for absorption.

Lymphatics.—There is a set of nodes lying along the lesser and the pyloric portion of the greater curvature, and others at the pyloric and cardiac ends. These are entered by lymphatic vessels which, beginning in the mucous membrane (fig. 910), accompany all the gastric veins, but chiefly those of the lesser curvature. Vessels also accompany the left gastro-epiploic veins to terminate in the splenic nodes. On its way to the receptaculum chyli, the gastric lymph passes through groups of nodes [lymphoglandulæ pancreaticolienales] situated above and behind the head and neck of the pancreas.

Figs. 912 and 913.—Dissections Showing the Muscular Layers of the Stomach. × 1. (From Toldt's Atlas.)



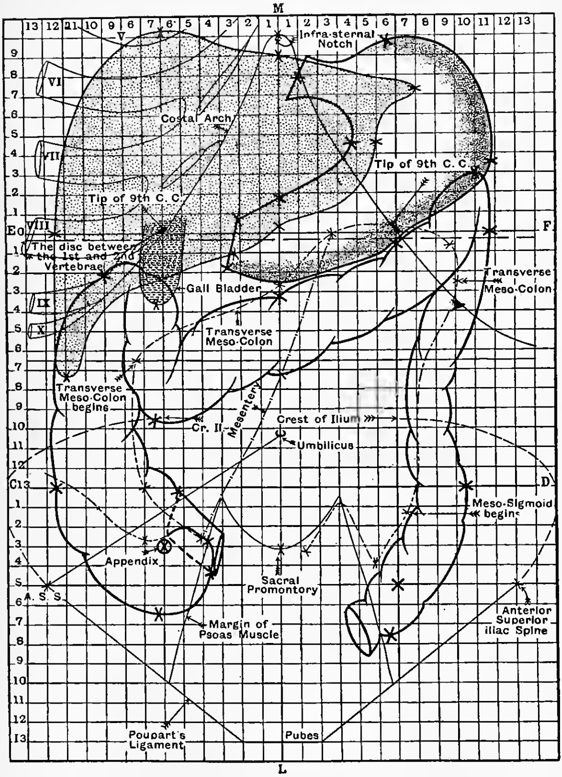
The arrangement of the lymphatic plexus within the stomach wall, beginning with blind rootlets in the mucosa, is shown in fig. 910.

Nerves.—The nerves of the stomach are derived in part from the vagi (which form the motor fibres of the stomach), the right vagus descending on the posterior wall, and the left on the anterior wall. The stomach also receives sympathetic branches from the cœliac plexus, following the arteries. Small ganglia occur along both vagus and sympathetic branches (Remak). The nerves join the gangliated plexuses, myenteric and submucous, in the wall of the stomach, from which branches are distributed to the muscularis and the mucosa as for the intestine in general.

Development.—The stomach at first lies in the mid-sagittal plane in the cervical region. It participates in the general descent of the viscera (the œsophagus becoming correspondingly lengthened) and reaches its permanent vertebral level in the 17 mm. embryo (Jackson). In the meantime, beginning in the 7.5 mm. embryo (F. T. Lewis), a rotation of the stomach has occurred. The rotation is around the long axis, so that the anterior border (lesser curvature) is turned to the right, and the posterior border (greater curvature) to the left. The right surface therefore becomes posterior and the left anterior. During the process of descent, the pyloric end is the first to become fixed (at about 12 mm.). As the cardiac end continues to descend, it is displaced to the left, so the oblique position of the stomach is established early. The stomach is at first spindle-shaped, but the upper end begins to enlarge at about 10 mm. The fundus develops somewhat later as a localized outgrowth (Keith and Jones).

The fœtal stomach is somewhat crowded to the left by the relatively large liver (fig. 953).

Fig. 914.—Outline Showing the Average Position of the Abdominal Viscera in 40 Bodies, on a Centimetre Scale (Reduced to .36 Natural Size). *ML*, anterior mid-line *EF*, horizontal line half-way between pubes and suprasternal margin ("transpyloric" line), *CD*, line half way between pubes and line *EF*. (Addison.)



and its relations to surrounding organs undergo considerable change. Even in the fœtus it is quite variable, but its general form and position do not differ essentially from the adult condition.

Glands.—According to Johnson, in an embryo of 16 mm., the lining epithelium shows the primitive foveolæ as pit-like depressions which become elongated, forming irregular anastomosing grooves, separated by villus-like projections. The pits multiply and deepen, and from their bottoms the gastric glands bud off (at 120 mm.). The parietal cells appear very early in the gland fundus, but the differentiation of gland cells is still incomplete at birth.

Figs. 915 and 916.—Diagrams of the Contact Areas of the Stomach, Anterior and Posterior Views.

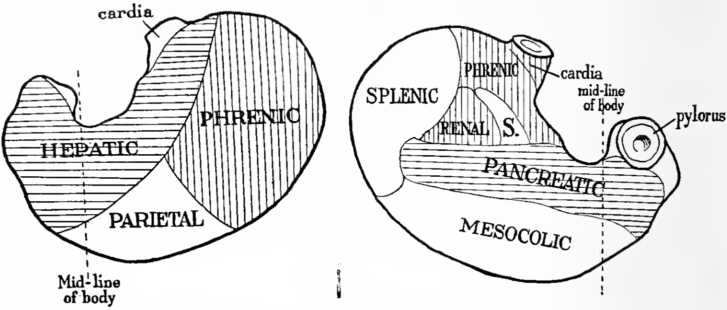


Fig. 917.—The Abdominal Viscera, From Behind. (Rüdinger.)

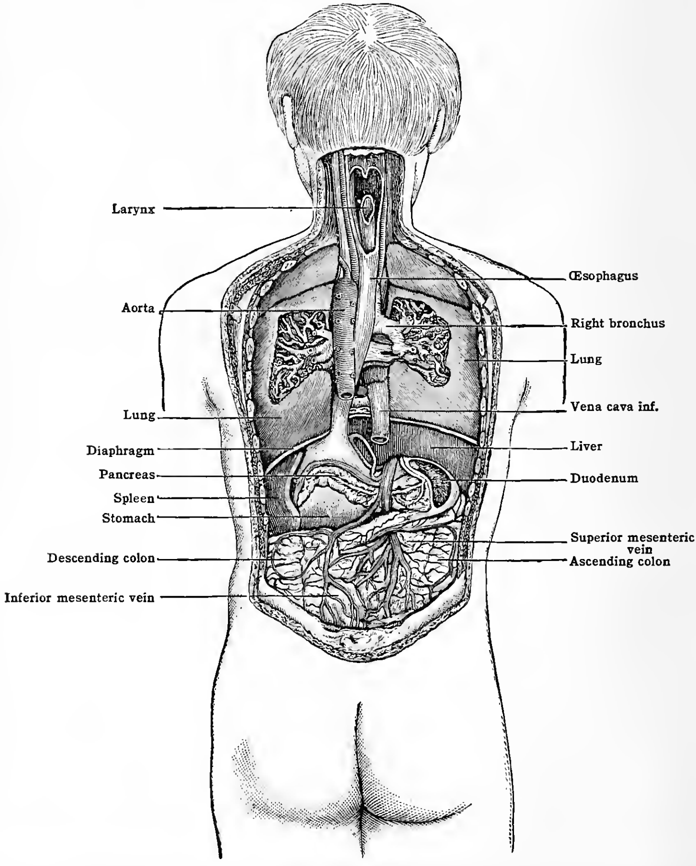


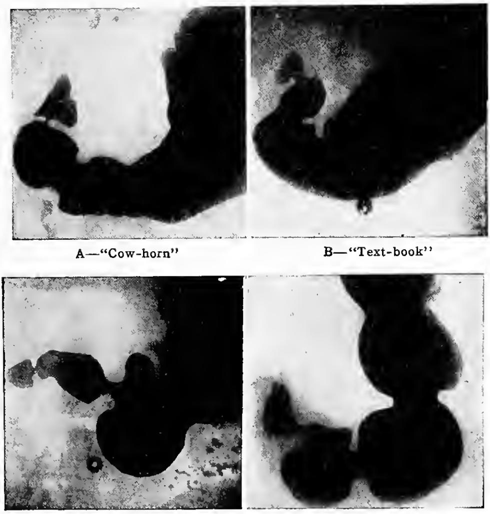
The circular layer of muscle is indicated at 16 mm.; the longitudinal much later, about 90 mm., and not completed before 240 mm. (F. T. Lewis).

Variations.—The great variability of the stomach in form, position and relations has already been repeatedly emphasized. These variations have been most carefully studied recently by various observers in the living body by means of the Rœntgen-rays. Some of the results of study by this method are shown in figs. 918, 919.

Peristalsis.—It would appear that most of the variations in the form of the stomach that have been described are merely various phases in the series of changes undergone by the stomach during the normal process of physiological digestion. The following account of these changes is based largely upon the radiographic observations of Cole. Earlier observations by various investigators upon the living stomach of man and lower animals (and especially the radiographic study of the cat by Cannon) have shown that the cardiac portion of the stomach is the first to become distended with food (and gas). Until a considerable degree of distention is reached, the pyloric portion usually remains a somewhat narrow contracted canal, along which distinct peristaltic contractions pass pylorusward.

Under favorable conditions, however, the peristaltic contractions may be observed to begin in the cardiac portion, although they are usually most distinct in the pyloric portion. Each individual contraction travels at the rate of about 2.5 cm. (1 inch) per second, so that it requires several seconds for a contraction to travel from fundus to pylorus. The number of simultaneous

Fig. 918.—Different Forms of the Stomach as Shown by The Rœntgen Rays. Fundus not represented. (Cole.)



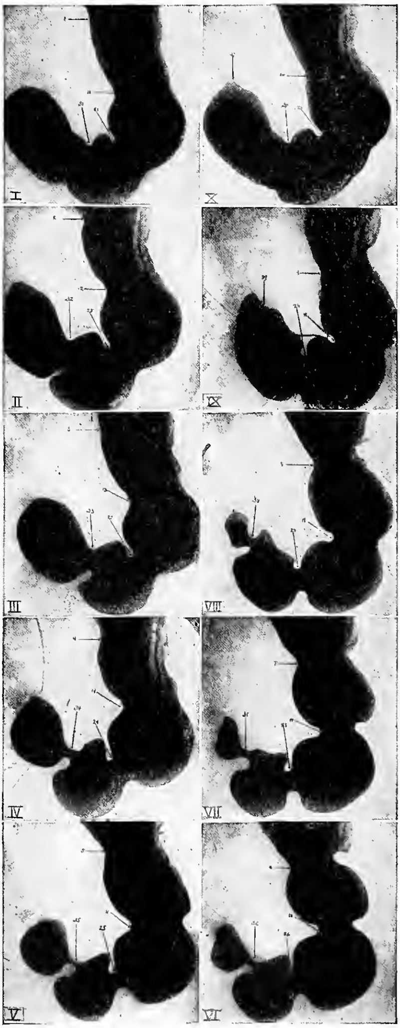
contractions present in the stomach varies from 1 to 6 or 7, 3 or 4 being the most common. In fig. 919, a series of 10 successive radiographs show the progression in a stomach with four simultaneous individual peristaltic contractions. The peristaltic movements are further complicated by the appearance (simultaneously in all) of successive periods of 'systole,' during which the peristaltic contractions become stronger and deeper, and 'diastole,' in which the contractions relax and become less distinct (Cole). In fig. 919, phases 1 to 6 represent the 'systole,' and 7 to 10 the 'diastole.' A 'systole' and a 'diastole' together make up a 'gastric cycle.' During the entire progress of an individual peristaltic contraction from fundus to pylorus, the number of 'cycles' appears to correspond to the number of peristaltic contractions present. Thus the figure represents a stomach of the 4-cycle type. The time required for a 'cycle' varies widely, the average (in the 3- or 4-cycle type) being about 2 or 3 seconds.

In the earlier stages of gastric digestion the pylorus usually remains closed, but after a variable time it relaxes slightly (lumen about 3 mm. in diameter) at intervals, allowing the chyme to be spurted into the duodenum.

Thus the various constrictions often found in the formalin-hardened stomachs, and the pyloric antrum, appear to be merely transient phases of the digestive process. The 'hour-glass' stomach is in many cases to be explained in this way; in others, however, the constriction is pathological and permanent. Various forms of abnormal lobulations and dilations also rarely occur.

Gastroptosis is a very common abnormality in which the body of the stomach extends vertically downward to the umbilicus, or lower, forming a sharp bend beyond which the pyloric portion turns upward to reach its termination. This form is especially common in women, due to tight lacing.

Fig. 919.—Serial Radiographs Taken at Short Intervals, Showing Diastole (Phases 7–10) and Systole (Phases 1–6), and the Progression toward the Pylorus of a Four-cycle Type of Gastric Peristalsis. Fundus of the stomach not shown. (Cole.)



Comparative.—The primitive stomach is perhaps merely a receptacle for food, true digestive glands being absent in many of the fishes. The vertebrate stomach is a dilated sac of variable form, but is typically somewhat looped, with cardiac and pyloric segments. In *birds*, there is a peculiar arrangement, correlated with the absence of teeth. The stomach is divided into an anterior glandular *proventriculus*, and a posterior muscular *gizzard* with a horny lining serving to grind the food. The *mammalian* stomach is the most variable in form and structure which are correlated with the method and character of alimentation. The cardiac end of the stomach is often lined to a variable extent with a prolongation of the œsophageal stratified squamous epithelium. The three kinds of glands, cardiac, fundic and pyloric, are typically present. In general, the stomach is larger and more complicated in herbivora than in carnivora. Instead of being a single sac, the stomach may be more or less divided into chambers. An incomplete division into cardiac and pyloric portions is so common that it may be considered typical. The most extreme specialization is found in the ruminants. In these the stomach has four chambers, the first two of which, however, are expansions of the œsophagus.

THE SMALL INTESTINE

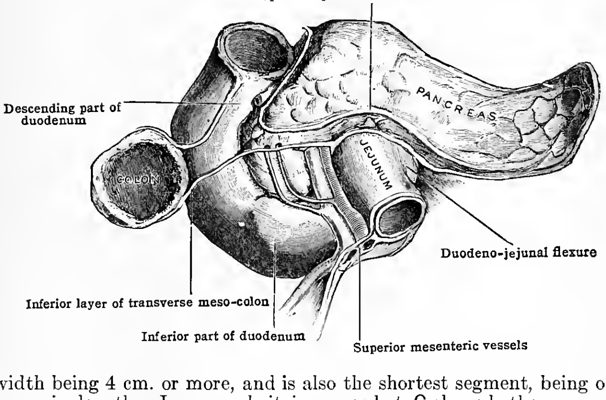
The **small intestine** [intestinum tenue] extends from the pylorus to the ileocæcal orifice, and occupies most of the abdominal cavity below the liver and stomach. It is a cylindrical tube whose diameter decreases from about 4 cm. above to about 2.5 cm. at the lower end. Its *length*, when removed from the body and measured fresh, averages about 7 metres (23 ft.); but when formalin-hardened *in situ*, the length (which is probably nearer that during life) is only about 4 metres. The length does not seem to vary according to sex, height or weight in the adult, but it is said to be relatively longer in the child.

The small intestine includes two main divisions, the *duodenum* and the *mesenteric small intestine*, the latter being further subdivided into *jejunum* and *ileum*.

THE DUODENUM

The **duodenum** is the first part of the small intestine, and is very definite in position and extent. It is firmly attached to the posterior abdominal wall, being almost entirely retroperitoneal. It is the widest part of the small intestine, the

Fig. 920.—The Duodenum and Pancreas, Anterior View.



average width being 4 cm. or more, and is also the shortest segment, being only about 25 cm. in length. In general, it is somewhat C-shaped, the concavity enclosing the head of the pancreas (figs. 920, 921, 922).

Parts.—For convenience of description, the duodenum is divided into the following parts: (1) the first or *superior portion* [pars superior] which is short (5 cm. or less), leading from the pylorus and forming the *superior flexure* [flexura duodenalis superior]; (2) the *descending portion* [pars descendens], about 7 or 8 cm. in length, which receives the bile and pancreatic ducts and joins the inferior portion at the *inferior flexure* [flexura duodenalis inferior]; and (3) the *inferior portion* [pars inferior], which is again subdivided into (a) *transverse* portion [pars horizontalis], about 10 cm. long, which usually ascends slightly and passes gradually into (b) the *ascending* portion [pars ascendens], 2 or 3 cm. long, terminating in the *duodeno-jejunal flexure* [flexura duodenojejunalis].

Position and relations.—As shown in fig. 914, the duodenum usually lies chiefly in the lower part of the epigastric region, only the inferior (transverse) portion extending into the umbilical region. All but the terminal (ascending) portion of the duodenum lies to the right of the mid-line.

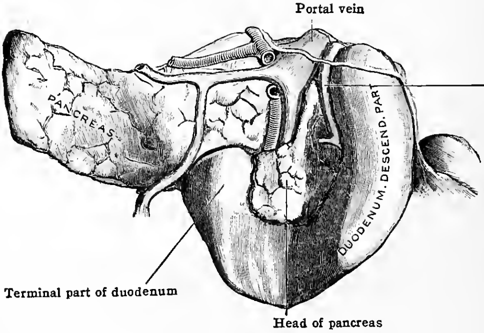
The *superior* portion usually lies at the level of the first lumbar vertebra (or the disk below). It is covered anteriorly, and to a variable extent posteriorly, by a prolongation of the peritoneum from the corresponding surfaces of the stomach. It is somewhat freely movable. When the stomach is empty, it extends from the pylorus almost horizontally to the right and backward. As the stomach becomes distended, however, the pylorus is carried to the right and downward for a variable distance, and the position of the superior part of the duodenum is correspondingly altered.

Superiorly it is in contact with the liver (quadrate lobe) and the neck of the gall-bladder and forms the lower boundary of the epiploic foramen; *anteriorly*, with the liver and (often) the transverse colon; *inferiorly* and *posteriorly*, with the head of the pancreas below, and with the common bile duct, hepatic vessels and portal vein above.

The second or *descending* portion of the duodenum extends along the right side of the first to the third lumbar vertebra. It is covered antero-laterally by peritoneum, excepting (usually) the area of contact with the transverse colon (figs. 906, 920).

Posteriorly (fig. 956) it is in contact with the right kidney, ureter and renal vessels, and below with the psoas muscle. *Anteriorly* (fig. 906) it is crossed by the transverse colon (the layers of the transverse mesocolon usually separated by an area of direct contact); above the colon, it may be in contact with the gall-bladder, and below the colon with coils of small intestine. The

FIG. 921.—THE DUODENUM AND PANCREAS, POSTERIOR VIEW.



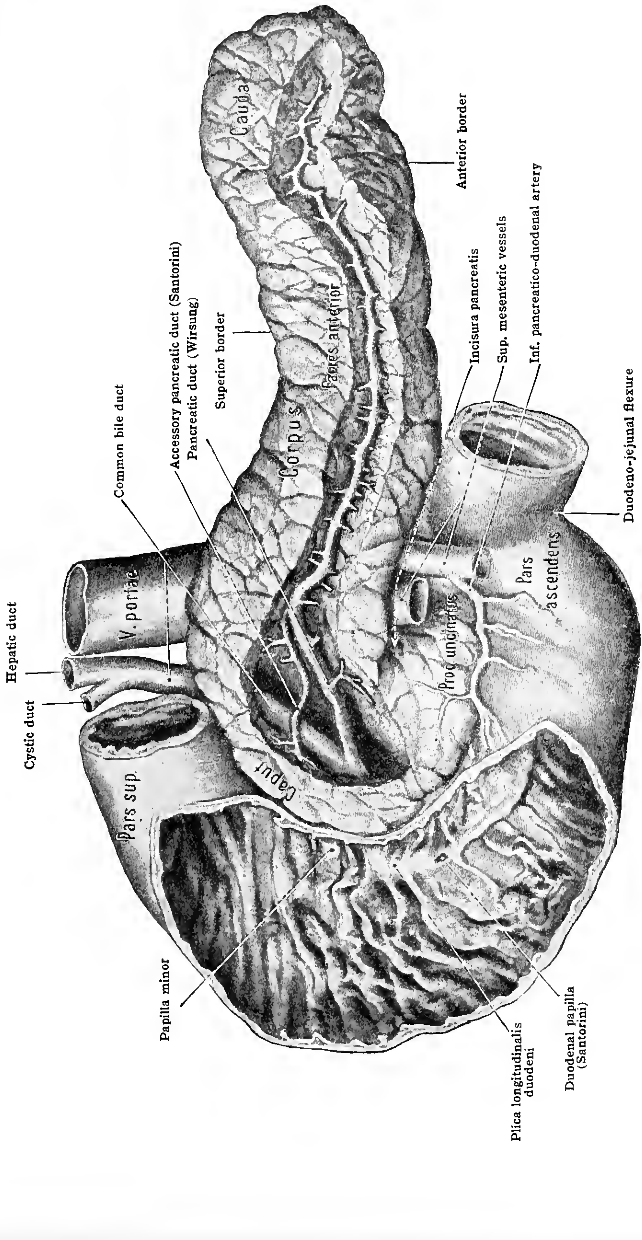
left or medial aspect of the descending duodenum (figs. 920, 921, 922) is in contact with the head of the pancreas, and some fibres from the muscular tunic are said to become intermingled with the pancreatic lobules. Somewhat posteriorly the common bile duct descends between pancreas and duodenum, and enters the descending duodenum, in common with the pancreatic duct, about 10 cm. below the pylorus. The loop formed by the pancreatico-duodenal arteries also runs along the descending duodenum.

The third or *transverse* portion of the duodenum usually crosses the body of the third lumbar vertebra, ascending slightly from the right to the left side (figs. 920, 921). It is covered anteriorly with peritoneum, excepting a small space where the superior mesenteric vessels enter the root of the mesentery.

Anteriorly it is further in contact with coils of small intestine; *superiorly*, with the head of the pancreas, and the inferior pancreatico-duodenal vessels; *posteriorly*, with the vena cava.

The terminal or *ascending* portion is covered anteriorly and laterally by peritoneum, and is in contact with coils of the ileum. To the *right* it is in relation with the head of the pancreas (processus uncinatus) and the superior mesenteric vessels; and *posteriorly* with the psoas muscle, aorta and left renal vessels. The *duodeno-jejunal flexure* usually lies opposite the second lumbar vertebra, and is in contact above with the inferior surface of the body of the pancreas, and the root of the transverse mesocolon.

FIG. 922.—DISSECTION OF THE DUODENUM AND PANCREAS, ANTERIOR VIEW. (Rauber-Kopsch.)



The end of the duodenum is firmly fixed in its place by the *suspensorius duodeni*. This name has been given to a fibro-muscular band that contains, according to Treitz, non-striated muscular fibres, and descends to the terminal part of the duodenum from the lumbar part of the diaphragm, passing to the left of the cœliac artery and behind the pancreas. Lockwood points out that this band is continued on, after being inserted into the duodenum, between the layers of the mesentery. He suggests the name of the 'suspensory muscle of the duodenum and mesentery,' and says, 'together with the other constituents of the root of the mesentery, it forms a band of considerable strength, sufficient not only to support the weight of the intestines and mesentery, but also to resist the pressure of the descent of the diaphragm.'

In connection with this fourth portion of the duodenum, mention may be made of certain peritoneal folds and fossæ which are of some surgical interest by reason of their being associated with retro-peritoneal hernia. Four such fossæ may be mentioned, namely, the superior and inferior duodenal fossæ, paraduodenal and the retroduodenal fossæ. On drawing the terminal portions of the duodenum to the right, two triangular folds of peritoneum, the superior and inferior duodenal folds, which extend from the wall of the duodenum to the posterior abdominal wall may be observed. Each fold has a free edge. Beneath each fold is found a pouch of peritoneum, constituting the **superior and inferior duodenal fossæ**. The former, the smaller, opens downward and is present in about 50 per cent., while the latter opens upward and is present in about 75 per cent., of the subjects examined (Jonnesco). The **paraduodenal fossa** (fossa of Landzert) is not often found in the adult; when present, it is situated to the left of the last part of the duodenum, and is formed by a fold of peritoneum enclosing the inferior mesenteric vein. The retroduodenal fossa is a rare form extending from below upward behind the transverse portion of the duodenum.
